

How to use the PowerShell documentation

Article • 01/17/2025

Welcome to the PowerShell online documentation. This site contains cmdlet reference for the following versions of PowerShell:

- PowerShell 7.6 (preview)
- PowerShell 7.5 (RC)
- PowerShell 7.4 (LTS)
- PowerShell 5.1

Navigating the documentation

The screenshot shows a web browser displaying the Microsoft Learn - PowerShell website. The URL is <https://learn.microsoft.com/en-us/powershell/scripting/overview?view=powershell-7.3>. The page title is "What is PowerShell?". The left sidebar has a "Version" dropdown set to "PowerShell 7.3" and a "Filter by title" input field. A search bar at the top right contains the placeholder "Search". The main content area features the article "What is PowerShell?", which includes a brief description of PowerShell as a cross-platform task automation solution and a "Command-line Shell" section detailing its features like history, tab completion, and pipelines. To the right, there's a sidebar titled "In this article" with links to "Command-line Shell", "Scripting language", "Automation platform", and "Next steps".

The web page contains multiple elements that help you navigate the documentation.

- **Site level navigation** - The site level navigation appears at the top of the page. It contains links to other content on the Microsoft Learn platform.

- **Related content navigation** - The related content bar is immediately below the site level navigation. It contains links to content related to the current documentation set, which is PowerShell in this case.
- **Version selector** - The version selector appears above the Table of Contents (TOC) and controls which version of the cmdlet reference appears in the TOC.
- **Table of Contents** - The TOC on the left side of the page is divided into two sections: conceptual and reference. Notice the line between the **Reference** node of the TOC. The conceptual documents appear above the line. Reference content is listed in **Reference** node below the line.
- **Action buttons** - The action buttons provide a way to add content to a collection, provide feedback, edit the content, or share the content with others.

Selecting the version of PowerShell

Use the version selector located above the TOC to select the version of PowerShell you want. By default, the page loads with the most current stable release version selected. The version selector controls which version of the cmdlet reference appears in the TOC under the **Reference** node. Some cmdlets work differently in different versions of PowerShell you are using. Be sure you are viewing the documentation for the correct version of PowerShell.

The version selector doesn't affect conceptual documentation. The conceptual documents appear above the **Reference** node in the TOC. The same conceptual articles appear for every version selected. If there are version-specific differences, the documentation makes note of those differences.

The screenshot shows a Microsoft Docs page for 'PowerShell Scripting'. The URL in the address bar is docs.microsoft.com/en-us/powershell/scripting/overview?view=powershell-6. The page title is 'PowerShell'. The sidebar on the left has a 'Version' dropdown set to 'PowerShell 6', with a 'Filter by title' input field below it. Under 'How to use this documentation', the 'Overview' section is expanded, showing links like 'Install', 'Get started', 'Learning PowerShell', etc. The main content area starts with a heading 'PowerShell' and a date '08/26/2018 • 2 minutes to read'. It describes PowerShell as a task-based command-line shell and scripting language built on .NET, used for managing operating systems. A 'PowerShell is open-source' section is present at the bottom, mentioning GitHub and DSC.

You can verify the version of PowerShell you are using by inspecting the `$PSVersionTable.PSVersion` value. The following example shows the output for Windows PowerShell 5.1.

```
PowerShell  
$PSVersionTable.PSVersion  
  
Output  
Major  Minor  Build  Revision  
-----  -----  -----  -----  
5       1       22621  963
```

Finding articles

There are two ways to search for content in Docs.

- The search box in the site-level navigation bar searches the entire site. It returns a list of matching articles from all documentation sets.
- The TOC filter box under the version selector allows filtering by words that appear in the title of an article. The filter displays a list of matching articles as you type. You can also select the option to search for the words in an article. When you search from here, the search is limited to the PowerShell documentation.

In the following example, the search in the site-level navigation bar returns 840 results for the word `idempotent`. Entering the word `invoke` in the TOC filter box shows a list of articles that contain the word `invoke` in the title. Entering the word `idempotent` in the TOC filter shows no articles. Clicking the search link searches for `idempotent` in the PowerShell documentation. This search only returns 9 results.

The screenshot shows a Microsoft Edge browser window displaying the Microsoft Learn - PowerShell documentation. The URL is <https://learn.microsoft.com/en-us/powershell/scripting/overview?...>. The page title is "What is PowerShell? - PowerShell". The left sidebar has a "Version" dropdown set to "PowerShell 7.3" and a "Filter by title" input field. The main content area shows the "What is PowerShell?" article, which includes a brief introduction, a "Command-line Shell" section, and a "Scripting language" section. To the right, there's a "Feedback" button and a "Additional resources" sidebar with sections for "Training", "Documentation", and "Discover PowerShell". A "Download PDF" button is located at the top right of the main content area.

Downloading the documentation as a PDF

To download the documentation as a PDF, click the **Download PDF** button at the bottom of the TOC.

Version

PowerShell 7.3

[Filter by title](#)

- If you are viewing a conceptual article, the Learn platform creates a PDF containing all the conceptual content for the selected version.
- If you are viewing a reference article, the Learn platform creates a PDF containing all the reference content for the selected version.

Finding articles for previous versions

Documentation for older versions of PowerShell is archived in our [Previous Versions](#) site. You can choose **Previous Versions** from the version selector.

The previous versions site contains documentation for the following topics:

- PowerShell 7.3
- PowerShell 7.2
- PowerShell 7.1
- PowerShell 7.0
- PowerShell 6
- PowerShell 5.0
 - PowerShell Workflows
 - PowerShell Web Access
- PowerShell 4.0
- PowerShell 3.0

What is PowerShell?

Article • 10/30/2024

PowerShell is a cross-platform task automation solution made up of a command-line shell, a scripting language, and a configuration management framework. PowerShell runs on Windows, Linux, and macOS.

Command-line Shell

PowerShell is a modern command shell that includes the best features of other popular shells. Unlike most shells that only accept and return text, PowerShell accepts and returns .NET objects. The shell includes the following features:

- Robust command-line [history](#)
- Tab completion and command prediction (See [about_PSReadLine](#))
- Supports command and parameter [aliases](#)
- [Pipeline](#) for chaining commands
- In-console [help](#) system, similar to Unix `man` pages

Scripting language

As a scripting language, PowerShell is commonly used for automating the management of systems. It's also used to build, test, and deploy solutions, often in CI/CD environments. PowerShell is built on the .NET Common Language Runtime (CLR). All inputs and outputs are .NET objects. No need to parse text output to extract information from output. The PowerShell scripting language includes the following features:

- Extensible through [functions](#), [classes](#), [scripts](#), and [modules](#)
- Extensible [formatting system](#) for easy output
- Extensible [type system](#) for creating dynamic types
- Built-in support for common data formats like [CSV](#), [JSON](#), and [XML](#)

Automation platform

The extensible nature of PowerShell has enabled an ecosystem of PowerShell modules to deploy and manage almost any technology you work with. For example:

Microsoft

- [Azure](#)

- Windows
- Exchange
- SQL

Third-party

- AWS ↗
- VMware ↗
- Google Cloud ↗

Configuration management

PowerShell Desired State Configuration ([DSC](#)) is a management framework in PowerShell that enables you to manage your enterprise infrastructure with configuration as code. With DSC, you can:

- Create declarative [configurations](#) and custom scripts for repeatable deployments
- Enforce configuration settings and report on configuration drift
- Deploy configuration using [push or pull](#) models

What is Windows PowerShell?

Article • 03/07/2024

Windows PowerShell and *PowerShell* are two separate products.

- *Windows PowerShell* is the version of PowerShell that ships in Windows. This version of PowerShell uses the full .NET Framework, which only runs on Windows. The latest version is Windows PowerShell 5.1. Microsoft is no longer updating Windows PowerShell with new features. Support for Windows PowerShell is tied to the version of Windows you are using.
- *PowerShell* is built on the new versions of .NET instead of the .NET Framework and runs on Windows, Linux, and macOS. Support for PowerShell is based on the version of .NET that it was built on. For more information about the support lifecycle for PowerShell, see the [PowerShell support lifecycle](#) documentation.

Further reading

- For a more detailed explanation of the differences between Windows PowerShell and PowerShell, see [Differences between Windows PowerShell 5.1 and PowerShell 7.x](#).
- For information about migrating from Windows PowerShell to PowerShell, see [Migrating from Windows PowerShell 5.1 to PowerShell 7](#).
- For more information about previous versions of Windows PowerShell, see [Previous versions of PowerShell](#).
- For more information about the terminology used in PowerShell documentation, see [Product terminology and branding guidelines](#).

What is a command shell?

Article • 02/13/2025

Many people use the terms *command shell*, *command-line tool*, and *terminal* interchangeably, which can be confusing. This article explains the difference between these concepts and provides examples of each.

A **command shell** is an interactive command-line interface for managing a computer, also known as a **Read-Eval-Print Loop** ([REPL ↗](#)).

A shell takes input from the keyboard, evaluates that input, and executes the input as a shell command or forwards the input to the operating system to be executed. Most shells can also read commands from a script file, and can include programming features like variables, flow control, and functions.

Types of command shells

There are two main types of command shells:

- General purpose command shells

General purpose command shells provide are designed to work with the operating system and allow you to run any command that the operating system supports.

They also include shell-specific commands and programming features. The following list contains some examples of general purpose command shells:

- [PowerShell](#)
- [Windows Command Shell](#)
- [bash ↗](#) - popular on Linux
- [zsh ↗](#) - popular on macOS

- Utility command shells

Utility command shells are designed to work with specific applications or services. These shells can only run commands that are specific to the application or service. Some utility shells support running commands from a batch script, but don't include programming features. Usually, these shells can only be used interactively.

- [AI Shell](#) - An interactive-only shell used to communicate with AI services such as Azure OpenAI.
- [netsh](#) - Network shell (netsh) is a command-line utility that allows you to configure and display the status of various network components on Windows.

It's both a command-line tool and a command shell. It also supports running commands from a script file.

Command-line tools

A **command-line tool** is a standalone program that you run from a command shell. Command-line tools are typically designed to perform a specific task, such as managing files, configuring settings, or querying for information. Command-line tools can be used in any shell that supports running external programs.

- [Azure CLI](#) - a collection of command-line tools for managing Azure resources that can be run in any supported shell.
- [Azure PowerShell](#) - a collection of PowerShell modules for managing Azure resources that can be run in any supported version of PowerShell.
- [OpenSSH for Windows](#) - includes a command-line client and a server that provides secure communication over a network.
- [Windows Commands](#) - a collection of command-line tools that are built into Windows.

In general, command-line tools don't provide a command shell (REPL) interface. The `netsh` command in Windows is an exception, as it's both a command-line tool and an interactive command shell.

Terminals

A **terminal** is an application that provides a text-based window for hosting command shells. Some terminals are designed to work with a specific shell, while others can host multiple shells. They can also include advanced features such as:

- Ability to create multiple panes within a single window
- Ability to create multiple tabs to host multiple shells
- Ability to change color schemes and fonts
- Support for copy and paste operations

The following list contains some examples of terminal applications:

- [Windows Terminal](#) - a modern terminal application for Windows that can host multiple shells.
- [Windows Console Host](#) - the default host application on Windows for text-based applications. It can also host the Windows Command Shell or PowerShell.
- [Terminal for macOS](#) - the default terminal application on macOS that can host the bash or zsh shell.

- [iTerm2 for macOS](#) - a popular 3rd-party terminal application for macOS.
- [Azure Cloud Shell](#) - a browser-based terminal application hosted in Microsoft Azure. Azure Cloud shell gives you the choice of using bash or PowerShell. Each shell comes preconfigured with many command-line tools for managing Azure resources.

What is a PowerShell command (cmdlet)?

Article • 03/07/2024

Commands for PowerShell are known as cmdlets (pronounced command-lets). In addition to cmdlets, PowerShell allows you to run any command available on your system.

What is a cmdlet?

Cmdlets are native PowerShell commands, not stand-alone executables. Cmdlets are collected into PowerShell modules that can be loaded on demand. Cmdlets can be written in any compiled .NET language or in the PowerShell scripting language itself.

Cmdlet names

PowerShell uses a *Verb-Noun* name pair to name cmdlets. For example, the `Get-Command` cmdlet included in PowerShell is used to get all the cmdlets that are registered in the command shell. The verb identifies the action that the cmdlet performs, and the noun identifies the resource on which the cmdlet performs its action.

Next steps

To learn more about PowerShell and how to find other cmdlets, see the PowerShell Bits tutorial [Discover PowerShell](#).

For more information about creating your own cmdlets, see the following resources:

Script-based cmdlets

- [about_Functions_Advanced](#)
- [about_Functions_CmdletBindingAttribute](#)
- [about_Functions_Advanced_Methods](#)

Compiled cmdlets (PowerShell SDK docs)

Discover PowerShell

Article • 03/07/2024

PowerShell is a command-line shell and a scripting language in one. PowerShell started out on Windows to help automate administrative tasks. Now, it runs cross platform and can be used for various tasks.

The thing that makes PowerShell unique is that it accepts and returns .NET objects, rather than text. This feature makes it easier to connect different commands in a *pipeline*.

What can PowerShell be used for?

Usage of PowerShell has grown since the days when it was Windows-only. It's still used for Windows task automation, but today, you can use it for tasks like:

- **Cloud management.** PowerShell can be used to manage cloud resources. For example, you can retrieve information about cloud resources, as well as update or deploy new resources.
- **CI/CD.** It can also be used as part of a Continuous Integration/Continuous Deployment pipeline.
- **Automate tasks for Active Directory and Exchange.** You can use it to automate almost any task on Windows like creating users in Active Directory and mailboxes in Exchange.

There are many more areas of usage but the preceding list gives you a hint that PowerShell has come a long way.

Who uses PowerShell?

PowerShell is a powerful tool that can help people working in a multitude of roles. Traditionally, PowerShell has been used by the System Administrator role but is now being used by people calling themselves DevOps, Cloud Ops, and even Developers.

PowerShell cmdlets

PowerShell comes with hundreds of preinstalled commands. PowerShell commands are called cmdlets (pronounced *command-lets*).

The name of each cmdlet consists of a *Verb-Noun* pair. For example, `Get-Process`. This naming convention makes it easier to understand what the cmdlet does. It also makes it easier to find the command you're looking for. When looking for a cmdlet to use, you can filter on the verb or noun.

Using cmdlets to explore PowerShell

When you first pick up PowerShell, it might feel intimidating as there seems to be so much to learn. PowerShell is designed to help you learn a little at a time, as you need it.

PowerShell includes cmdlets that help you discover PowerShell. Using these three cmdlets, you can discover what commands are available, what they do, and what types they operate on.

- `Get-Verb`. Running this command returns a list of verbs that most commands adhere to. The response includes a description of what these verbs do. Since most commands follow this naming convention, it sets expectations on what a command does. This helps you select the appropriate command and what to name a command, should you be creating one.
- `Get-Command`. This command retrieves a list of all commands installed on your machine.
- `Get-Member`. It operates on object based output and is able to discover what object, properties and methods are available for a command.
- `Get-Help`. Invoking this command with the name of a command as an argument displays a help page describing various parts of a command.

Using these commands, you can discover almost anything you need to know about PowerShell.

Verb

Verb is an important concept in PowerShell. It's a naming standard that most cmdlets follow. It's also a naming standard you're expected to follow when you write your own commands. The idea is that the *Verb* says what you're trying to do, like read or maybe change data. PowerShell has a standardized list of verbs. To get a full list of all possible verbs, use the `Get-Verb` cmdlet:

```
PowerShell
Get-Verb
```

The cmdlet returns a long list of verbs. The **Description** provides context for what the verb is meant to do. Here's the first few rows of output:

Output			
Verb	AliasPrefix	Group	Description
Add	a	Common	Adds a resource to a container, or attaches an item to another item
Clear	cl	Common	Removes all the resources from a container but does not delete the container
Close	cs	Common	Changes the state of a resource to make it inaccessible, unavailable, or unusab...
Copy	cp	Common	Copies a resource to another name or to another container
Enter	et	Common	Specifies an action that allows the user to move into a resource
Exit	ex	Common	Sets the current environment or context to the most recently used context
...			

Find commands with Get-Command

The `Get-Command` cmdlet returns a list of all available commands installed on your system. The list you get back is quite large. You can limit the amount of information that comes back by filtering the response using parameters or helper cmdlets.

Filter on name

You can filter the output of `Get-Command` using different parameters. Filtering allows you to find commands that have certain properties. The **Name** parameter allows you to find a specific command by name.

PowerShell			
Get-Command -Name Get-Process			
Output			
CommandType	Name	Version	Source
Cmdlet	Get-Process	7.0.0.0	Microsoft.PowerShell.Management

What if you want to find all the commands that work with processes? You can use a wildcard `*` to match other forms of the string. For example:

PowerShell

```
Get-Command -Name *-Process
```

Output

CommandType	Name	Version	Source
Cmdlet	Debug-Process	7.0.0.0	Microsoft.PowerShell.Management
Cmdlet	Get-Process	7.0.0.0	Microsoft.PowerShell.Management
Cmdlet	Start-Process	7.0.0.0	Microsoft.PowerShell.Management
Cmdlet	Stop-Process	7.0.0.0	Microsoft.PowerShell.Management
Cmdlet	Wait-Process	7.0.0.0	Microsoft.PowerShell.Management

Filtering on Noun and Verb

There are other parameters that filter on verb and noun values. The verb part of a command's name is the leftmost part. The verb should be one of the values returned by the `Get-Verb` cmdlet. The rightmost part of a command is the noun part. A noun can be anything.

- **Filter on verb.** In the command `Get-Process`, the verb part is `Get`. To filter on the verb part, use the `Verb` parameter.

PowerShell

```
Get-Command -Verb 'Get'
```

This example lists all commands that use the verb `Get`.

- **Filter on noun.** In the command `Get-Process`, the noun part is `Process`. To filter on the noun, use the `Noun` parameter. The following example returns all cmdlets that have nouns starting with the letter `U`.

PowerShell

```
Get-Command -Noun U*
```

Also, you can combine parameters to narrow down your search, for example:

PowerShell

```
Get-Command -Verb Get -Noun U*
```

Output

CommandType	Name	Version	Source
Cmdlet	Get-UICulture	7.0.0.0	
Microsoft.PowerShell.Utility			
Cmdlet	Get-Unique	7.0.0.0	
Microsoft.PowerShell.Utility			
Cmdlet	Get-Uptime	7.0.0.0	
Microsoft.PowerShell.Utility			

Use helper cmdlets to filter results

You can also use other cmdlets to filter results.

- `Select-Object`. This versatile command helps you pick out specific properties from one or more objects. You can also limit the number of items you get back. The following example returns the **Name** and **Source** property values for the first 5 commands available in the current session.

PowerShell

```
Get-Command | Select-Object -First 5 -Property Name, Source
```

Output

Name	Source
Add-AppPackage	Appx
Add-AppPackageVolume	Appx
Add-AppProvisionedPackage	Dism
Add-AssertionOperator	Pester
Add-ProvisionedAppPackage	Dism

For more information, see [Select-Object](#).

- `Where-Object`. This cmdlet lets you filter the objects returned based on the values of properties. The command takes an expression that can test the value of a property. The following example returns all processes where the `ProcessName` starts with `p`.

PowerShell

```
Get-Process | Where-Object {$_.ProcessName -like "p*"}  
The Get-Process cmdlet returns a collection of process objects. To filter the response, pipe the output to Where-Object. Piping means that two or more commands are connected via a pipe | character. The output from one command is sent as the input for the next command. The filter expression for Where-Object uses the -like operator to match processes that start with the letter p.
```

Explore objects with Get-Member

Once you've been able to locate the cmdlet you want, you want to know more about what output it produces. The Get-Member cmdlet displays the type, properties, and methods of an object. Pipe the output you want to inspect to Get-Member.

PowerShell

```
Get-Process | Get-Member
```

The result displays the returned type as TypeName and all the properties and methods of the object. Here's an excerpt of such a result:

Output

Name	MemberType	Definition
Handles	AliasProperty	Handles = Handlecount
Name	AliasProperty	Name = ProcessName
...		

Using the MemberType parameter you can limit the information returned.

PowerShell

```
Get-Process | Get-Member -MemberType Method
```

By default PowerShell only displays a few properties. The previous example displayed the Name, MemberType and Definition members. You can use Select-Object to specify

properties you want to see. For example, you want to display only the `Name` and `Definition` properties:

```
PowerShell
```

```
Get-Process | Get-Member | Select-Object Name, Definition
```

Search by parameter type

`Get-Member` showed us that `Get-Process` returns `Process` type objects. The `ParameterType` parameter of `Get-Command` can be used to find other commands that take `Process` objects as input.

```
PowerShell
```

```
Get-Command -ParameterType Process
```

```
Output
```

CommandType	Name	Version	Source
Cmdlet	Debug-Process	7.0.0.0	
Microsoft.PowerShell.Managem...			
Cmdlet	Enter-PSThread	7.1.0.0	
Microsoft.PowerShell.Core			
Cmdlet	Get-Process	7.0.0.0	
Microsoft.PowerShell.Managem...			
Cmdlet	Get-PSThreadInfo	7.1.0.0	
Microsoft.PowerShell.Core			
Cmdlet	Stop-Process	7.0.0.0	
Microsoft.PowerShell.Managem...			
Cmdlet	Wait-Process	7.0.0.0	
Microsoft.PowerShell.Managem...			

Knowing the output type of a command can help narrow down your search for related commands.

Installing PowerShell on Windows

Article • 04/28/2025

There are multiple ways to install PowerShell in Windows. Each install method is designed to support different scenarios and workflows. Choose the method that best suits your needs.

- [WinGet](#) - Recommended way to install PowerShell on Windows clients
- [MSI package](#) - Best choice for Windows Servers and enterprise deployment scenarios
- [ZIP package](#) - Easiest way to "side load" or install multiple versions
 - Use this method for Windows Nano Server, Windows IoT, and Arm-based systems
- [.NET Global tool](#) - A good choice for .NET developers that install and use other global tools
- [Microsoft Store package](#) - An easy way to install for casual users of PowerShell but has limitations

ⓘ Note

The installation commands in this article are for the latest stable release of PowerShell. To install a different version of PowerShell, adjust the command to match the version you need. The following links direct you to the release page for each version in the PowerShell repository on GitHub.

- v7.5.0 - Stable release: <https://aka.ms/powershell-release?tag=stable>
- v7.4.7 - LTS release: <https://aka.ms/powershell-release?tag=lts>
- v7.6.0-preview.2 - Preview release: <https://aka.ms/powershell-release?tag=preview>

Download links for every package are found in the **Assets** section of the Release page. The **Assets** section may be collapsed, so you may need to click to expand it.

Install PowerShell using WinGet (recommended)

WinGet, the Windows Package Manager, is a command-line tool enables users to discover, install, upgrade, remove, and configure applications on Windows client computers. This tool is the client interface to the Windows Package Manager service. The `winget` command-line tool is bundled with Windows 11 and modern versions of Windows 10 by default as the **App Installer**.

ⓘ Note

See the [winget documentation](#) for a list of system requirements and install instructions. `winget` isn't available on Windows Server 2022 or earlier versions. Windows Server 2025

Preview Build 26085 and later includes winget for Windows Server with Desktop Experience only.

The following commands can be used to install PowerShell using the published winget packages:

Search for the latest version of PowerShell

PowerShell

```
winget search Microsoft.PowerShell
```

Output

Name	Id	Version	Source
<hr/>			
PowerShell	Microsoft.PowerShell	7.5.1.0	winget
PowerShell Preview	Microsoft.PowerShell.Preview	7.6.0.4	winget

Install PowerShell or PowerShell Preview using the `id` parameter

PowerShell

```
winget install --id Microsoft.PowerShell --source winget
```

PowerShell

```
winget install --id Microsoft.PowerShell.Preview --source winget
```

ⓘ Note

On Windows systems using X86 or X64 processor, winget installs the MSI package. On systems using the Arm64 processor, winget installs the Microsoft Store (MSIX) package. For more information, see [Installing from the Microsoft Store](#).

Installing the MSI package

To install PowerShell on Windows, use the following links to download the install package from GitHub.

- [PowerShell-7.5.1-win-x64.msi ↗](#)

- [PowerShell-7.5.1-win-x86.msi](#)
- [PowerShell-7.5.1-win-arm64.msi](#)

Once downloaded, double-click the installer file and follow the prompts.

The installer creates a shortcut in the Windows Start Menu.

- By default the package is installed to `$Env:ProgramFiles\PowerShell\<version>`
- You can launch PowerShell via the Start Menu or `$Env:ProgramFiles\PowerShell\<version>\pwsh.exe`

Note

PowerShell 7.4 installs to a new directory and runs side-by-side with Windows PowerShell 5.1. PowerShell 7.4 is an in-place upgrade that removes previous versions of PowerShell 7. Preview versions of PowerShell can be installed side-by-side with other versions of PowerShell.

- PowerShell 7.4 is installed to `$Env:ProgramFiles\PowerShell\7`
- The `$Env:ProgramFiles\PowerShell\7` folder is added to `$Env:PATH`

If you need to run PowerShell 7.4 side-by-side with other versions, use the [ZIP install](#) method to install the other version to a different folder.

Support for Microsoft Update in PowerShell 7.2 and newer

PowerShell 7.2 and newer has support for Microsoft Update. When you enable this feature, you'll get the latest PowerShell 7 updates in your traditional Microsoft Update (MU) management flow, whether that's with Windows Update for Business, WSUS, Microsoft Endpoint Configuration Manager, or the interactive MU dialog in Settings.

The PowerShell MSI package includes following command-line options:

- `USE_MU` - This property has two possible values:
 - `1` (default) - Opts into updating through Microsoft Update, WSUS, or Configuration Manager
 - `0` - Don't opt into updating through Microsoft Update, WSUS, or Configuration Manager
- `ENABLE_MU`
 - `1` (default) - Opts into using Microsoft Update for Automatic Updates
 - `0` - Don't opt into using Microsoft Update

Note

Enabling updates may have been set in a previous installation or manual configuration. Using `ENABLE_MU=0` doesn't remove the existing settings. Also, this setting can be overruled by Group Policy settings controlled by your administrator.

For more information, see the [PowerShell Microsoft Update FAQ](#).

Install the MSI package from the command line

MSI packages can be installed from the command line allowing administrators to deploy packages without user interaction. The MSI package includes the following properties to control the installation options:

- `ADD_EXPLORER_CONTEXT_MENU_OPENPOWERSHELL` - This property controls the option for adding the `Open PowerShell` item to the context menu in Windows Explorer.
- `ADD_FILE_CONTEXT_MENU_RUNPOWERSHELL` - This property controls the option for adding the `Run with PowerShell` item to the context menu in Windows Explorer.
- `ENABLE_PSREMOTING` - This property controls the option for enabling PowerShell remoting during installation.
- `REGISTER_MANIFEST` - This property controls the option for registering the Windows Event Logging manifest.
- `ADD_PATH` - This property controls the option for adding PowerShell to the Windows PATH environment variable.
- `DISABLE_TELEMETRY` - This property controls the option for disabling PowerShell's telemetry by setting the `POWERSHELL_TELEMETRY_OPTOUT` environment variable.
- `INSTALLFOLDER` - This property controls the installation directory. The default is `$Env:ProgramFiles\PowerShell\`. This is the location where the installer creates the versioned subfolder. You can't change the name of the versioned subfolder.
 - For current releases, the versioned subfolder is `7`
 - For preview releases, the versioned subfolder is `7-preview`

The following example shows how to silently install PowerShell with all the install options enabled.

PowerShell

```
msiexec.exe /package PowerShell-7.5.1-win-x64.msi /quiet  
ADD_EXPLORER_CONTEXT_MENU_OPENPOWERSHELL=1 ADD_FILE_CONTEXT_MENU_RUNPOWERSHELL=1  
ENABLE_PSREMOTING=1 REGISTER_MANIFEST=1 USE_MU=1 ENABLE_MU=1 ADD_PATH=1
```

For a full list of command-line options for `Msiexec.exe`, see [Command line options](#).

Installing the ZIP package

PowerShell binary ZIP archives are provided to enable advanced deployment scenarios.

Download one of the following ZIP archives from the [current release](#) page.

- [PowerShell-7.5.1-win-x64.zip](#)
- [PowerShell-7.5.1-win-x86.zip](#)
- [PowerShell-7.5.1-win-arm64.zip](#)

Depending on how you download the file you may need to unblock the file using the `Unblock-File` cmdlet. Unzip the contents to the location of your choice and run `pwsh.exe` from there.

Unlike installing the MSI packages, installing the ZIP archive doesn't check for prerequisites. For remoting over WSMAN to work properly, ensure that you've met the [prerequisites](#).

Use this method to install the ARM-based version of PowerShell on computers like the Microsoft Surface Pro X. For best results, install PowerShell to the `$Env:ProgramFiles\PowerShell\7` folder.

Install as a .NET Global tool

If you already have the .NET Core SDK installed, you can install PowerShell as a .NET Global tool.

```
dotnet tool install --global PowerShell
```

The dotnet tool installer adds `$HOME\.dotnet\tools` to your `$Env:PATH` environment variable. However, the currently running shell doesn't have the updated `$Env:PATH`. You can start PowerShell from a new shell by typing `pwsh`.

Installing from the Microsoft Store

PowerShell can be installed from the Microsoft Store. You can find the PowerShell release in the [Microsoft Store](#) site or in the Store application in Windows.

Benefits of the Microsoft Store package:

- Automatic updates built right into Windows

- Integrates with other software distribution mechanisms like Intune and Configuration Manager
- Can install on Windows systems using x86, x64, or Arm64 processors

Known limitations

By default, Windows Store packages run in an application sandbox that virtualizes access to some filesystem and registry locations. Changes to virtualized file and registry locations don't persist outside of the application sandbox.

This sandbox blocks all changes to the application's root folder. Any system-level configuration settings stored in `$PSHOME` can't be modified. This includes the WSMAN configuration. This prevents remote sessions from connecting to Store-based installs of PowerShell. User-level configurations and SSH remoting are supported.

The following commands need write to `$PSHOME`. These commands aren't supported in a Microsoft Store instance of PowerShell.

- `Register-PSSessionConfiguration`
- `Update-Help -Scope AllUsers`
- `Enable-ExperimentalFeature -Scope AllUsers`
- `Set-ExecutionPolicy -Scope LocalMachine`

For more information, see [Understanding how packaged desktop apps run on Windows](#).

Beginning in PowerShell 7.2, the PowerShell package is now exempt from file and registry virtualization. Changes to virtualized file and registry locations now persist outside of the application sandbox. However, changes to the application's root folder are still blocked.

 **Important**

You must be running on Windows build 1903 or higher for this exemption to work.

Installing a preview version

Preview releases of PowerShell 7 install to `$Env:ProgramFiles\PowerShell\7-preview` so they can be run side-by-side with non-preview releases of PowerShell. PowerShell 7.4 is the next preview release.

Upgrading an existing installation

For best results when upgrading, you should use the same install method you used when you first installed PowerShell. If you aren't sure how PowerShell was installed, you can check the value of the `$PSHOME` variable, which always points to the directory containing PowerShell that the current session is running.

- If the value is `$HOME\.dotnet\tools`, PowerShell was installed with the [.NET Global tool](#).
- If the value is `$Env:ProgramFiles\PowerShell\7`, PowerShell was installed as an [MSI package](#) or with [WinGet](#) on a computer with an X86 or x64 processor.
- If the value starts with `$Env:ProgramFiles\WindowsApps\`, PowerShell was installed as a [Microsoft Store package](#) or with [WinGet](#) on computer with an ARM processor.
- If the value is anything else, it's likely that PowerShell was installed as a [ZIP package](#).

If you installed via the MSI package, that information also appears in the [Programs and Features Control Panel](#).

To determine whether PowerShell may be upgraded with WinGet, run the following command:

```
PowerShell  
winget list --id Microsoft.PowerShell --upgrade-available
```

If there is an available upgrade, the output indicates the latest available version. Use the following command to upgrade PowerShell using WinGet:

```
PowerShell  
winget upgrade --id Microsoft.PowerShell
```

Deploying on Windows 10 IoT Enterprise

Windows 10 IoT Enterprise comes with Windows PowerShell, which we can use to deploy PowerShell 7.

```
PowerShell  
  
# Replace the placeholder information for the following variables:  
$deviceip = '<device ip address'  
$zipfile = 'PowerShell-7.5.1-win-arm64.zip'  
$downloadfolder = 'U:\Users\Administrator\Downloads' # The download location is local to the device.  
# There should be enough space for the zip file and the unzipped contents.  
  
# Create PowerShell session to target device  
Set-Item -Path WSMan:\localhost\Client\TrustedHosts $deviceip
```

```

$S = New-PSSession -ComputerName $deviceIp -Credential Administrator
# Copy the ZIP package to the device
Copy-Item $zipfile -Destination $downloadfolder -ToSession $S

#Connect to the device and expand the archive
Enter-PSSession $S
Set-Location U:\Users\Administrator\Downloads
Expand-Archive .\PowerShell-7.5.1-win-arm64.zip

# Set up remoting to PowerShell 7
Set-Location .\PowerShell-7.5.1-win-arm64
# Be sure to use the -PowerShellHome parameter otherwise it tries to create a new
# endpoint with Windows PowerShell 5.1
.\Install-PowerShellRemoting.ps1 -PowerShellHome .

```

When you set up PowerShell Remoting you get an error message and are disconnected from the device. PowerShell has to restart WinRM. Now you can connect to PowerShell 7 endpoint on device.

PowerShell

```

# Be sure to use the -Configuration parameter. If you omit it, you connect to
Windows PowerShell 5.1
Enter-PSSession -ComputerName $deviceIp -Credential Administrator -Configuration
PowerShell.7.5.1

```

Deploying on Windows 10 IoT Core

Windows 10 IoT Core adds Windows PowerShell when you include *IOT_POWERSHELL* feature, which we can use to deploy PowerShell 7. The steps defined above for Windows 10 IoT Enterprise can be followed for IoT Core as well.

For adding the latest PowerShell in the shipping image, use [Import-PSCoreRelease](#) command to include the package in the workarea and add *OPENSRC_POWERSHELL* feature to your image.

(!) Note

For ARM64 architecture, Windows PowerShell isn't added when you include *IOT_POWERSHELL*. So the zip based install doesn't work. You need to use [Import-PSCoreRelease](#) command to add it in the image.

Deploying on Nano Server

These instructions assume that the Nano Server is a "headless" OS that has a version of PowerShell already running on it. For more information, see the [Nano Server Image Builder](#) documentation.

PowerShell binaries can be deployed using two different methods.

1. Offline - Mount the Nano Server VHD and unzip the contents of the zip file to your chosen location within the mounted image.
2. Online - Transfer the zip file over a PowerShell Session and unzip it in your chosen location.

In both cases, you need the [Windows x64 ZIP release package](#). Run the commands within an "Administrator" instance of PowerShell.

Offline Deployment of PowerShell

1. Use your favorite zip utility to unzip the package to a directory within the mounted Nano Server image.
2. Unmount the image and boot it.
3. Connect to the built-in instance of Windows PowerShell.

Online Deployment of PowerShell

Deploy PowerShell to Nano Server using the following steps.

PowerShell

```
# Replace the placeholder information for the following variables:  
$ipaddr = '<Nano Server IP address>'  
$credential = Get-Credential # <An Administrator account on the system>  
$zipfile = 'PowerShell-7.5.1-win-x64.zip'  
# Connect to the built-in instance of Windows PowerShell  
$session = New-PSSession -ComputerName $ipaddr -Credential $credential  
# Copy the file to the Nano Server instance  
Copy-Item $zipfile C:\ -ToSession $session  
# Enter the interactive remote session  
Enter-PSSession $session  
# Extract the ZIP file  
Expand-Archive -Path C:\PowerShell-7.5.1-win-x64.zip -DestinationPath 'C:\Program  
Files\PowerShell 7'
```

PowerShell remoting

PowerShell supports the PowerShell Remoting Protocol (PSRP) over both WSMAN and SSH. For more information, see:

- [SSH Remoting in PowerShell](#)
- [WSMAN Remoting in PowerShell](#)

Supported versions of Windows

Microsoft supports PowerShell until [PowerShell reaches end-of-support](#) or the version of [Windows reaches end-of-support](#).

- Docker images containing PowerShell 7.4 and PowerShell 7.5-preview for x64 for Windows Server 2022, Windows Server Core 2022, and Windows Server Nano build 1809 are available from the [Microsoft Artifact Registry](#).
- PowerShell 7.4 and higher can be installed on Windows 10 build 1607 and higher, Windows 11, Windows Server 2016 and higher.

Note

Support for a specific version of Windows is determined by the Microsoft Support Lifecycle policies. For more information, see:

- [Windows client lifecycle FAQ](#)
- [Modern Lifecycle Policy FAQ](#)

You can check the version that you are using by running `winver.exe`.

Installation support

Microsoft supports the installation methods in this document. There may be other third-party methods of installation available from other sources. While those tools and methods may work, Microsoft can't support those methods.

Install PowerShell on Linux

Article • 09/05/2023

PowerShell can be installed on several different Linux distributions. Most Linux platforms and distributions have a major release each year, and provide a package manager that's used to install PowerShell. PowerShell can be installed on some distributions of Linux that aren't supported by Microsoft. In those cases, you may find support from the community for PowerShell on those platforms.

For more information, see the [PowerShell Support Lifecycle](#) documentation.

This article lists the supported Linux distributions and package managers. All PowerShell releases remain supported until either the version of PowerShell or the version of the Linux distribution reaches end-of-support.

For the best compatibility, choose a long-term release (LTS) version.

Alpine

Microsoft supports PowerShell until [PowerShell reaches end-of-support](#) or the version of [Alpine reaches end-of-life](#).

Docker images containing PowerShell 7.4 and PowerShell 7.5-preview for x64 are available from the [Microsoft Artifact Registry](#) for the following versions of Alpine:

- Alpine 3.20 - OS support ends on 2026-04-01

Docker images of PowerShell aren't available for Alpine 3.21.

Important

The Docker images are built from official operating system (OS) images provided by the OS distributor. These images may not have the latest security updates. Microsoft recommends that you update the OS packages to the latest version to ensure the latest security updates are applied.

For more information, see [Install PowerShell on Alpine](#).

Debian

Debian uses APT (Advanced Package Tool) as a package manager.

Microsoft supports PowerShell until [PowerShell reaches end-of-support](#) or the version of [Debian reaches end-of-life](#).

Install package files (.deb) are also available from <https://packages.microsoft.com/>.

Docker images containing PowerShell 7.4 and PowerShell 7.5-preview for x64 are available from the [Microsoft Artifact Registry](#) for the following versions of Debian:

- Debian 12 (Bookworm) - OS support ends on 2026-06-10

Important

The Docker images are built from official operating system (OS) images provided by the OS distributor. These images may not have the latest security updates. Microsoft recommends that you update the OS packages to the latest version to ensure the latest security updates are applied.

For more information, see [Install PowerShell on Debian](#).

Red Hat Enterprise Linux (RHEL)

RHEL 7 uses yum and RHEL 8 uses the dnf package manager.

Microsoft supports PowerShell until [PowerShell reaches end-of-support](#) or the version of [RHEL reaches end-of-support](#).

Install package files (.rpm) are also available from <https://packages.microsoft.com/>.

Docker images containing PowerShell 7.4 and PowerShell 7.5-preview for x64 are available from the [Microsoft Artifact Registry](#) for the following versions of RHEL:

- RHEL 9 - OS support ends on 2032-05-31
- RHEL 8 - OS support ends on 2029-05-31

PowerShell is tested on Red Hat Universal Base Images (UBI). For more information, see the [UBI information page](#).

Important

The Docker images are built from official operating system (OS) images provided by the OS distributor. These images may not have the latest security updates. Microsoft recommends

that you update the OS packages to the latest version to ensure the latest security updates are applied.

For more information, see [Install PowerShell on RHEL](#).

Ubuntu

Ubuntu uses APT (Advanced Package Tool) as a package manager.

Microsoft supports PowerShell until [PowerShell reaches end-of-support](#) or the version of [Ubuntu reaches end-of-support](#).

Install package files (.deb) are also available from <https://packages.microsoft.com/>.

Docker images containing PowerShell 7.4 and PowerShell 7.5-preview for x64 and Arm32 are available from the [Microsoft Artifact Registry](#) for the following versions of Ubuntu:

- Ubuntu 24.04 (Noble Numbat) - OS support ends on 2029-04-01
- Ubuntu 22.04 (Jammy Jellyfish) - OS support ends on 2027-04-01
- Ubuntu 20.04 (Focal Fossa) - OS support ends on 2025-04-02

Ubuntu 24.10 (Oracular Oriole) is an interim release. Microsoft doesn't support [interim releases](#) of Ubuntu. For more information, see [Community supported distributions](#).

Important

The Docker images are built from official operating system (OS) images provided by the OS distributor. These images may not have the latest security updates. Microsoft recommends that you update the OS packages to the latest version to ensure the latest security updates are applied.

For more information, see [Install PowerShell on Ubuntu](#).

Community supported distributions

PowerShell can be installed on many distributions of Linux that aren't supported by Microsoft. In those cases, you may find support from the community for PowerShell on those platforms.

To be supported by Microsoft, the Linux distribution must meet the following criteria:

- The version and architecture of the distribution is supported by .NET Core.
- The version of the distribution is supported for at least one year.

- The version of the distribution isn't an interim release or equivalent.
- The PowerShell team has tested the version of the distribution.

For more information, see [Community support for PowerShell on Linux](#).

Alternate installation methods

There are three other ways to install PowerShell on Linux, including Linux distributions that aren't officially supported. You can try to install PowerShell using the PowerShell Snap Package. You can also try deploying PowerShell binaries directly using the Linux `tar.gz` package. For more information, see [Alternate ways to install PowerShell on Linux](#).

Installing PowerShell on Alpine Linux

Article • 04/28/2025

All packages are available on our GitHub [releases](#) page. After the package is installed, run `pwsh` from a terminal. Run `pwsh-preview` if you installed a preview release. Before installing, check the list of [Supported versions](#) below.

ⓘ Note

PowerShell 7.4 is an in-place upgrade that removes previous versions of PowerShell 7. Preview versions of PowerShell can be installed side-by-side with other versions of PowerShell. If you need to run PowerShell 7.4 side-by-side with a previous version, reinstall the previous version using the [binary archive](#) method.

ⓘ Note

The installation commands in this article are for the latest stable release of PowerShell. To install a different version of PowerShell, adjust the command to match the version you need. The following links direct you to the release page for each version in the PowerShell repository on GitHub.

- v7.5.0 - Stable release: <https://aka.ms/powershell-release?tag=stable>
- v7.4.7 - LTS release: <https://aka.ms/powershell-release?tag=lts>
- v7.6.0-preview.2 - Preview release: <https://aka.ms/powershell-release?tag=preview>

Download links for every package are found in the **Assets** section of the Release page. The **Assets** section may be collapsed, so you may need to click to expand it.

Installation steps

Installation on Alpine is based on downloading tar.gz package from the [releases](#) page. The URL to the package depends on the version of PowerShell you want to install.

- PowerShell 7.4 -
<https://github.com/PowerShell/PowerShell/releases/download/v7.4.7/powershell-7.4.7-linux-musl-x64.tar.gz>
- PowerShell 7.5 -
<https://github.com/PowerShell/PowerShell/releases/download/v7.5.1/powershell-7.5.1-linux-musl-x64.tar.gz>

Then, in the terminal, execute the following shell commands to install PowerShell 7.4:

```
sh

# install the requirements
sudo apk add --no-cache \
    ca-certificates \
    less \
    ncurses-terminfo-base \
    krb5-libs \
    libgcc \
    libintl \
    libssl3 \
    libstdc++ \
    tzdata \
    userspace-rcu \
    zlib \
    icu-libs \
    curl

apk -X https://dl-cdn.alpinelinux.org/alpine/edge/main add --no-cache \
    lttng-ust \
    openssh-client \

# Download the powershell '.tar.gz' archive
curl -L
https://github.com/PowerShell/PowerShell/releases/download/v7.5.1/powershell-
7.5.1-linux-musl-x64.tar.gz -o /tmp/powershell.tar.gz

# Create the target folder where powershell will be placed
sudo mkdir -p /opt/microsoft/powershell/7

# Expand powershell to the target folder
sudo tar zxf /tmp/powershell.tar.gz -C /opt/microsoft/powershell/7

# Set execute permissions
sudo chmod +x /opt/microsoft/powershell/7/pwsh

# Create the symbolic link that points to pwsh
sudo ln -s /opt/microsoft/powershell/7/pwsh /usr/bin/pwsh

# Start PowerShell
pwsh
```

Uninstall PowerShell

```
sh

sudo rm -rf /usr/bin/pwsh /opt/microsoft/powershell
```

PowerShell paths

- `$PSHOME` is `/opt/microsoft/powershell/7/`
- The profiles scripts are stored in the following locations:
 - AllUsersAllHosts - `$PSHOME/profile.ps1`
 - AllUsersCurrentHost - `$PSHOME/Microsoft.PowerShell_profile.ps1`
 - CurrentUserAllHosts - `~/.config/powershell/profile.ps1`
 - CurrentUserCurrentHost - `~/.config/powershell/Microsoft.PowerShell_profile.ps1`
- Modules are stored in the following locations:
 - User modules - `~/.local/share/powershell/Modules`
 - Shared modules - `/usr/local/share/powershell/Modules`
 - Default modules - `$PSHOME/Modules`
- PSReadLine history is recorded in
`~/.local/share/powershell/PSReadLine/ConsoleHost_history.txt`

The profiles respect PowerShell's per-host configuration, so the default host-specific profiles exists at `Microsoft.PowerShell_profile.ps1` in the same locations.

PowerShell respects the [XDG Base Directory Specification](#) on Linux.

Supported versions

Microsoft supports PowerShell until [PowerShell reaches end-of-support](#) or the version of [Alpine reaches end-of-life](#).

Docker images containing PowerShell 7.4 and PowerShell 7.5-preview for x64 are available from the [Microsoft Artifact Registry](#) for the following versions of Alpine:

- Alpine 3.20 - OS support ends on 2026-04-01

Docker images of PowerShell aren't available for Alpine 3.21.

Important

The Docker images are built from official operating system (OS) images provided by the OS distributor. These images may not have the latest security updates. Microsoft recommends that you update the OS packages to the latest version to ensure the latest security updates are applied.

Installation support

Microsoft supports the installation methods in this document. There may be other methods of installation available from other third-party sources. While those tools and methods may work, Microsoft can't support those methods.

Installing PowerShell on Debian

Article • 04/28/2025

All packages are available on our GitHub [releases](#) page. Before installing, check the list of [Supported versions](#) below. After the package is installed, run `pwsh` from a terminal. Run `pwsh-lts` if you installed a preview release.

⚠ Note

PowerShell 7.4 is an in-place upgrade that removes previous versions of PowerShell 7. Preview versions of PowerShell can be installed side-by-side with other versions of PowerShell. If you need to run PowerShell 7.4 side-by-side with a previous version, reinstall the previous version using the [binary archive](#) method.

Debian uses APT (Advanced Package Tool) as a package manager.

⚠ Note

The installation commands in this article are for the latest stable release of PowerShell. To install a different version of PowerShell, adjust the command to match the version you need. The following links direct you to the release page for each version in the PowerShell repository on GitHub.

- v7.5.0 - Stable release: <https://aka.ms/powershell-release?tag=stable>
- v7.4.7 - LTS release: <https://aka.ms/powershell-release?tag=lts>
- v7.6.0-preview.2 - Preview release: <https://aka.ms/powershell-release?tag=preview>

Download links for every package are found in the **Assets** section of the Release page. The **Assets** section may be collapsed, so you may need to click to expand it.

Installation on Debian 11 or 12 via the Package Repository

Microsoft builds and supports a variety of software products for Linux systems and makes them available via Linux packaging clients (apt, dnf, yum, etc). These Linux software packages are hosted on the *Linux package repository for Microsoft products*, <https://packages.microsoft.com>, also known as *PMC*.

Installing PowerShell from PMC is the preferred method of installation.

⚠ Note

This script only works for supported versions of Debian.

```
sh

#####
# Prerequisites

# Update the list of packages
sudo apt-get update

# Install pre-requisite packages.
sudo apt-get install -y wget

# Get the version of Debian
source /etc/os-release

# Download the Microsoft repository GPG keys
wget -q https://packages.microsoft.com/config/debian/$VERSION_ID/packages-microsoft-prod.deb

# Register the Microsoft repository GPG keys
sudo dpkg -i packages-microsoft-prod.deb

# Delete the Microsoft repository GPG keys file
rm packages-microsoft-prod.deb

# Update the list of packages after we added packages.microsoft.com
sudo apt-get update

#####
# Install PowerShell
sudo apt-get install -y powershell

# Start PowerShell
pwsh
```

Installation via direct download

PowerShell 7.2 introduced a universal package that makes installation easier. Download the universal package from the [releases ↗](#) page onto your Debian machine.

The link to the current version is:

- PowerShell 7.4 (LTS) universal package for supported versions of Debian
 - https://github.com/PowerShell/PowerShell/releases/download/v7.4.7/powershell_7.4.7-1.deb_amd64.deb

- PowerShell 7.5 universal package for supported versions of Debian
 - https://github.com/PowerShell/PowerShell/releases/download/v7.5.1/powershell_7.5.1-1.deb_amd64.deb

The following shell script downloads and installs the current release of PowerShell. You can change the URL to download the version of PowerShell that you want to install.

```
sh

#####
# Prerequisites

# Update the list of packages
sudo apt-get update

# Install pre-requisite packages.
sudo apt-get install -y wget

# Download the PowerShell package file
wget
https://github.com/PowerShell/PowerShell/releases/download/v7.5.1/powershell_7.5.1-1.deb_amd64.deb

#####
# Install the PowerShell package
sudo dpkg -i powershell_7.5.1-1.deb_amd64.deb

# Resolve missing dependencies and finish the install (if necessary)
sudo apt-get install -f

# Delete the downloaded package file
rm powershell_7.5.1-1.deb_amd64.deb

# Start PowerShell
pwsh
```

Uninstall PowerShell

```
sh

sudo apt-get remove powershell
```

PowerShell paths

- \$PSHOME is /opt/microsoft/powershell/7/
- The profiles scripts are stored in the following locations:

- AllUsersAllHosts - `$PSHOME/profile.ps1`
- AllUsersCurrentHost - `$PSHOME/Microsoft.PowerShell_profile.ps1`
- CurrentUserAllHosts - `~/.config/powershell/profile.ps1`
- CurrentUserCurrentHost - `~/.config/powershell/Microsoft.PowerShell_profile.ps1`
- Modules are stored in the following locations:
 - User modules - `~/.local/share/powershell/Modules`
 - Shared modules - `/usr/local/share/powershell/Modules`
 - Default modules - `$PSHOME/Modules`
- PSReadLine history is recorded in
`~/.local/share/powershell/PSReadLine/ConsoleHost_history.txt`

PowerShell respects the [XDG Base Directory Specification](#) on Linux.

Supported versions

Microsoft supports PowerShell until [PowerShell reaches end-of-support](#) or the version of [Debian reaches end-of-life](#).

Install package files (`.deb`) are also available from <https://packages.microsoft.com/>.

Docker images containing PowerShell 7.4 and PowerShell 7.5-preview for x64 are available from the [Microsoft Artifact Registry](#) for the following versions of Debian:

- Debian 12 (Bookworm) - OS support ends on 2026-06-10

Important

The Docker images are built from official operating system (OS) images provided by the OS distributor. These images may not have the latest security updates. Microsoft recommends that you update the OS packages to the latest version to ensure the latest security updates are applied.

Installation support

Microsoft supports the installation methods in this document. There may be other methods of installation available from other third-party sources. While those tools and methods may work, Microsoft can't support those methods.

Installing PowerShell on Red Hat Enterprise Linux (RHEL)

Article • 04/28/2025

All packages are available on our GitHub [releases](#) page. Before installing, check the list of [Supported versions](#) below. After the package is installed, run `pwsh` from a terminal. Run `pwsh-preview` if you installed a preview release.

⚠ Note

PowerShell 7.4 is an in-place upgrade that removes previous versions of PowerShell 7. Preview versions of PowerShell can be installed side-by-side with other versions of PowerShell. If you need to run PowerShell 7.4 side-by-side with a previous version, reinstall the previous version using the [binary archive](#) method.

RHEL 7 uses `yum` and RHEL 8 and higher uses the `dnf` package manager.

⚠ Note

The installation commands in this article are for the latest stable release of PowerShell. To install a different version of PowerShell, adjust the command to match the version you need. The following links direct you to the release page for each version in the PowerShell repository on GitHub.

- v7.5.0 - Stable release: <https://aka.ms/powershell-release?tag=stable>
- v7.4.7 - LTS release: <https://aka.ms/powershell-release?tag=lts>
- v7.6.0-preview.2 - Preview release: <https://aka.ms/powershell-release?tag=preview>

Download links for every package are found in the **Assets** section of the Release page. The **Assets** section may be collapsed, so you may need to click to expand it.

Installation via the Package Repository

Microsoft builds and supports a variety of software products for Linux systems and makes them available via Linux packaging clients (apt, dnf, yum, etc). These Linux software packages are hosted on the *Linux package repository for Microsoft products*, <https://packages.microsoft.com>, also known as *PMC*.

Installing PowerShell from PMC is the preferred method of installation.

ⓘ Note

This script only works for supported versions of RHEL.

```
sh

#####
# Prerequisites

# Get version of RHEL
source /etc/os-release
if [ ${VERSION_ID%.} -lt 8 ]
then majorver=7
elif [ ${VERSION_ID%.} -lt 9 ]
then majorver=8
else majorver=9
fi

# Download the Microsoft RedHat repository package
curl -sSL -O https://packages.microsoft.com/config/rhel/$majorver/packages-
microsoft-prod.rpm

# Register the Microsoft RedHat repository
sudo rpm -i packages-microsoft-prod.rpm

# Delete the downloaded package after installing
rm packages-microsoft-prod.rpm

# Update package index files
sudo dnf update
# Install PowerShell
sudo dnf install powershell -y
```

Installation via direct download

PowerShell 7.2 introduced a universal package that makes installation easier. Download the universal package from the [releases ↗](#) page onto your RHEL machine.

The link to the current version is:

- PowerShell 7.4.7 universal package for supported versions of RHEL
 - https://github.com/PowerShell/PowerShell/releases/download/v7.4.7/powershell-7.4.7-1.rh.x86_64.rpm
- PowerShell 7.5.1 universal package for supported versions of RHEL
 - https://github.com/PowerShell/PowerShell/releases/download/v7.5.1/powershell-7.5.1-1.rh.x86_64.rpm

The following shell script downloads and installs the current preview release of PowerShell. You can change the URL to download the version of PowerShell that you want to install.

On RHEL 8 or 9:

```
sh  
  
sudo dnf install  
https://github.com/PowerShell/PowerShell/releases/download/v7.5.1/powershell-  
7.5.1-1.rh.x86_64.rpm
```

Uninstall PowerShell

On RHEL 8 or 9:

```
sh  
  
sudo dnf remove powershell
```

Support for Arm processors

PowerShell 7.2 and newer supports running on RHEL using a 64-bit Arm processor. Use the binary archive installation method of installing PowerShell that's described in [Alternate ways to install PowerShell on Linux](#).

PowerShell paths

- `$PSHOME` is `/opt/microsoft/powershell/7/`
- The profiles scripts are stored in the following locations:
 - AllUsersAllHosts - `$PSHOME/profile.ps1`
 - AllUsersCurrentHost - `$PSHOME/Microsoft.PowerShell_profile.ps1`
 - CurrentUserAllHosts - `~/.config/powershell/profile.ps1`
 - CurrentUserCurrentHost - `~/.config/powershell/Microsoft.PowerShell_profile.ps1`
- Modules are stored in the following locations:
 - User modules - `~/.local/share/powershell/Modules`
 - Shared modules - `/usr/local/share/powershell/Modules`
 - Default modules - `$PSHOME/Modules`
- PSReadLine history is recorded in
`~/.local/share/powershell/PSReadLine/ConsoleHost_history.txt`

PowerShell respects the [XDG Base Directory Specification](#) on Linux.

Supported versions

Microsoft supports PowerShell until [PowerShell reaches end-of-support](#) or the version of [RHEL reaches end-of-support](#).

Install package files (`.rpm`) are also available from <https://packages.microsoft.com/>.

Docker images containing PowerShell 7.4 and PowerShell 7.5-preview for x64 are available from the [Microsoft Artifact Registry](#) for the following versions of RHEL:

- RHEL 9 - OS support ends on 2032-05-31
- RHEL 8 - OS support ends on 2029-05-31

PowerShell is tested on Red Hat Universal Base Images (UBI). For more information, see the [UBI information page](#).

Important

The Docker images are built from official operating system (OS) images provided by the OS distributor. These images may not have the latest security updates. Microsoft recommends that you update the OS packages to the latest version to ensure the latest security updates are applied.

Installation support

Microsoft supports the installation methods in this document. There may be other methods of installation available from other third-party sources. While those tools and methods may work, Microsoft can't support those methods.

Installing PowerShell on Ubuntu

Article • 04/28/2025

All packages are available on our GitHub [releases](#) page. Before installing, check the list of [Supported versions](#) below. After the package is installed, run `pwsh` from a terminal. Run `pwsh-lts` if you installed a preview release.

ⓘ Note

PowerShell 7.4 is an in-place upgrade that removes previous versions of PowerShell 7. Preview versions of PowerShell can be installed side-by-side with other versions of PowerShell. If you need to run PowerShell 7.4 side-by-side with a previous version, reinstall the previous version using the [binary archive](#) method.

Ubuntu uses APT (Advanced Package Tool) as a package manager.

ⓘ Note

The installation commands in this article are for the latest stable release of PowerShell. To install a different version of PowerShell, adjust the command to match the version you need. The following links direct you to the release page for each version in the PowerShell repository on GitHub.

- v7.5.0 - Stable release: <https://aka.ms/powershell-release?tag=stable>
- v7.4.7 - LTS release: <https://aka.ms/powershell-release?tag=lts>
- v7.6.0-preview.2 - Preview release: <https://aka.ms/powershell-release?tag=preview>

Download links for every package are found in the **Assets** section of the Release page. The **Assets** section may be collapsed, so you may need to click to expand it.

Installation via Package Repository the Package Repository

Microsoft builds and supports a variety of software products for Linux systems and makes them available via Linux packaging clients (apt, dnf, yum, etc). These Linux software packages are hosted on the *Linux package repository for Microsoft products*, <https://packages.microsoft.com>, also known as *PMC*.

Installing PowerShell from PMC is the preferred method of installation.

ⓘ Note

This script only works for supported versions of Ubuntu.

```
sh

#####
# Prerequisites

# Update the list of packages
sudo apt-get update

# Install pre-requisite packages.
sudo apt-get install -y wget apt-transport-https software-properties-common

# Get the version of Ubuntu
source /etc/os-release

# Download the Microsoft repository keys
wget -q https://packages.microsoft.com/config/ubuntu/$VERSION_ID/packages-microsoft-prod.deb

# Register the Microsoft repository keys
sudo dpkg -i packages-microsoft-prod.deb

# Delete the Microsoft repository keys file
rm packages-microsoft-prod.deb

# Update the list of packages after we added packages.microsoft.com
sudo apt-get update

#####
# Install PowerShell
sudo apt-get install -y powershell

# Start PowerShell
pwsh
```

ⓘ Important

Ubuntu comes preconfigured with a package repository that includes .NET packages, but not PowerShell. Using these instructions to install PowerShell registers the Microsoft repository as a package source. You can install PowerShell and some versions of .NET from this repository. However, the Ubuntu package repository has different versions of the .NET packages. This can cause problems when installing .NET for other purposes. For more information about these problems, see [Troubleshoot .NET package mix ups on Linux](#).

You must choose the feed you want to use to install .NET. You can set the priority of the package repositories to favor one over the other. For instructions on how to set the priorities, see [My Linux distribution provides .NET packages, and I want to use them](#).

Installation via direct download

PowerShell 7.2 introduced a universal package that makes installation easier. Download the universal package from the [releases ↗](#) page onto your Ubuntu machine.

The link to the current version is:

- PowerShell 7.4 (LTS) universal package for supported versions of Ubuntu
 - https://github.com/PowerShell/PowerShell/releases/download/v7.4.7/powershell_7.4.7-1.deb_amd64.deb
- PowerShell 7.5 universal package for supported versions of Ubuntu
 - https://github.com/PowerShell/PowerShell/releases/download/v7.5.1/powershell-preview_7.5.1-1.deb_amd64.deb

The following shell script downloads and installs the current preview release of PowerShell. You can change the URL to download the version of PowerShell that you want to install.

```
sh

#####
# Prerequisites

# Update the list of packages
sudo apt-get update

# Install pre-requisite packages.
sudo apt-get install -y wget

# Download the PowerShell package file
wget
https://github.com/PowerShell/PowerShell/releases/download/v7.5.1/powershell_7.5.1-1.deb_amd64.deb

#####
# Install the PowerShell package
sudo dpkg -i powershell_7.5.1-1.deb_amd64.deb

# Resolve missing dependencies and finish the install (if necessary)
sudo apt-get install -f

# Delete the downloaded package file
rm powershell_7.5.1-1.deb_amd64.deb
```

```
# Start PowerShell Preview  
pwsh
```

Uninstall PowerShell

```
sh  
  
sudo apt-get remove powershell
```

Support for Arm processors

PowerShell 7.2 and newer supports running on Ubuntu using 32-bit Arm processors. Use the binary archive installation method of installing PowerShell that's described in [Alternate ways to install PowerShell on Linux](#).

PowerShell paths

- `$PSHOME` is `/opt/microsoft/powershell/7/`
- The profiles scripts are stored in the following locations:
 - AllUsersAllHosts - `$PSHOME/profile.ps1`
 - AllUsersCurrentHost - `$PSHOME/Microsoft.PowerShell_profile.ps1`
 - CurrentUserAllHosts - `~/.config/powershell/profile.ps1`
 - CurrentUserCurrentHost - `~/.config/powershell/Microsoft.PowerShell_profile.ps1`
- Modules are stored in the following locations:
 - User modules - `~/.local/share/powershell/Modules`
 - Shared modules - `/usr/local/share/powershell/Modules`
 - Default modules - `$PSHOME/Modules`
- PSReadLine history is recorded in
`~/.local/share/powershell/PSReadLine/ConsoleHost_history.txt`

PowerShell respects the [XDG Base Directory Specification](#) on Linux.

Supported versions

Microsoft supports PowerShell until [PowerShell reaches end-of-support](#) or the version of [Ubuntu reaches end-of-support](#).

Install package files (`.deb`) are also available from <https://packages.microsoft.com/>.

Docker images containing PowerShell 7.4 and PowerShell 7.5-preview for x64 and Arm32 are available from the [Microsoft Artifact Registry](#) for the following versions of Ubuntu:

- Ubuntu 24.04 (Noble Numbat) - OS support ends on 2029-04-01
- Ubuntu 22.04 (Jammy Jellyfish) - OS support ends on 2027-04-01
- Ubuntu 20.04 (Focal Fossa) - OS support ends on 2025-05-31

Ubuntu 24.10 (Oracular Oriole) is an interim release. Microsoft doesn't support [interim releases](#) of Ubuntu. For more information, see [Community supported distributions](#).

 **Important**

The Docker images are built from official operating system (OS) images provided by the OS distributor. These images may not have the latest security updates. Microsoft recommends that you update the OS packages to the latest version to ensure the latest security updates are applied.

Installation support

Microsoft supports the installation methods in this document. There may be other methods of installation available from other third-party sources. While those tools and methods may work, Microsoft can't support those methods.

Community support for PowerShell on Linux

Article • 05/13/2025

You can install PowerShell on some distributions of Linux that aren't supported by Microsoft. In those cases, you might find support from the community for PowerShell on those platforms.

Supported Linux distributions must meet the following criteria:

- The version and architecture of the distribution is supported by .NET Core.
- The version of the distribution is supported for at least one year.
- The version of the distribution isn't an interim release or equivalent.
- The PowerShell team has tested the version of the distribution.

For more information, see the [PowerShell Support Lifecycle](#) documentation.

The following distributions are examples of distributions supported by the community. Each distribution has its own community support mechanisms. Consult the distribution's website to find their community resources. You can also get help from these [PowerShell Community](#) resources.

Ubuntu interim releases

The documented steps to install PowerShell on [Ubuntu](#) might work on Ubuntu interim releases. However, Microsoft only supports PowerShell on the Long Term Servicing (LTS) releases of Ubuntu. Microsoft doesn't support [interim releases](#) of Ubuntu.

Arch Linux

PowerShell is available from the [Arch Linux](#) User Repository (AUR). Packages in the AUR are maintained by the Arch community. To install the [latest release binary](#), see the [Arch Linux wiki](#) or [Using PowerShell in Docker](#).

Kali

Installation - Kali

```
sh
```

```
# Install PowerShell package
apt update && apt -y install powershell

# Start PowerShell
pwsh
```

Uninstallation - Kali

```
sh

# Uninstall PowerShell package
apt -y remove powershell
```

Gentoo

You can install PowerShell on Gentoo Linux using packages from the Gentoo package repository. For information about installing these packages, see the [PowerShell](#) page in the Gentoo wiki.

SLES and openSUSE

You may be able to install PowerShell on SLES and openSUSE using the SNAP package manager. Also, the following article provides information on how to install PowerShell on openSUSE:

- [PowerShell - openSUSE Wiki](#)

Raspberry Pi OS

[Raspberry Pi OS](#) (formerly Raspbian) is a free operating system based on Debian.

Important

.NET isn't supported on ARMv6 architecture devices, including Raspberry Pi Zero and Raspberry Pi devices released before Raspberry Pi 2.

Install on Raspberry Pi OS

Download the tar.gz package from the [releases](#) page onto your Raspberry Pi computer. The links to the current versions are:

- PowerShell 7.4 - latest LTS release
 - <https://github.com/PowerShell/PowerShell/releases/download/v7.4.10/powershell-7.4.10-linux-arm32.tar.gz>
 - <https://github.com/PowerShell/PowerShell/releases/download/v7.4.10/powershell-7.4.10-linux-arm64.tar.gz>
- PowerShell 7.5 - latest stable release
 - <https://github.com/PowerShell/PowerShell/releases/download/v7.5.1/powershell-7.5.1-linux-arm32.tar.gz>
 - <https://github.com/PowerShell/PowerShell/releases/download/v7.5.1/powershell-7.5.1-linux-arm64.tar.gz>

Use the following shell commands to download and install the package. This script detects whether you're running a 32-bit or 64-bit OS and installs the latest stable version of PowerShell for that processor type.

```
sh

#####
# Prerequisites

# Update package lists
sudo apt-get update

# Install dependencies
sudo apt-get install jq libssl1.1 libunwind8 -y

#####
# Download and extract PowerShell

# Grab the latest tar.gz
bits=$(getconf LONG_BIT)
release=$(curl -sL
https://api.github.com/repos/PowerShell/PowerShell/releases/latest)
package=$(echo $release | jq -r ".assets[].browser_download_url" | grep "linux-
arm${bits}.tar.gz")
wget $package

# Make folder to put powershell
mkdir ~/powershell

# Unpack the tar.gz file
tar -xvf "./${package##*/}" -C ~/powershell

# Start PowerShell
~/powershell/pwsh
```

Optionally, you can create a symbolic link to start PowerShell without specifying the path to the `pwsh` binary.

```
sh

# Start PowerShell from bash with sudo to create a symbolic link
sudo ~/powershell/pwsh -Command 'New-Item -ItemType SymbolicLink -Path
"/usr/bin/pwsh" -Target "$PSHOME/pwsh" -Force'

# alternatively you can run following to create a symbolic link
# sudo ln -s ~/powershell/pwsh /usr/bin/pwsh

# Now to start PowerShell you can just run "pwsh"
```

Uninstallation - Raspberry Pi OS

```
sh

rm -rf ~/powershell
```

Alternate ways to install PowerShell on Linux

Article • 04/28/2025

All packages are available on our GitHub [releases](#) page. After the package is installed, run `pwsh` from a terminal. Run `pwsh-preview` if you installed a preview release.

There are three other ways to install PowerShell on a Linux distribution:

- Install using a [Snap Package](#)
- Install using the [binary archives](#)
- Install as a [.NET Global tool](#)

Snap Package

Snaps are application packages that are easy to install, secure, cross-platform and dependency-free. Snaps are discoverable and installable from the Snap Store. Snap packages are supported the same as the distribution you're running the package on.

Important

The Snap Store contains PowerShell snap packages for many Linux distributions that are not officially supported by Microsoft. For support, see the list of available [Community Support](#) options.

Getting snapd

`snapd` is required to run snaps. Use [these instructions](#) to make sure you have `snapd` installed.

Installation via Snap

There are two PowerShell for Linux is published to the [Snap store](#): `powershell` and `powershell-preview`.

Use the following command to install the latest stable version of PowerShell:

```
sh  
  
# Install PowerShell  
sudo snap install powershell --classic
```

```
# Start PowerShell  
pwsh
```

If you don't specify the `--channel` parameter, Snap installs the latest stable version. To install the latest LTS version, use the following method:

```
sh  
  
# Install PowerShell  
sudo snap install powershell --channel=lts/stable --classic  
  
# Start PowerShell  
pwsh
```

ⓘ Note

Microsoft only supports the `latest/stable` and `lts/stable` channels for the `powershell` package. Do not install packages from the other channels.

To install a preview version, use the following method:

```
sh  
  
# Install PowerShell  
sudo snap install powershell-preview --classic  
  
# Start PowerShell  
pwsh-preview
```

ⓘ Note

Microsoft only supports the `latest/stable` channel for the `powershell-preview` package. Do not install packages from the other channels.

After installation, Snap will automatically upgrade. You can trigger an upgrade using `sudo snap refresh powershell` or `sudo snap refresh powershell-preview`.

Uninstallation

```
sh  
  
sudo snap remove powershell
```

or

```
sh  
sudo snap remove powershell-preview
```

Binary Archives

PowerShell binary `tar.gz` archives are provided for Linux platforms to enable advanced deployment scenarios.

!*Note*

You can use this method to install any version of PowerShell including the latest:

- Stable release: <https://aka.ms/powershell-release?tag=stable>
- LTS release: <https://aka.ms/powershell-release?tag=lts>
- Preview release: <https://aka.ms/powershell-release?tag=preview>

Dependencies

PowerShell builds portable binaries for all Linux distributions. But, .NET Core runtime requires different dependencies on different distributions, and PowerShell does too.

It's possible that when you install PowerShell, specific dependencies may not be installed, such as when manually installing from the binary archives. The following list details Linux distributions that are supported by Microsoft and have dependencies you may need to install. Check the distribution page for more information:

- [Alpine](#)
- [Debian](#)
- [RHEL](#)
- [SLES](#)
- [Ubuntu](#)

To deploy PowerShell binaries on Linux distributions that aren't officially supported, you need to install the necessary dependencies for the target OS in separate steps. For example, our [Amazon Linux dockerfile](#) installs dependencies first, and then extracts the Linux `tar.gz` archive.

Installation using a binary archive file

ⓘ Important

This method can be used to install PowerShell on any version of Linux, including distributions that are not officially supported by Microsoft. Be sure to install any necessary dependencies. For support, see the list of available [Community Support](#) options.

The following example shows the steps for installing the x64 binary archive. You must choose the correct binary archive that matches the processor type for your platform.

- `powershell-7.5.1-linux-arm32.tar.gz`
- `powershell-7.5.1-linux-arm64.tar.gz`
- `powershell-7.5.1-linux-x64.tar.gz`

Use the following shell commands to download and install PowerShell from the `.tar.gz` binary archive. Change the URL to match the version of PowerShell you want to install.

```
sh

# Download the powershell '.tar.gz' archive
curl -L -o /tmp/powershell.tar.gz
https://github.com/PowerShell/PowerShell/releases/download/v7.5.1/powershell-
7.5.1-linux-x64.tar.gz

# Create the target folder where powershell will be placed
sudo mkdir -p /opt/microsoft/powershell/7

# Expand powershell to the target folder
sudo tar zxf /tmp/powershell.tar.gz -C /opt/microsoft/powershell/7

# Set execute permissions
sudo chmod +x /opt/microsoft/powershell/7/pwsh

# Create the symbolic link that points to pwsh
sudo ln -s /opt/microsoft/powershell/7/pwsh /usr/bin/pwsh
```

Uninstalling binary archives

```
sh

sudo rm -rf /usr/bin/pwsh /opt/microsoft/powershell
```

Install as a .NET Global tool

If you already have the [.NET Core SDK](#) installed, it's easy to install PowerShell as a [.NET Global tool](#).

```
sh  
dotnet tool install --global PowerShell
```

The dotnet tool installer adds `~/.dotnet/tools` to your `PATH` environment variable. However, the currently running shell does not have the updated `PATH`. You should be able to start PowerShell from a new shell by typing `pwsh`.

Installing PowerShell on macOS

Article • 04/29/2025

PowerShell 7 or higher requires macOS 11 and higher. All packages are available on our GitHub [releases](#) page. After the package is installed, run `pwsh` from a terminal. Before installing, check the list of [Supported versions](#) below.

ⓘ Note

PowerShell 7.4 is an in-place upgrade that removes previous versions of PowerShell 7.

Preview versions of PowerShell can be installed side-by-side with other versions of PowerShell. If you need to run PowerShell 7.4 side-by-side with a previous version, reinstall the previous version using the [binary archive](#) method.

ⓘ Note

The installation commands in this article are for the latest stable release of PowerShell. To install a different version of PowerShell, adjust the command to match the version you need. The following links direct you to the release page for each version in the PowerShell repository on GitHub.

- v7.5.0 - Stable release: <https://aka.ms/powershell-release?tag=stable>
- v7.4.7 - LTS release: <https://aka.ms/powershell-release?tag=lts>
- v7.6.0-preview.2 - Preview release: <https://aka.ms/powershell-release?tag=preview>

Download links for every package are found in the **Assets** section of the Release page. The **Assets** section may be collapsed, so you may need to click to expand it.

Install the latest stable release of PowerShell

There are several ways to install PowerShell on macOS. Choose one of the following methods:

- Install using [Homebrew](#). Homebrew is the preferred package manager for macOS.
- Install PowerShell via [Direct Download](#)
- Install from [binary archives](#).

If the `brew` command isn't found, you need to install Homebrew following [their instructions](#).

Bash

```
/bin/bash -c "$(curl -fsSL  
https://raw.githubusercontent.com/Homebrew/install/HEAD/install.sh)"
```

Once `brew` is installed you can install PowerShell.

The following command installs the latest stable release of PowerShell:

```
sh  
  
brew install --cask powershell
```

Finally, verify that your install is working properly:

```
sh  
  
pwsh
```

When new versions of PowerShell are released, update Homebrew's formulae and upgrade PowerShell:

```
sh  
  
brew update  
brew upgrade powershell
```

ⓘ Note

The commands above can be called from within a PowerShell (`pwsh`) host, but then the PowerShell shell must be exited and restarted to complete the upgrade and refresh the values shown in `$PSVersionTable`.

Install the latest preview release of PowerShell

After you've installed Homebrew, you can install PowerShell.

```
sh  
  
brew install powershell/tap/powershell-preview
```

Run the following command to start the preview version of PowerShell:

```
sh
```

```
pwsh-preview
```

When new versions of PowerShell are released, update Homebrew's formulae and upgrade PowerShell:

```
sh
```

```
brew update  
brew upgrade powershell-preview
```

 **Note**

The commands above can be called from within a PowerShell (pwsh) host, but then the PowerShell shell must be exited and restarted to complete the upgrade, and refresh the values shown in `$PSVersionTable`.

Install the latest LTS release of PowerShell

```
sh
```

```
brew install powershell/tap/powershell-lts
```

You can now verify your install

```
sh
```

```
pwsh-lts
```

When new versions of PowerShell are released, run the following command.

```
sh
```

```
brew upgrade powershell-lts
```

 **Note**

Whether you use the cask or the tap method, when updating to a newer version of PowerShell, use the same method you used to initially install PowerShell. If you use a

different method, opening a new pwsh session will continue to use the older version of PowerShell.

If you do decide to use different methods, there are ways to correct the issue using the [Homebrew link method](#).

Installation via Direct Download

Starting with version 7.2, PowerShell supports the Apple M-series Arm-based processors. Download the install package from the [releases](#) page onto your computer. The links to the current versions are:

- PowerShell 7.4
 - x64 processors - [powershell-7.4.7-osx-x64.pkg](#)
 - Arm64 processors - [powershell-7.4.7-osx-arm64.pkg](#)
- PowerShell 7.5
 - x64 processors - [powershell-7.5.1-osx-x64.pkg](#)
 - Arm64 processors - [powershell-7.5.1-arm64.pkg](#)

You can double-click the file and follow the prompts, or install it from the terminal using the following commands. Change the name of the file to match the file you downloaded.

```
sh  
sudo installer -pkg ./Downloads/powershell-7.5.1-osx-x64.pkg -target /
```

If you are running on macOS Big Sur 11.5 or higher you may receive the following error message when installing the package:

"powershell-7.5.1-osx-x64.pkg" cannot be opened because Apple cannot check it for malicious software.

There are two ways to work around this issue:

Using the Finder

1. Find the package in Finder.
2. Control-click (click while pressing the `ctrl` key) on the package.
3. Select **Open** from the context menu.

From the command line

1. Run `sudo xattr -rd com.apple.quarantine ./Downloads/powershell-7.5.1-osx-x64.pkg`. If you are using PowerShell 7 or higher, you can use the `Unblock-File` cmdlet. Include the full path to the `.pkg` file.
2. Install the package as you normally would.

! Note

This is a known issue related to package notarization that will be addressed in the future.

Install as a .NET Global tool

If you already have the [.NET Core SDK](#) installed, it's easy to install PowerShell as a [.NET Global tool](#).

```
dotnet tool install --global PowerShell
```

The dotnet tool installer adds `~/.dotnet/tools` to your `PATH` environment variable. However, the currently running shell doesn't have the updated `PATH`. You should be able to start PowerShell from a new shell by typing `pwsh`.

Binary Archives

PowerShell binary `tar.gz` archives are provided for the macOS platform to enable advanced deployment scenarios. When you install using this method you must also manually install any dependencies.

! Note

You can use this method to install any version of PowerShell including the latest:

- Stable release: <https://aka.ms/powershell-release?tag=stable> ↗
- LTS release: <https://aka.ms/powershell-release?tag=lts> ↗
- Preview release: <https://aka.ms/powershell-release?tag=preview> ↗

Installing binary archives on macOS

Download the install package from the [releases](#) page onto your computer. The links to the current versions are:

- PowerShell 7.4 (LTS)
 - x64 processors - [powershell-7.4.7-osx-x64.tar.gz](#)
 - Arm64 processors - [powershell-7.4.7-osx-arm64.tar.gz](#)
- PowerShell 7.5-preview
 - x64 processors - [powershell-7.5.1-osx-x64.tar.gz](#)
 - Arm64 processors - [powershell-7.5.1-osx-arm64.tar.gz](#)

Use the following commands to install PowerShell from the binary archive. Change the download URL to match the version you want to install.

```
sh

# Download the powershell '.tar.gz' archive
curl -L -o /tmp/powershell.tar.gz
https://github.com/PowerShell/PowerShell/releases/download/v7.5.1/powershell-
7.5.1-osx-x64.tar.gz

# Create the target folder where powershell is placed
sudo mkdir -p /usr/local/microsoft/powershell/7

# Expand powershell to the target folder
sudo tar zxf /tmp/powershell.tar.gz -C /usr/local/microsoft/powershell/7

# Set execute permissions
sudo chmod +x /usr/local/microsoft/powershell/7/pwsh

# Create the symbolic link that points to pwsh
sudo ln -s /usr/local/microsoft/powershell/7/pwsh /usr/local/bin/pwsh
```

Uninstalling PowerShell

If you installed PowerShell with Homebrew, use the following command to uninstall:

```
sh

brew uninstall --cask powershell
```

If you installed PowerShell via direct download, PowerShell must be removed manually:

```
sh

sudo rm -rf /usr/local/bin/pwsh /usr/local/microsoft/powershell
```

To remove the additional PowerShell paths, refer to the [paths](#) section in this document and remove the paths using `sudo rm`.

 **Note**

This isn't necessary if you installed with Homebrew.

Paths

- `$PSHOME` is `/usr/local/microsoft/powershell/7`
 - The macOS install package creates a symbolic link, `/usr/local/bin/pwsh` that points to `pwsh` in the `$PSHOME` location.
- User profiles are read from `~/.config/powershell/profile.ps1`
- Default profiles are read from `$PSHOME/profile.ps1`
- User modules are read from `~/.local/share/powershell/Modules`
- Shared modules are read from `/usr/local/share/powershell/Modules`
- Default modules are read from `$PSHOME/Modules`
- PSReadLine history are recorded to
`~/.local/share/powershell/PSReadLine/ConsoleHost_history.txt`

PowerShell respects the [XDG Base Directory Specification](#) on macOS.

Supported versions

Microsoft supports PowerShell until [PowerShell reaches end-of-support](#) or the version of macOS reaches end-of-support.

- macOS 15 (Sequoia) x64 and Arm64
- macOS 14 (Sonoma) x64 and Arm64
- macOS 13 (Ventura) x64 and Arm64

Apple determines the support lifecycle of macOS. For more information, see the following:

- [macOS release notes](#)
- [Apple Security Updates](#)

Installation support

Microsoft supports the installation methods in this document. There may be other methods of installation available from other sources. While those tools and methods may work, Microsoft

can't support those methods.

PowerShell on Arm processors

Article • 12/12/2024

Support for the Arm processor is based on the support policy of the version of .NET that PowerShell uses. While .NET supports many more operating systems and versions, PowerShell support is limited to the versions that have been tested.

It may be possible to use Arm-based versions of PowerShell on other Linux distributions and versions, but we don't officially support it.

PowerShell 7.4

Arm versions of PowerShell 7.4 can be installed on the following platforms:

[] Expand table

OS	Architectures	Lifecycle
Windows 11 Client Version 22000+	Arm64	Windows ↗
Windows 10 Client Version 1607+	Arm64	Windows ↗
macOS	Arm64	macOS ↗
Raspberry Pi OS (Debian 12)	Arm32	Raspberry Pi OS ↗ and Debian ↗
Ubuntu 22.04, 20.04	Arm32	Ubuntu ↗

Support is based on the [.NET 8.0 Supported OS Lifecycle Policy](#) ↗.

Use PowerShell in Docker

Article • 03/26/2025

The .NET team publishes Docker images with PowerShell preinstalled. This article shows you how to get started using PowerShell in the Docker container.

Find available images

These images require Docker 17.05 or newer. Also, you must be able to run Docker without `sudo` or local administrative rights. For install instructions, see Docker's official [documentation](#).

The .NET team publishes several Docker images designed for different development scenarios. Only the image for the .NET SDK contains PowerShell. For more information, see [Official .NET Docker images](#).

Use PowerShell in a container

The following command downloads the image containing the latest available stable versions of the .NET SDK and PowerShell.

```
Console
```

```
docker pull mcr.microsoft.com/dotnet/sdk:9.0
```

Use the following command to start an interactive PowerShell session in the container.

```
Console
```

```
docker run -it mcr.microsoft.com/dotnet/sdk:9.0 pwsh
```

To download and run the latest Long Term Support (LTS) version of PowerShell, change the image name to `mcr.microsoft.com/dotnet/sdk:8.0`. When you use these image tags, Docker downloads the appropriate image for your host operating system. If you want an image for a specific operating system, you can specify the operating system in the image tag. See the [Microsoft Artifact Registry](#) for a list of available tags.

- For more information about tags, the [Supported tag policy](#)
- For more information about supported operating systems, see the [Supported platforms policy](#)

Support lifecycle

The [.NET support policy](#) defines how these images are supported. These images are provided for development and testing purposes only. If you need a production-ready image, you should build your own images. For more information about these Docker images, visit the [dotnet-docker](#) repository on GitHub.

The images previously published by the PowerShell team will be marked as deprecated in the Microsoft Container Registry (MCR).

Telemetry

By default, PowerShell collects limited telemetry without personal data to help aid development of future versions of PowerShell. To opt-out of sending telemetry, create an environment variable called `POWERSHELL_TELEMETRY_OPTOUT` set to a value of `1` before starting PowerShell from the installed location. The telemetry we collect falls under the [Microsoft Privacy Statement](#).

Microsoft Update for PowerShell FAQ

FAQ

Beginning with PowerShell 7.2, when you install using the MSI package you have the option of enabling Microsoft Update support for PowerShell.

General Information

What is the Microsoft Update feature in PowerShell?

The Microsoft Update feature of PowerShell allows you to get the latest PowerShell 7 updates in your traditional Microsoft Update (MU) management flow, whether that's with Windows Update for Business, WSUS, Microsoft Endpoint Configuration Manager, or the interactive MU dialog in Settings. Microsoft Update and the related services enable you to deploy updates:

- On your schedule
- After testing for your environment
- At scale across your enterprise

How soon after release are updates advertised by Microsoft Update?

When a new version of PowerShell is released, it can take up to two weeks for that version to become available through Microsoft Update. Updates are delivered as optional software updates, even if the update contains a security fix.

If you need to deploy the update before it becomes available in Microsoft Update, download the update from the [Releases](#) page on GitHub.

Why is the latest LTS version not marked as LTS?

We mark the earliest minor version LTS until it goes out of support. For example, both PowerShell 7.2 and 7.4 are LTS releases and have a year of overlapping support. PowerShell 7.2 was marked as the latest LTS in MU until it reached end of support in November 2024.

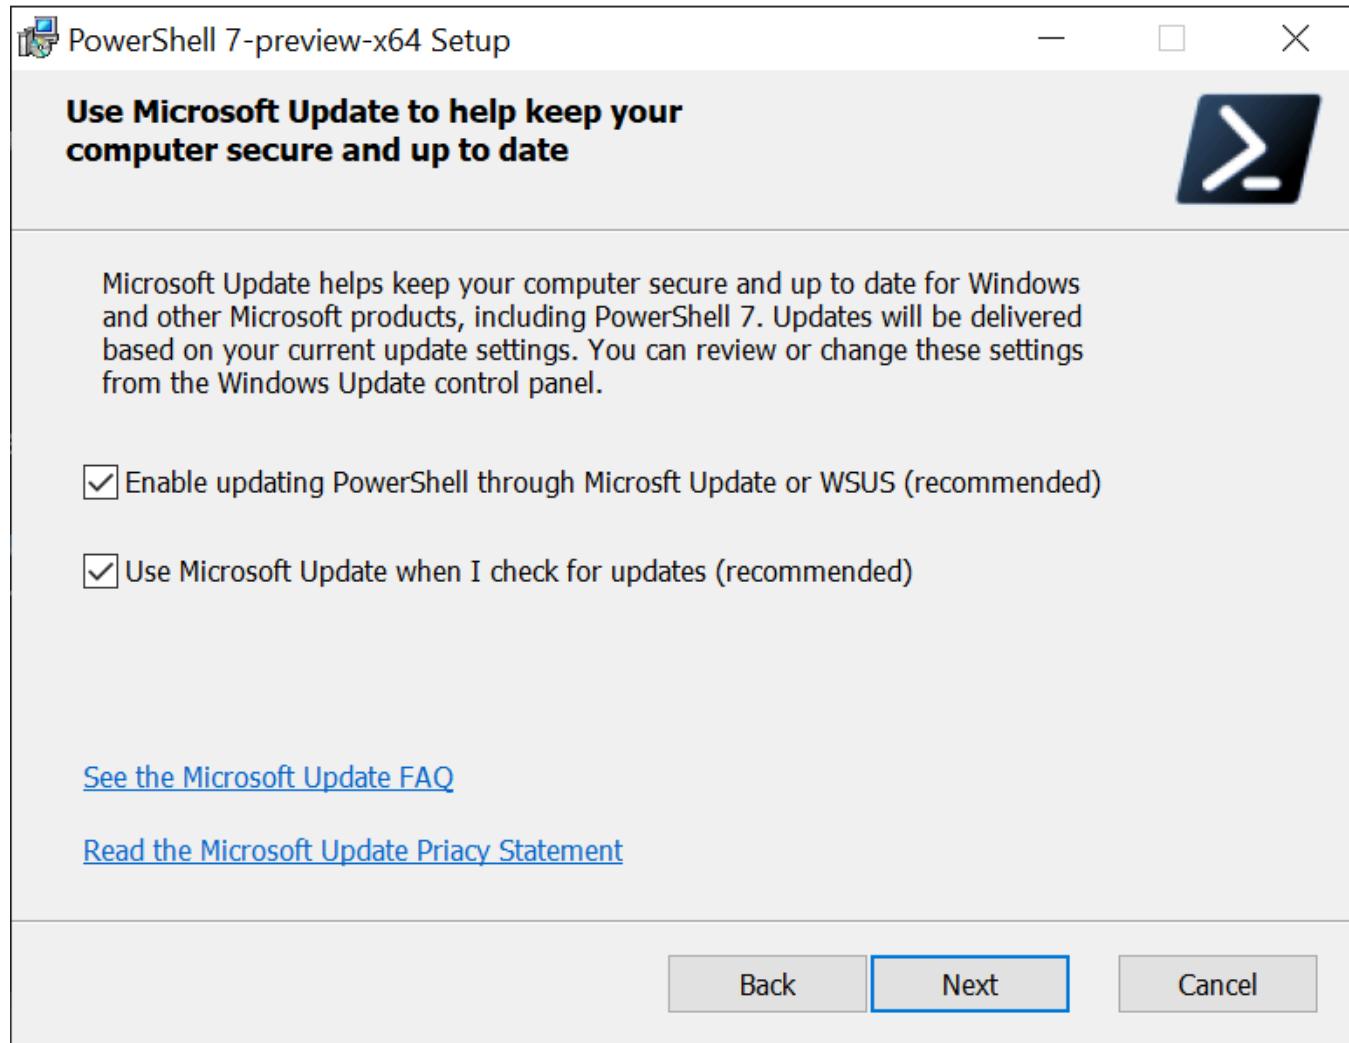

Configuration

What version of Windows is required to support the Microsoft Update feature?

You must have Windows Version 1809 or newer installed on an x64-based system. Version 1809 is the Windows 10 October 2018 Update or Windows Server 2019. Versions prior to 1809 do not support Microsoft Update for PowerShell.

Do I need to check both boxes in the setup dialog?

While the two options on the dialog are independent, in most cases, it's best to check both boxes.

What does each checkbox do?

The first checkbox enables updates for PowerShell. These updates can be delivered by Microsoft Update, a WSUS server, or SCCM. If this checkbox is unchecked, you cannot receive updates through any of these channels.

The second checkbox enables Microsoft Update on your system. This allows you to receive updates for any supported Microsoft software, not just Windows. If the box is unchecked, you will not receive the update from Microsoft Update, but you can receive updates from WSUS or SCCM.

What if I want to opt-out later?

If you want to opt-out of updates later, you can run the MSI install package and uncheck the first checkbox. Unchecking the second checkbox has no effect.

Can I enable these update options from the command line or in a script?

Yes. The MSI package includes two new MSI options for enabling the update features:

- `USE_MU` - This property has two possible values:
 - `1` (default) - Opts into updating through Microsoft Update, WSUS, or SCCM
 - `0` - Do not opt into updating through Microsoft Update, WSUS, or SCCM
- `ENABLE_MU`
 - `1` (default) - Opts into using Microsoft Update for Automatic Updates
 - `0` - Do not opt into using Microsoft Update

Note

Setting `ENABLE_MU=0` does not disable Microsoft Update.

Troubleshooting

Why haven't I received an update for the new release?

There can be several reasons for not receiving the update:

- We may not have published the update yet. Our goal is to make the update available to Microsoft Update within two weeks of release, but there is no guarantee for that availability.
- There are group policy settings that control Microsoft Update. Your system administrator may have policies set that prevent you from using Microsoft Update. The checkbox in the installer cannot override the Group Policy.
- Make sure you have checked both checkboxes. When doing a repair installation, the installer doesn't show the check box options. To enable MU updates run the following command:

PowerShell

```
msiexec.exe /fmu .\PowerShell-7.4.10-win-x64.msi USE_MU=1 ENABLE_MU=1
```

For more information about running `msiexec.exe` from the command line, see [msiexec](#).

I am on PowerShell 7.x, why have I not been upgraded to 7.y?

The Microsoft Update feature for PowerShell only updates versions in the same release channel. PowerShell 7.4 is the latest long term supported (LTS) version. PowerShell 7.5 is the latest stable (non-LTS) version. Microsoft Update provides updates for the next patch level versions of either version. For example:

- If you are running 7.4, you will receive updates for 7.4.
- If you are running 7.5, you will receive updates for 7.5.

Microsoft Update will never upgrade an LTS release to a stable non-LTS release. However, a stable non-LTS release will be upgraded to the higher LTS release when support for the stable release ends.

Preview releases are never upgraded to the GA release version. However, they will be upgraded to the next available preview release. For example: Consider the scenario where you have 7.4 (LTS) installed and the 7.5-rc.1 (preview) release installed. When 7.5.0 (Stable) released, your 7.4 (LTS) installation is not upgraded to 7.5.0. Also, 7.5.0 can't upgrade 7.5-rc.1. However, 7.6-preview.2 can upgrade 7.5-rc.1.

For more information, see [PowerShell Support Lifecycle](#).

Introduction

Article • 06/25/2024

 Expand table

This content originally appeared in the book *PowerShell 101* by Mike F. Robbins. We thank Mike for granting us permission to reuse the content here. We edited the content for publication on this platform. You can still get the original book from Leanpub at [PowerShell 101](#).

About this book

Before PowerShell, I began my career as an IT Pro, pointing and clicking in the GUI. I wrote this book to save IT Pros from themselves by reducing the learning curve and helping them avoid being reluctant to learn PowerShell.

Instead of a book that covers topics with fictitious scenarios, this book is a condensed version targeting the specific topics that an IT Pro needs to know to succeed with PowerShell in a real-world production environment. It's a collection of what I wish someone had told me when I started learning PowerShell. I include tips, tricks, and best practices that I learned while using PowerShell since 2007.

Each chapter includes a curated collection of links to specific help articles that expand on the information covered. These resources expand on the concepts discussed and broaden your understanding of PowerShell.

Who is this book for?

This book is for anyone wanting to learn PowerShell. Whether you're a beginner or an experienced user, this book helps you improve your PowerShell skills.

This book focuses on Windows PowerShell version 5.1 running on Windows 11 and Windows Server 2022 in a Microsoft Active Directory domain environment. However, the basic concepts apply to all versions of PowerShell running on any supported platform.

Lab environment

The examples in this book were created and tested on Windows 11 and Windows Server 2022 operating systems, using Windows PowerShell version 5.1. If you're running a

different operating system or version of PowerShell, your results might vary from the ones presented in this book.

About the author

Mike F. Robbins, a former Microsoft MVP, is the lead technical writer for [Azure PowerShell](#) at Microsoft. With extensive experience in PowerShell, he is a scripting, automation, and efficiency expert. As a lifelong learner, Mike continuously strives to improve his skills and empower others by sharing his knowledge and experience. He is also a published author of several books, including:

- Author of [PowerShell 101: The No-Nonsense Guide to Windows PowerShell](#)
- Creator of [The PowerShell Conference Book](#)
- Coauthor of [Windows PowerShell TFM 4th Edition](#)
- Contributing author in the [PowerShell Deep Dives](#) book

When Mike's not writing documentation for Microsoft, he shares his thoughts and insights on his blog at [mikefrobbins.com](#) and interacts with his followers on Twitter @mikefrobbins.

Chapter 1 - Getting started with PowerShell

Article • 08/02/2024

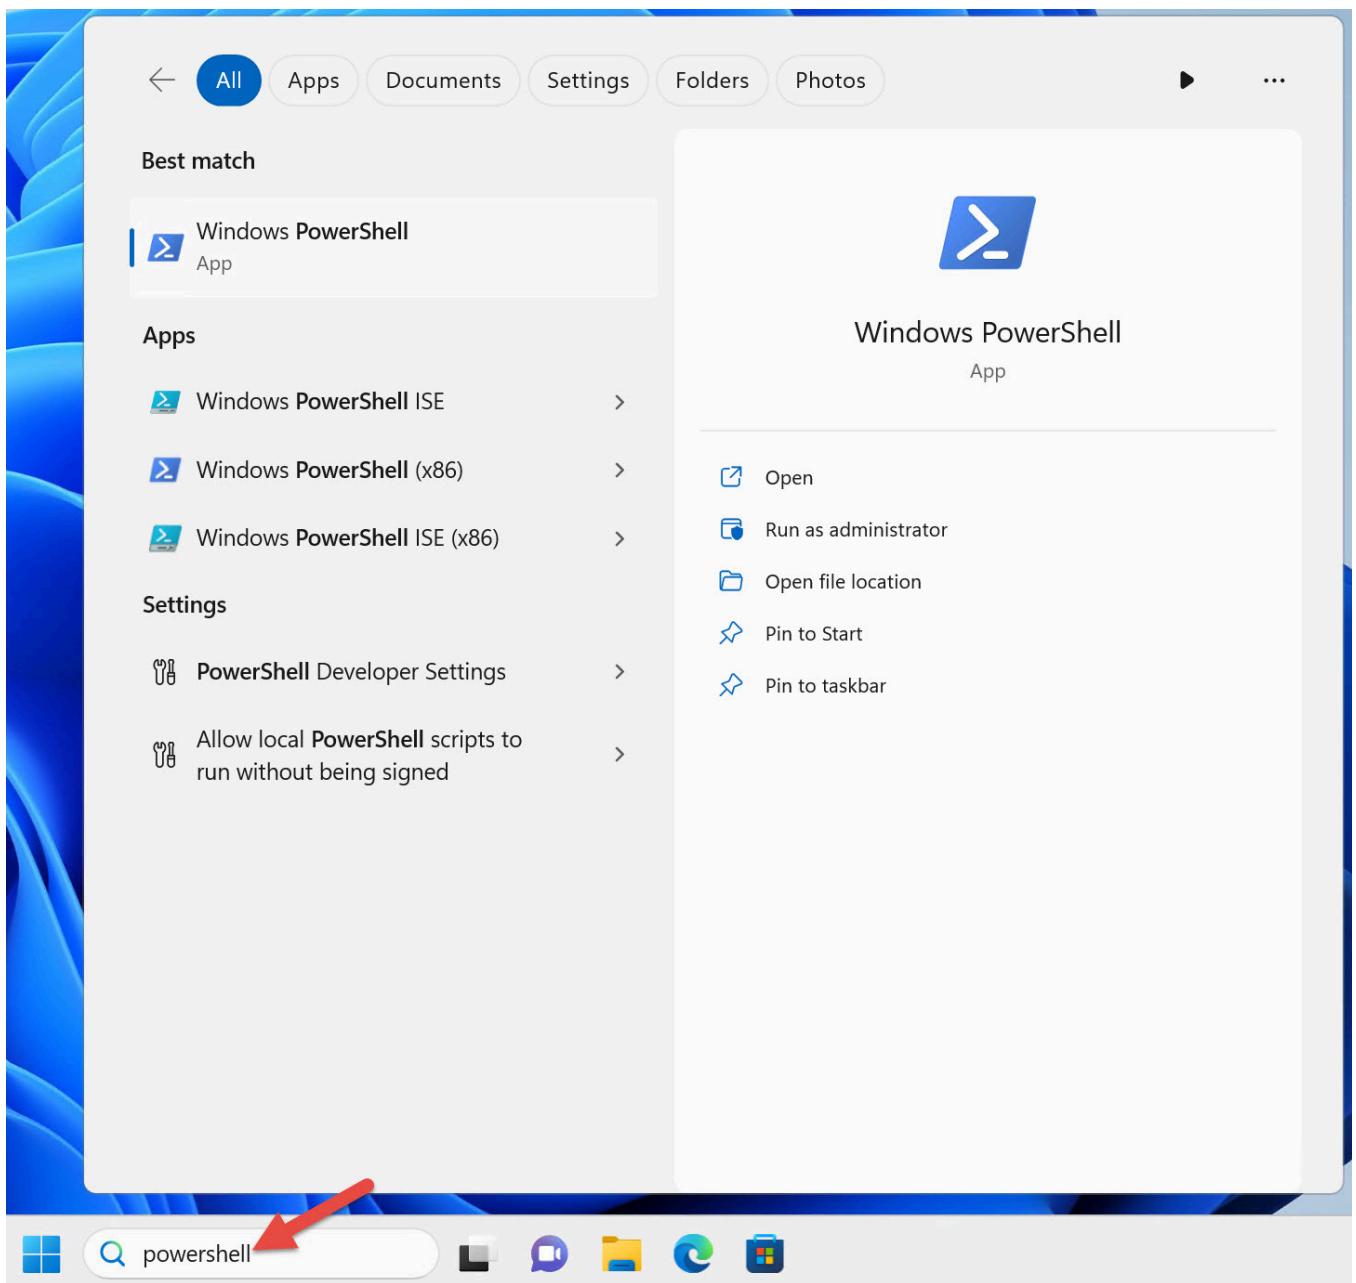

This chapter focuses on finding and launching PowerShell and solving the initial pain points that new users experience with PowerShell. Follow along and walk through the examples in this chapter on your lab environment computer.

What is PowerShell?

Windows PowerShell is an easy-to-use command-line shell and scripting environment for automating administrative tasks of Windows-based systems. Windows PowerShell is preinstalled on all modern versions of the Windows operating system.

Where to find PowerShell

The easiest way to find PowerShell on Windows 11 is to type `PowerShell` into the search bar, as shown in Figure 1-1. Notice that there are four different shortcuts for Windows PowerShell.

Windows PowerShell shortcuts on a 64-bit version of Windows:

- Windows PowerShell
- Windows PowerShell ISE
- Windows PowerShell (x86)
- Windows PowerShell ISE (x86)

On a 64-bit version of Windows, you have a 64-bit version of the Windows PowerShell console and the Windows PowerShell Integrated Scripting Environment (ISE) and a 32-bit version of each one, as indicated by the (x86) suffix on the shortcuts.

! Note

Windows 11 only ships as a 64-bit operating system. There is no 32-bit version of Windows 11. However, Windows 11 includes 32-bit versions of Windows PowerShell and the Windows PowerShell ISE.

You only have two shortcuts if you're running an older 32-bit version of Windows. Those shortcuts don't have the (x86) suffix but are 32-bit versions.

I recommend using the 64-bit version of Windows PowerShell if you're running a 64-bit operating system unless you have a specific reason for using the 32-bit version.

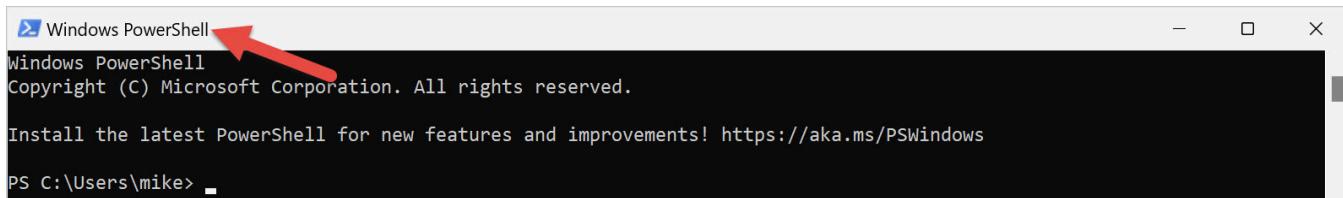

Depending on what version of Windows 11 you're running, Windows PowerShell might open in [Windows Terminal](#).

Microsoft no longer updates the PowerShell ISE. The ISE only works with Windows PowerShell 5.1. [Visual Studio Code](#) (VS Code) with the [PowerShell extension](#) works with both versions of PowerShell. VS Code and the PowerShell extension don't ship in Windows. Install VS Code and the extension on the computer where you create PowerShell scripts. You don't need to install them on all the computers where you run PowerShell.

How to launch PowerShell

I use three different Active Directory user accounts in the production environments I support. I mirrored those accounts in the lab environment used in this book. I sign into my Windows 11 computer as a domain user without domain or local administrator rights.

Launch the PowerShell console by clicking the **Windows PowerShell** shortcut, as shown in Figure 1-1. Notice that the title bar of the console says **Windows PowerShell**, as shown in Figure 1-2.

Some commands run fine when you run PowerShell as an ordinary user. However, PowerShell doesn't participate in [User Access Control \(UAC\)](#). That means it's unable to prompt for elevation for tasks that require the approval of an administrator.

⚠ Note

UAC is a Windows security feature that helps prevent malicious code from running with elevated privileges.

When signed on as an ordinary user, PowerShell returns an error when you run a command that requires elevation. For example, stopping a Windows service:

```
PowerShell

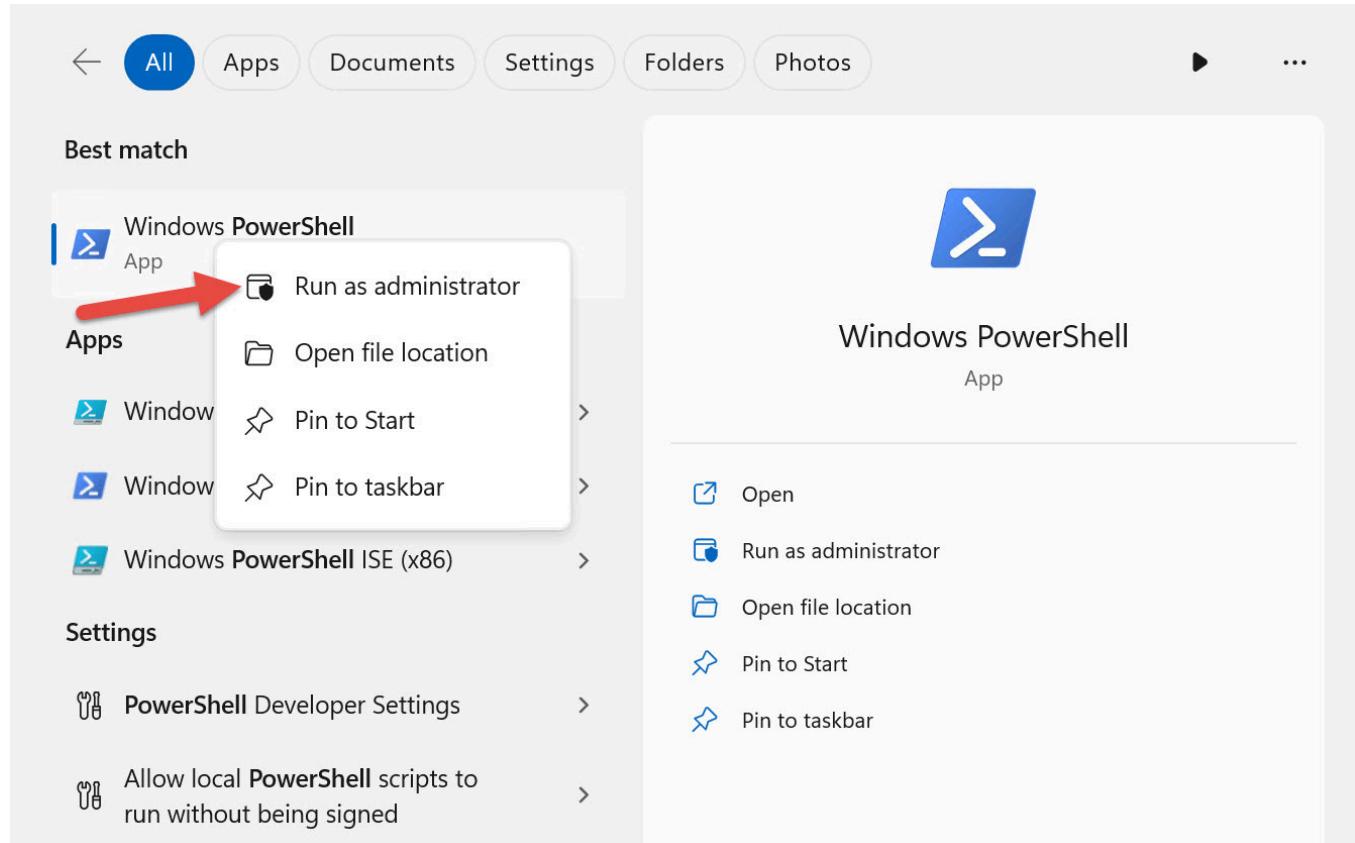

Stop-Service -Name W32Time

Output

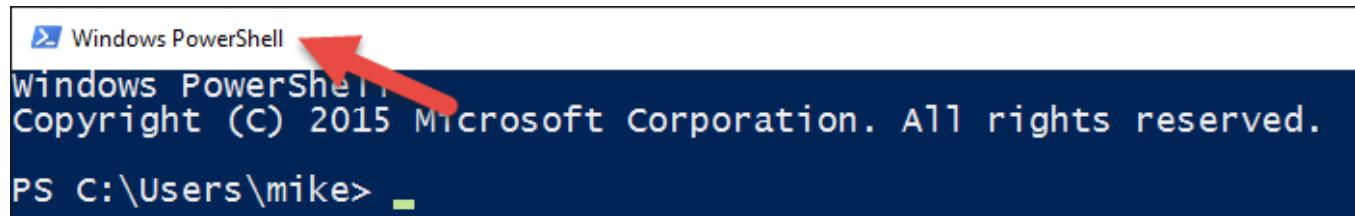

Stop-Service : Service 'Windows Time (W32Time)' cannot be stopped due to
the following error: Cannot open W32Time service on computer '.'.
At line:1 char:1
+ Stop-Service -Name W32Time
+ ~~~~~
+ CategoryInfo          : CloseError: (System.ServiceProcess.ServiceCon
troller:ServiceController) [Stop-Service], ServiceCommandException
+ FullyQualifiedErrorId : CouldNotStopService,Microsoft.PowerShell.Com
ands.StopServiceCommand
```

The solution is to run PowerShell elevated as a user who is a local administrator. That's how I configured my second domain user account. Following the principle of least privilege, this account shouldn't be a domain administrator or have any elevated privileges in the domain.

To start PowerShell with elevated rights, right-click the **Windows PowerShell** shortcut and select **Run as administrator**, as shown in Figure 1-3.

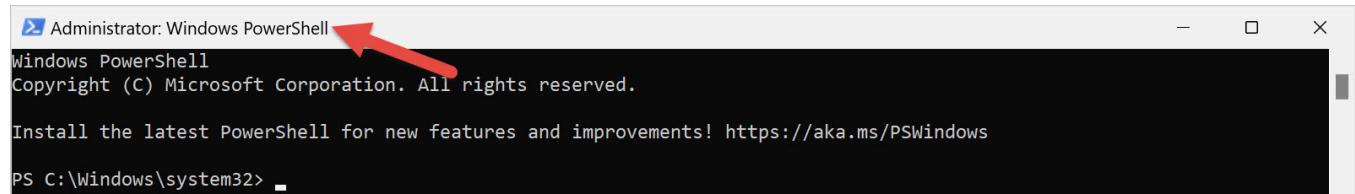

Windows prompts you for credentials because you logged into Windows as an ordinary user. Enter the credentials of your domain user who is a local administrator, as shown in Figure 1-4.

A screenshot of a Windows PowerShell window. The title bar says "Windows PowerShell". The content area shows the PowerShell prompt "PS C:\Users\mike>". A red arrow points to the title bar.

Notice that the title bar of the elevated console windows says **Administrator: Windows PowerShell**, as shown in Figure 1-5.

A screenshot of an elevated Windows PowerShell window. The title bar says "Administrator: Windows PowerShell". The content area shows the PowerShell prompt "PS C:\Windows\system32>". A red arrow points to the title bar.

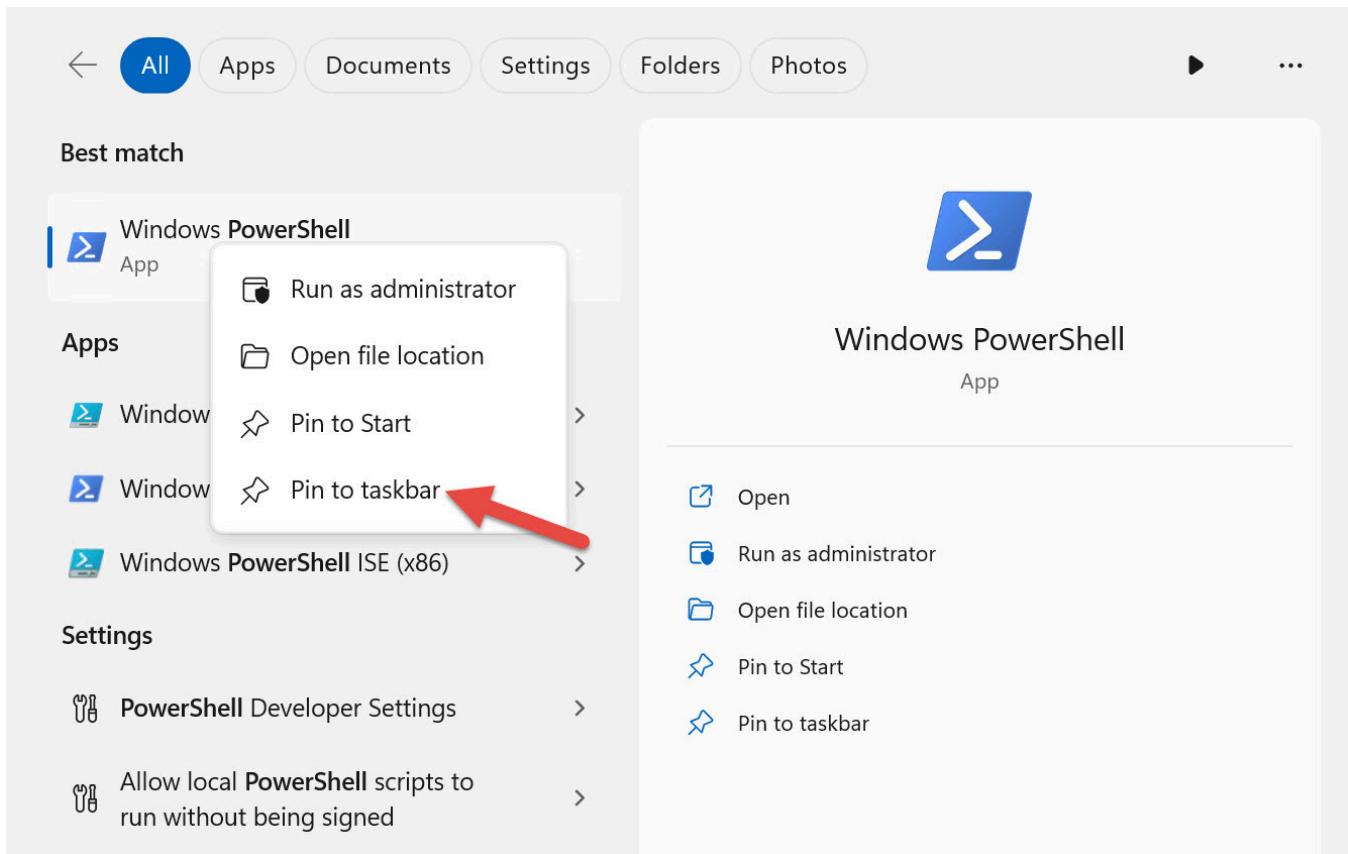

Now that you're running PowerShell elevated as an administrator, UAC is no longer a problem when you run a command that requires elevation.

 **Important**

You should only run PowerShell elevated as an administrator when absolutely necessary.

When you target remote computers, there's no need to run PowerShell elevated. Running PowerShell elevated only affects commands that run against your local computer.

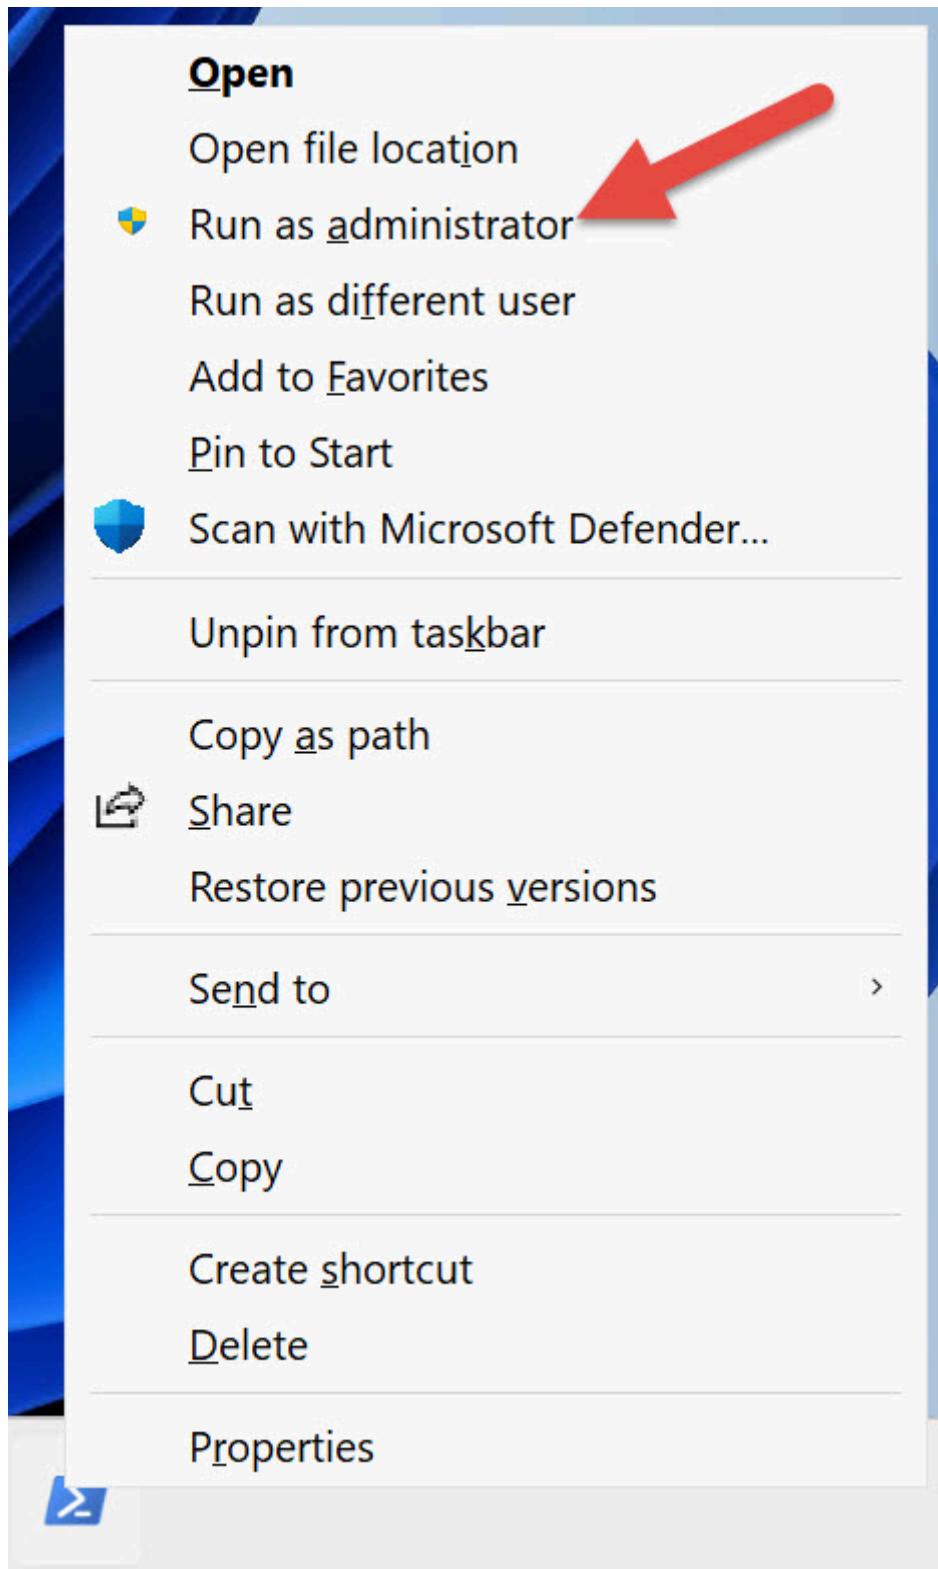

You can simplify finding and launching PowerShell. Pin the PowerShell or Windows Terminal shortcut to your taskbar. Search for PowerShell again, except this time right-click on it and select **Pin to taskbar** as shown in Figure 1-6.

ⓘ Important

The original version of this book, published in 2017, recommended pinning a shortcut to the taskbar to launch an elevated instance automatically every time you start PowerShell. However, due to potential security concerns, I no longer recommend it. Any applications you launch from an elevated instance of PowerShell also bypass UAC and run elevated. For example, if you launch a web browser from an elevated instance of PowerShell, any website you visit containing malicious code also runs elevated.

When you need to run PowerShell with elevated permissions, right-click the PowerShell shortcut pinned to your taskbar while pressing `Shift`. Select **Run as administrator**, as shown in Figure 1-7.

Determine your version of PowerShell

There are automatic variables in PowerShell that store state information. One of these variables is `$PSVersionTable`, which contains version information about your PowerShell session.

```
PowerShell
$PSVersionTable
```

Output

Name	Value
PSVersion	5.1.22621.2428
PSEdition	Desktop
PSCompatibleVersions	{1.0, 2.0, 3.0, 4.0...}
BuildVersion	10.0.22621.2428
CLRVersion	4.0.30319.42000
WSManStackVersion	3.0
PSRemotingProtocolVersion	2.3
SerializationVersion	1.1.0.1

If you're running a version of Windows PowerShell older than 5.1, you should update your version of Windows. Windows PowerShell 5.1 is preinstalled on the currently supported versions of Windows.

PowerShell version 7 isn't a replacement for Windows PowerShell 5.1; it installs side-by-side with Windows PowerShell. Windows PowerShell version 5.1 and PowerShell version 7 are two different products. For more information about the differences between Windows PowerShell version 5.1 and PowerShell version 7, see [Migrating from Windows PowerShell 5.1 to PowerShell 7](#).

Tip

PowerShell version 6, formerly known as PowerShell Core, is no longer supported.

Execution policy

PowerShell execution policy controls the conditions under which you can run PowerShell scripts. The execution policy in PowerShell is a safety feature designed to help prevent the unintentional execution of malicious scripts. However, it's not a security boundary because it can't stop determined users from deliberately running scripts. A determined user can bypass the execution policy in PowerShell.

You can set an execution policy for the local computer, current user, or a PowerShell session. You can also set execution policies for users and computers with Group Policy.

The following table shows the default execution policy for current Windows operating systems.

Expand table

Windows Operating System Version	Default Execution Policy
Windows Server 2022	Remote Signed
Windows Server 2019	Remote Signed
Windows Server 2016	Remote Signed
Windows 11	Restricted
Windows 10	Restricted

Regardless of the execution policy setting, you can run any PowerShell command interactively. The execution policy only affects commands running in a script. Use the `Get-ExecutionPolicy` cmdlet to determine the current execution policy setting.

Check the execution policy setting on your computer.

```
PowerShell
Get-ExecutionPolicy

Output
Restricted
```

List the execution policy settings for all scopes.

```
PowerShell
Get-ExecutionPolicy -List

Output
Scope ExecutionPolicy
-----
MachinePolicy      Undefined
UserPolicy         Undefined
Process           Undefined
CurrentUser        Undefined
LocalMachine       Undefined
```

All Windows client operating systems have the default execution policy setting of `Restricted`. You can't run PowerShell scripts using the `Restricted` execution policy setting. To test the execution policy, save the following code as a `.ps1` file named `Get-TimeService.ps1`.

Tip

A PowerShell script is a plaintext file that contains the commands you want to run.

PowerShell script files use the `.ps1` file extension. To create a PowerShell script, use a code editor like Visual Studio Code (VS Code) or any text editor such as Notepad.

When you run the following command interactively, it completes without error.

```
PowerShell
```

```
Get-Service -Name W32Time
```

However, PowerShell returns an error when you run the same command from a script.

```
PowerShell
```

```
.\Get-TimeService.ps1
```

```
Output
```

```
.\Get-TimeService.ps1 : File C:\tmp\Get-TimeService.ps1 cannot be loaded
because running scripts is disabled on this system. For more information,
see about_Execution_Policies at
https://go.microsoft.com/fwlink/?LinkID=135170.
At line:1 char:1
+ .\Get-TimeService.ps1
+ ~~~~~
+ CategoryInfo          : SecurityError: () [], PSSecurityException
+ FullyQualifiedErrorId : UnauthorizedAccess
```

When you run a command in PowerShell that generates an error, read the error message before retrying the command. Notice the error message tells you why the command failed:

... running scripts is disabled on this system.

To enable the execution of scripts, change the execution policy with the `Set-ExecutionPolicy` cmdlet. `LocalMachine` is the default scope when you don't specify the `Scope` parameter. You must run PowerShell elevated as an administrator to change the execution policy for the local machine. Unless you're signing your scripts, I recommend using the `RemoteSigned` execution policy. `RemoteSigned` prevents you from running downloaded scripts that aren't signed by a trusted publisher.

Before you change the execution policy, read the [about_Execution_Policies](#) help article to understand the security implications.

Change the execution policy setting on your computer to `RemoteSigned`.

PowerShell

```
Set-ExecutionPolicy -ExecutionPolicy RemoteSigned
```

If you have successfully changed the execution policy, PowerShell displays the following warning:

Output

Execution Policy Change

The execution policy helps protect you from scripts that you do not trust. Changing the execution policy might expose you to the security risks described in the [about_Execution_Policies](#) help topic at <https://go.microsoft.com/fwlink/?LinkID=135170>. Do you want to change the execution policy?
[Y] Yes [A] Yes to All [N] No [L] No to All [S] Suspend [?] Help
(default is "N"):`y`

If you're not running PowerShell elevated as an administrator, PowerShell returns the following error message:

Output

```
Set-ExecutionPolicy : Access to the registry key 'HKEY_LOCAL_MACHINE\SOFTWAR
E\Microsoft\PowerShell\1\ShellIds\Microsoft.PowerShell' is denied. To
change the execution policy for the default (LocalMachine) scope, start
Windows PowerShell with the "Run as administrator" option. To change the
execution policy for the current user, run "Set-ExecutionPolicy -Scope
CurrentUser".
At line:1 char:1
+ Set-ExecutionPolicy -ExecutionPolicy RemoteSigned
+ ~~~~~
+ CategoryInfo          : PermissionDenied: (:) [Set-ExecutionPolicy],
UnauthorizedAccessException
+ FullyQualifiedErrorId : System.UnauthorizedAccessException,Microsoft.
PowerShell.Commands.SetExecutionPolicyCommand
```

It's also possible to change the execution policy for the current user without requiring you to run PowerShell elevated as an administrator. This step is unnecessary if you successfully set the execution policy for the local machine to `RemoteSigned`.

PowerShell

```
Set-ExecutionPolicy -ExecutionPolicy RemoteSigned -Scope CurrentUser
```

With the execution policy set to `RemoteSigned`, the `Get-TimeService.ps1` script runs successfully.

PowerShell

```
.\Get-TimeService.ps1
```

Output

Status	Name	DisplayName
-----	-----	-----
Running	W32Time	Windows Time

Summary

In this chapter, you learned where to find and how to launch PowerShell. You also learned how to determine the version of PowerShell and the purpose of execution policies.

Review

1. How do you determine what PowerShell version a computer is running?
2. When should you launch PowerShell elevated as an administrator?
3. What's the default execution policy on Windows client computers, and what does it prevent you from doing?
4. How do you determine the current PowerShell execution policy setting?
5. How do you change the PowerShell execution policy?

References

To learn more about the concepts covered in this chapter, read the following PowerShell help articles.

- [about_Automatic_Variables](#)
- [about_Execution_Policies](#)

Next steps

In the next chapter, you'll learn about the discoverability of commands in PowerShell. You'll also learn how to download PowerShell's help files so you can view the help in your PowerShell session.

Chapter 2 - The Help system

Article • 06/27/2024

In an experiment designed to assess proficiency in PowerShell, two distinct groups of IT professionals — beginners and experts — were first given a written examination without access to a computer. Surprisingly, the test scores indicated comparable skills across both groups. A subsequent test was then administered, mirroring the first but with one key difference: participants had access to an offline computer equipped with PowerShell. The results revealed a significant skills gap between the two groups this time.

What factors contributed to the outcomes observed between the two assessments?

Experts don't always know the answers, but they know how to figure out the answers.

The outcomes observed in the results of the two tests were because experts don't memorize thousands of PowerShell commands. Instead, they excel at using the Help system within PowerShell, enabling them to discover and learn how to use commands when necessary.

Becoming proficient with the Help system is the key to success with PowerShell.

I heard Jeffrey Snover, the creator of PowerShell, share a similar story on multiple occasions.

Discoverability

Compiled commands in PowerShell are known as cmdlets, pronounced as "*command-let*", not "*CMD-let*". The naming convention for cmdlets follows a singular **Verb-Noun** format to make them easily discoverable. For instance, `Get-Process` is the cmdlet to determine what processes are running, and `Get-Service` is the cmdlet to retrieve a list of services. Functions, also known as script cmdlets, and aliases are other types of PowerShell commands that are discussed later in this book. The term "*PowerShell command*" describes any command in PowerShell, regardless of whether it's a cmdlet, function, or alias.

You can also run operating system native commands from PowerShell, such as traditional command-line programs like `ping.exe` and `ipconfig.exe`.

The three core cmdlets in PowerShell

- `Get-Help`
- `Get-Command`
- `Get-Member` (covered in chapter 3)

I'm often asked: "*How do you figure out what the commands are in PowerShell?*". Both `Get-Help` and `Get-Command` are invaluable resources for discovering and understanding commands in PowerShell.

Get-Help

The first thing you need to know about the Help system in PowerShell is how to use the `Get-Help` cmdlet.

`Get-Help` is a multipurpose command that helps you learn how to use commands once you find them. You can also use `Get-Help` to locate commands, but in a different and more indirect way when compared to `Get-Command`.

When using `Get-Help` to locate commands, it initially performs a wildcard search for command names based on your input. If that doesn't find any matches, it conducts a comprehensive full-text search across all PowerShell help articles on your system. If that also fails to find any results, it returns an error.

Here's how to use `Get-Help` to view the help content for the `Get-Help` cmdlet.

```
PowerShell
Get-Help -Name Get-Help
```

Beginning with PowerShell version 3.0, the help content doesn't ship preinstalled with the operating system. When you run `Get-Help` for the first time, a message asks if you want to download the PowerShell help files to your computer.

Answering **Yes** by pressing `y` executes the `Update-Help` cmdlet, downloading the help content.

```
Output
Do you want to run Update-Help?
The Update-Help cmdlet downloads the most current Help files for Windows
PowerShell modules, and installs them on your computer. For more information
about the Update-Help cmdlet, see
```

```
https://go.microsoft.com/fwlink/?LinkId=210614.  
[Y] Yes [N] No [S] Suspend [?] Help (default is "Y"):
```

If you don't receive this message, run `Update-Help` from an elevated PowerShell session running as an administrator.

Once the update is complete, the help article is displayed.

Take a moment to run the example on your computer, review the output, and observe how the help system organizes the information.

- NAME
- SYNOPSIS
- SYNTAX
- DESCRIPTION
- RELATED LINKS
- REMARKS

As you review the output, keep in mind that help articles often contain a vast amount of information, and what you see by default isn't the entire help article.

Parameters

When you run a command in PowerShell, you might need to provide additional information or input to the command. Parameters allow you to specify options and arguments that change the behavior of a command. The **SYNTAX** section of each help article outlines the available parameters for the command.

`Get-Help` has several parameters that you can specify to return the entire help article or a subset for a command. To view all the available parameters for `Get-Help`, see the **SYNTAX** section of its help article, as shown in the following example.

Output

```

```

Parameter sets

When you review the **SYNTAX** section for `Get-Help`, notice that the information appears to be repeated six times. Each of those blocks is an individual parameter set, indicating the `Get-Help` cmdlet features six distinct sets of parameters. A closer look reveals each parameter set contains at least one unique parameter, making it different from the others.

Parameter sets are mutually exclusive. Once you specify a unique parameter that only exists in one parameter set, PowerShell limits you to using the parameters contained within that parameter set. For instance, you can't use the **Full** and **Detailed** parameters of `Get-Help` together because they belong to different parameter sets.

Each of the following parameters belongs to a different parameter set for the `Get-Help` cmdlet.

- Full
- Detailed
- Examples
- Online
- Parameter
- ShowWindow

The command syntax

If you're new to PowerShell, comprehending the cryptic information — characterized by square and angle brackets — in the **SYNTAX** section might seem overwhelming. However, learning these syntax elements is essential to becoming proficient with PowerShell. The more frequently you use the PowerShell Help system, the easier it becomes to remember all the nuances.

View the syntax of the `Get-EventLog` cmdlet.

```
PowerShell

Get-Help Get-EventLog
```

The following output shows the relevant portion of the help article.

```
Output

...
SYNTAX
  Get-EventLog [-LogName] <System.String> [[-InstanceId]
    <System.Int64[]>] [-After <System.DateTime>] [-AsBaseObject] [-Before
    <System.DateTime>] [-ComputerName <System.String[]>] [-EntryType {Error
    | Information | FailureAudit | SuccessAudit | Warning}] [-Index
    <System.Int32[]>] [-Message <System.String>] [-Newest <System.Int32>]
    [-Source <System.String[]>] [-UserName <System.String[]>]
    [<CommonParameters>]

  Get-EventLog [-AsString] [-ComputerName <System.String[]>] [-List]
    [<CommonParameters>]
...
```

The syntax information includes pairs of square brackets (`[]`). Depending on their usage, these square brackets serve two different purposes.

- Elements enclosed in square brackets are optional.
- An empty set of square brackets following a datatype, such as `<string[]>`, indicates that the parameter can accept multiple values passed as an array or a

collection object.

Positional parameters

Some cmdlets are designed to accept positional parameters. Positional parameters allow you to provide a value without specifying the name of the parameter. When using a parameter positionally, you must specify its value in the correct position on the command line. You can find the positional information for a parameter in the **PARAMETERS** section of a command's help article. When you explicitly specify parameter names, you can use the parameters in any order.

For the `Get-EventLog` cmdlet, the first parameter in the first parameter set is **LogName**. **LogName** is enclosed in square brackets, indicating it's a positional parameter.

Syntax

```
Get-EventLog [-LogName] <System.String>
```

Since **LogName** is a positional parameter, you can specify it by either name or position. According to the angle brackets following the parameter name, the value for **LogName** must be a single string. The absence of square brackets enclosing both the parameter name and datatype indicates that **LogName** is a required parameter within this particular parameter set.

The second parameter in that parameter set is **InstanceId**. Both the parameter name and datatype are entirely enclosed in square brackets, signifying that **InstanceId** is an optional parameter.

Syntax

```
[[-InstanceId] <System.Int64[]>]
```

Furthermore, **InstanceId** has its own pair of square brackets, indicating that it's a positional parameter similar to the **LogName** parameter. Following the datatype, an empty set of square brackets implies that **InstanceId** can accept multiple values.

Switch parameters

A parameter that doesn't require a value is called a switch parameter. You can easily identify switch parameters because there's no datatype following the parameter name. When you specify a switch parameter, its value is `true`. When you don't specify a switch parameter, its value is `false`.

The second parameter set includes a **List** parameter, which is a switch parameter. When you specify the **List** parameter, it returns a list of event logs on the local computer.

Syntax

```
[-List]
```

A simplified approach to syntax

There's a more user-friendly method to obtain the same information as the cryptic command syntax for some commands, except in plain English. PowerShell returns the complete help article when using `Get-Help` with the **Full** parameter, making it easier to understand a command's usage.

PowerShell

```
Get-Help -Name Get-Help -Full
```

Take a moment to run the example on your computer, review the output, and observe how the help system organizes the information.

- NAME
- SYNOPSIS
- SYNTAX
- DESCRIPTION
- PARAMETERS
- INPUTS
- OUTPUTS
- NOTES
- EXAMPLES
- RELATED LINKS

By specifying the **Full** parameter with the `Get-Help` cmdlet, the output includes several extra sections. Among these sections, **PARAMETERS** often provides a detailed explanation for each parameter. However, the extent of this information varies depending on the specific command you're investigating.

Output

```
...
-Detailed <System.Management.Automation.SwitchParameter>
    Adds parameter descriptions and examples to the basic help display.
    This parameter is effective only when the help files are installed
```

on the computer. It has no effect on displays of conceptual (`About_`) help.

Required?	true
Position?	named
Default value	False
Accept pipeline input?	False
Accept wildcard characters?	false

-Examples <System.Management.Automation.SwitchParameter>

Displays only the name, synopsis, and examples. This parameter is effective only when the help files are installed on the computer. It has no effect on displays of conceptual (`About_`) help.

Required?	true
Position?	named
Default value	False
Accept pipeline input?	False
Accept wildcard characters?	false

-Full <System.Management.Automation.SwitchParameter>

Displays the entire help article for a cmdlet. Full includes parameter descriptions and attributes, examples, input and output object types, and additional notes.

This parameter is effective only when the help files are installed on the computer. It has no effect on displays of conceptual (`About_`) help.

Required?	false
Position?	named
Default value	False
Accept pipeline input?	False
Accept wildcard characters?	false

...

When you ran the previous command to display the help for the `Get-Help` command, you probably noticed the output scrolled by too quickly to read it.

If you're using the PowerShell console, Windows Terminal, or VS Code and need to view a help article, the `help` function can be useful. It pipes the output of `Get-Help` to `more.com`, displaying one page of help content at a time. I recommend using the `help` function instead of the `Get-Help` cmdlet because it provides a better user experience and it's less to type.

ⓘ Note

The ISE doesn't support using `more.com`, so running `help` works the same way as `Get-Help`.

Run each of the following commands in PowerShell on your computer.

PowerShell

```
Get-Help -Name Get-Help -Full  
help -Name Get-Help -Full  
help Get-Help -Full
```

Did you observe any variations in the output when you ran the previous commands?

In the previous example, the first line uses the `Get-Help` cmdlet, the second uses the `help` function, and the third line omits the **Name** parameter while using the `help` function. Since **Name** is a positional parameter, the third example takes advantage of its position instead of explicitly stating the parameter's name.

The difference is that the last two commands display their output one page at a time. When using the `help` function, press the `Spacebar` to display the next page of content or `Q` to quit. If you need to terminate any command running interactively in PowerShell, press `Ctrl + C`.

To quickly find information about a specific parameter, use the **Parameter** parameter. This approach returns content containing only the parameter-specific information, rather than the entire help article. This is the easiest way to find information about a specific parameter.

The following example uses the `help` function with the **Parameter** parameter to return information from the help article for the **Name** parameter of `Get-Help`.

PowerShell

```
help Get-Help -Parameter Name
```

The help information shows that the **Name** parameter is positional and must be specified in the first position (position zero) when used positionally.

Output

```
-Name <System.String>  
Gets help about the specified command or concept. Enter the name of a cmdlet, function, provider, script, or workflow, such as `Get-Member`, a conceptual article name, such as `about_Objects`, or an alias, such as `ls`. Wildcard characters are permitted in cmdlet and provider names, but you can't use wildcard characters to find the names of function help and script help articles.
```

To get help for a script that isn't located in a path that's listed in

the `\$env:Path` environment variable, type the script's path and file name.

If you enter the exact name of a help article, `Get-Help` displays the article contents.

If you enter a word or word pattern that appears in several help article titles, `Get-Help` displays a list of the matching titles.

If you enter any text that doesn't match any help article titles, `Get-Help` displays a list of articles that include that text in their contents.

The names of conceptual articles, such as `about_Objects`, must be entered in English, even in non-English versions of PowerShell.

Required?	false
Position?	0
Default value	None
Accept pipeline input?	True (ByPropertyName)
Accept wildcard characters?	true

The **Name** parameter expects a string value as identified by the `<String>` datatype next to the parameter name.

There are several other parameters you can specify with `Get-Help` to return a subset of a help article. To see how they work, run the following commands on your computer.

PowerShell

```
Get-Help -Name Get-Command -Full
Get-Help -Name Get-Command -Detailed
Get-Help -Name Get-Command -Examples
Get-Help -Name Get-Command -Online
Get-Help -Name Get-Command -Parameter Noun
Get-Help -Name Get-Command -ShowWindow
```

I typically use `help <command name>` with the **Full** or **Online** parameter. If you only have an interest in the examples, use the **Examples** parameter. If you only have an interest in a specific parameter, use the **Parameter** parameter.

When you use the **ShowWindow** parameter, it displays the help content in a separate searchable window. You can move that window to a different monitor if you have multiple monitors. However, the **ShowWindow** parameter has a known bug that might prevent it from displaying the entire help article. The **ShowWindow** parameter also requires an operating system with a Graphical User Interface (GUI). It returns an error when you attempt to use it on Windows Server Core.

If you have internet access, you can use the **Online** parameter instead. The **Online** parameter opens the help article in your default web browser. The online content is the most up-to-date content. The browser allows you to search the help content and view other related help articles.

ⓘ Note

The **Online** parameter isn't supported for **About** articles.

PowerShell

```
help Get-Command -Online
```

Finding commands with Get-Help

To find commands with `Get-Help`, specify a search term surrounded by asterisk (*) wildcard characters for the value of the **Name** parameter. The following example uses the **Name** parameter positionally.

PowerShell

```
help *process*
```

Output

Name	Category	Module	Synops
Enter-PSHostProcess	Cmdlet	Microsoft.PowerShell.Core	Con...
Exit-PSHostProcess	Cmdlet	Microsoft.PowerShell.Core	Clo...
Get-PSHostProcessInfo	Cmdlet	Microsoft.PowerShell.Core	Get...
Debug-Process	Cmdlet	Microsoft.PowerShell.M...	Deb...
Get-Process	Cmdlet	Microsoft.PowerShell.M...	Get...
Start-Process	Cmdlet	Microsoft.PowerShell.M...	Sta...
Stop-Process	Cmdlet	Microsoft.PowerShell.M...	Sto...
Wait-Process	Cmdlet	Microsoft.PowerShell.M...	Wai...
Invoke-LapsPolicyProcessing	Cmdlet	LAPS	Inv...
ConvertTo-ProcessMitigationPolicy	Cmdlet	ProcessMitigations	Con...
Get-ProcessMitigation	Cmdlet	ProcessMitigations	Get...
Set-ProcessMitigation	Cmdlet	ProcessMitigations	Set...

In this scenario, you aren't required to add the (*) wildcard characters. If `Get-Help` can't find a command matching the value you provided, it does a full-text search for that

value. The following example produces the same results as specifying the `*` wildcard character on each end of `process`.

```
PowerShell
```

```
help process
```

When you specify a wildcard character within the value, `Get-Help` only searches for commands that match the pattern you provided. It doesn't perform a full-text search. The following command doesn't return any results.

```
PowerShell
```

```
help pr*cess
```

PowerShell generates an error if you specify a value that begins with a dash without enclosing it in quotes because it interprets it as a parameter name. No such parameter name exists for the `Get-Help` cmdlet.

```
PowerShell
```

```
help -process
```

If you're attempting to search for commands that end with `-process`, you must add an `*` to the beginning of the value.

```
PowerShell
```

```
help *-process
```

When you search for PowerShell commands with `Get-Help`, it's better to be vague rather than too specific.

When you searched for `process` earlier, the results only returned commands that included `process` in their name. But if you search for `processes`, it doesn't find any matches for command names. As previously stated, when help doesn't find any matches, it performs a comprehensive full-text search of every help article on your system and returns those results. This type of search often produces more results than expected, including information not relevant to you.

```
PowerShell
```

help processes

Output

When you searched for `process`, it returned 12 results. However, when searching for `processes`, it produced 78 results. If your search only finds one match, `Get-Help` displays the help content instead of listing the search results.

```
PowerShell
help *hotfix*

```

Output

```
NAME
    Get-HotFix

SYNOPSIS
    Gets the hotfixes that are installed on local or remote computers.
```

SYNTAX

```
Get-HotFix [-ComputerName <System.String[]>] [-Credential <System.Management.Automation.PSCredential>] [-Description <System.String[]>] [<CommonParameters>]

Get-HotFix [[-Id] <System.String[]>] [-ComputerName <System.String[]>] [-Credential <System.Management.Automation.PSCredential>] [<CommonParameters>]
```

DESCRIPTION

> This cmdlet is only available on the Windows platform. The `Get-HotFix` cmdlet uses the Win32_QuickFixEngineering WMI class to list hotfixes that are installed on the local computer or specified remote computers.

RELATED LINKS

Online Version: https://learn.microsoft.com/powershell/module/microsoft.powershell.management/get-hotfix?view=powershell-5.1&WT.mc_id=ps-gethelp

Win32_QuickFixEngineering class

REMARKS

To see the examples, type: "Get-Help Get-HotFix -Examples".
For more information, type: "Get-Help Get-HotFix -Detailed".
For technical information, type: "Get-Help Get-HotFix -Full".
For online help, type: "Get-Help Get-HotFix -Online"

You can also find commands that lack help articles with `Get-Help`, although this capability isn't commonly known. The `more` function is one of the commands that doesn't have a help article. To confirm that you can find commands with `Get-Help` that don't include help articles, use the `help` function to find `more`.

PowerShell

```
help *more*
```

The search only found one match, so it returned the basic syntax information you see when a command doesn't have a help article.

Output

NAME

more

SYNTAX

```
more [[-paths] <string[]>]
```

ALIASES

None

REMARKS

None

The PowerShell help system also contains conceptual **About** help articles. You must update the help content on your system to get the **About** articles. For more information, see the [Updating help](#) section of this chapter.

Use the following command to return a list of all **About** help articles on your system.

```
PowerShell
```

```
help About_*
```

When you limit the results to one **About** help article, `Get-Help` displays the content of that article.

```
PowerShell
```

```
help about_Updatable_Help
```

Updating help

Earlier in this chapter, you updated the PowerShell help articles on your computer the first time you ran the `Get-Help` cmdlet. You should periodically run the `Update-Help` cmdlet on your computer to obtain any updates to the help content.

 **Important**

In Windows PowerShell 5.1, you must run `Update-Help` as an administrator in an elevated PowerShell session.

In the following example, `Update-Help` downloads the PowerShell help content for all modules installed on your computer. You should use the **Force** parameter to ensure that you download the latest version of the help content.

```
PowerShell
```

```
Update-Help -Force
```

As shown in the following results, a module returned an error. Errors aren't uncommon and usually occur when the module's author doesn't configure updatable help correctly.

Output

```
Update-Help : Failed to update Help for the module(s) 'BitsTransfer' with UI culture(s) {en-US} : Unable to retrieve the HelpInfo XML file for UI culture en-US. Make sure the HelpInfoUri property in the module manifest is valid or check your network connection and then try the command again.  
At line:1 char:1  
+ Update-Help  
+ ~~~~~~  
    + CategoryInfo          : ResourceUnavailable: (:) [Update-Help], Except  
      ion  
    + FullyQualifiedErrorId : UnableToRetrieveHelpInfoXml,Microsoft.PowerShe  
      ll.Commands.UpdateHelpCommand
```

`Update-Help` requires internet access to download the help content. If your computer doesn't have internet access, use the `Save-Help` cmdlet on a computer with internet access to download and save the updated help content. Then, use the **SourcePath** parameter of `Update-Help` to specify the location of the saved updated help content.

Get-Command

`Get-Command` is another multipurpose command that helps you find commands. When you run `Get-Command` without any parameters, it returns a list of all PowerShell commands on your system. You can also use `Get-Command` to get command syntax similar to `Get-Help`.

How do you determine the syntax for `Get-Command`? You could use `Get-Help` to display the help article for `Get-Command`, as shown in the [Get-Help](#) section of this chapter. You can also use `Get-Command` with the **Syntax** parameter to view the syntax for any command. This shortcut helps you quickly determine how to use a command without navigating through its help content.

PowerShell

```
Get-Command -Name Get-Command -Syntax
```

Using `Get-Command` with the `Syntax` parameter provides a more concise view of the syntax that shows the parameters and their value types, without listing the specific allowable values like `Get-Help` shows.

Output

```
Get-Command [[-ArgumentList] <Object[]>] [-Verb <string[]>]
[-Noun <string[]>] [-Module <string[]>]
[-FullyQualifiedModule <ModuleSpecification[]>] [-TotalCount <int>]
[-Syntax] [-ShowCommandInfo] [-All] [-ListImported]
[-ParameterName <string[]>] [-ParameterType <PSTypeName[]>]
[<CommonParameters>]

Get-Command [[-Name] <string[]>] [[-ArgumentList] <Object[]>]
[-Module <string[]>] [-FullyQualifiedModule <ModuleSpecification[]>]
[- CommandType <CommandTypes>] [-TotalCount <int>] [-Syntax]
[-ShowCommandInfo] [-All] [-ListImported] [-ParameterName <string[]>]
[-ParameterType <PSTypeName[]>] [<CommonParameters>]
```

If you need more detailed information about how to use a command, use `Get-Help`.

PowerShell

```
help Get-Command -Full
```

The **SYNTAX** section of `Get-Help` provides a more user-friendly display by expanding enumerated values for parameters. It shows you the actual values you can use, making it easier to understand the available options.

Output

```
...
Get-Command [[-Name] <System.String[]>] [[-ArgumentList]
<System.Object[]>] [-All] [-CommandType {Alias | Function | Filter |
Cmdlet | ExternalScript | Application | Script | Workflow |
Configuration | All}] [-FullyQualifiedModule
<Microsoft.PowerShell.Commands.ModuleSpecification[]>] [-ListImported]
[-Module <System.String[]>] [-ParameterName <System.String[]>]
[-ParameterType <System.Management.Automation.PSTypeName[]>]
[-ShowCommandInfo] [-Syntax] [-TotalCount <System.Int32>]
[<CommonParameters>]

Get-Command [[-ArgumentList] <System.Object[]>] [-All]
[-FullyQualifiedModule
<Microsoft.PowerShell.Commands.ModuleSpecification[]>] [-ListImported]
[-Module <System.String[]>] [-Noun <System.String[]>] [-ParameterName
<System.String[]>] [-ParameterType
<System.Management.Automation.PSTypeName[]>] [-ShowCommandInfo]
[-Syntax] [-TotalCount <System.Int32>] [-Verb <System.String[]>]
```

```
[<CommonParameters>]
```

```
...
```

The **PARAMETERS** section of the help for `Get-Command` reveals that the **Name**, **Noun**, and **Verb** parameters accept wildcard characters.

Output

```
...
```

```
-Name <System.String[]>
```

Specifies an array of names. This cmdlet gets only commands that have the specified name. Enter a name or name pattern. Wildcard characters are permitted.

To get commands that have the same name, use the **All** parameter. When two commands have the same name, by default, `Get-Command` gets the command that runs when you type the command name.

Required?	false
-----------	-------

Position?	0
-----------	---

Default value	None
---------------	------

Accept pipeline input?	True (ByPropertyName, ByValue)
------------------------	--------------------------------

Accept wildcard characters?	true
-----------------------------	------

```
-Noun <System.String[]>
```

Specifies an array of command nouns. This cmdlet gets commands, which include cmdlets, functions, and aliases, that have names that include the specified noun. Enter one or more nouns or noun patterns. Wildcard characters are permitted.

Required?	false
-----------	-------

Position?	named
-----------	-------

Default value	None
---------------	------

Accept pipeline input?	True (ByPropertyName)
------------------------	-----------------------

Accept wildcard characters?	true
-----------------------------	------

```
-Verb <System.String[]>
```

Specifies an array of command verbs. This cmdlet gets commands, which include cmdlets, functions, and aliases, that have names that include the specified verb. Enter one or more verbs or verb patterns. Wildcard characters are permitted.

Required?	false
-----------	-------

Position?	named
-----------	-------

Default value	None
---------------	------

Accept pipeline input?	True (ByPropertyName)
------------------------	-----------------------

Accept wildcard characters?	true
-----------------------------	------

```
...
```

The following example uses the `*` wildcard character with the value for the **Name** parameter of `Get-Command`.

```
PowerShell
```

```
Get-Command -Name *service*
```

When you use wildcard characters with the **Name** parameter of `Get-Command`, it returns PowerShell commands and native commands, as shown in the following results.

Output

CommandType	Name	Version
Function	Get-NetFirewallServiceFilter	2.0.0.0
Function	Set-NetFirewallServiceFilter	2.0.0.0
Cmdlet	Get-Service	3.1.0.0
Cmdlet	New-Service	3.1.0.0
Cmdlet	New-WebServiceProxy	3.1.0.0
Cmdlet	Restart-Service	3.1.0.0
Cmdlet	Resume-Service	3.1.0.0
Cmdlet	Set-Service	3.1.0.0
Cmdlet	Start-Service	3.1.0.0
Cmdlet	Stop-Service	3.1.0.0
Cmdlet	Suspend-Service	3.1.0.0
Application	SecurityHealthService.exe	10.0.2...
Application	SensorDataService.exe	10.0.2...
Application	services.exe	10.0.2...
Application	services.msc	0.0.0.0
Application	TieringEngineService.exe	10.0.2...
Application	Windows.WARP.JITService.exe	10.0.2...

You can limit the results of `Get-Command` to PowerShell commands using the **CommandType** parameter.

```
PowerShell
```

```
Get-Command -Name *service* -CommandType Cmdlet, Function, Alias, Script
```

Another option might be to use either the **Verb** or **Noun** parameter or both since only PowerShell commands have verbs and nouns.

The following example uses `Get-Command` to find commands on your computer that work with processes. Use the **Noun** parameter and specify `Process` as its value.

```
PowerShell
```

```
Get-Command -Noun Process
```

Output		
CommandType	Name	Version
Cmdlet	Debug-Process	3.1.0.0
Cmdlet	Get-Process	3.1.0.0
Cmdlet	Start-Process	3.1.0.0
Cmdlet	Stop-Process	3.1.0.0
Cmdlet	Wait-Process	3.1.0.0

Summary

In this chapter, you learned how to find commands with `Get-Help` and `Get-Command`. You also learned how to use the help system to understand how to use commands once you find them. In addition, you learned how to update the help system on your computer when new help content is available.

Review

1. Is the `DisplayName` parameter of `Get-Service` positional?
2. How many parameter sets does the `Get-Process` cmdlet have?
3. What PowerShell commands exist for working with event logs?
4. What's the PowerShell command for returning a list of PowerShell processes running on your computer?
5. How do you update the PowerShell help content stored on your computer?

References

To learn more about the concepts covered in this chapter, read the following PowerShell help articles.

- [Get-Help](#)
- [Get-Command](#)

- [about_Command_Syntax](#)

Next steps

In the next chapter, you'll learn about objects, properties, methods, and the `Get-Member` cmdlet.

Chapter 3 - Discovering objects, properties, and methods

Article • 08/19/2024

PowerShell is an object-oriented scripting language. It represents data and system states using structured objects derived from .NET classes defined in the .NET Framework. By leveraging the .NET Framework, PowerShell offers access to various system capabilities, including file system, registry, and Windows Management Instrumentation (WMI) classes. PowerShell also has access to the .NET Framework class library, which contains a vast collection of classes that you can use to develop robust PowerShell scripts.

In PowerShell, each item or state is an instance of an object that can be explored and manipulated. The `Get-Member` cmdlet is one of the primary tools provided by PowerShell for object discovery, which reveals an object's characteristics. This chapter explores how PowerShell leverages objects and how you can discover and manipulate these objects to streamline your scripts and manage your systems more efficiently.

Prerequisites

To follow the specific examples in this chapter, ensure that your lab environment computer is part of your lab environment Active Directory domain. You must also install the Active Directory PowerShell module bundled with the Windows Remote Server Administration Tools (RSAT). If you're using Windows 10 build 1809 or later, including Windows 11, you can install RSAT as a Windows feature.

Note

Active Directory is unsupported for Windows Home editions.

- For information about installing RSAT, see [Windows Management modules](#).
- For older versions of Windows, see [RSAT for Windows](#).

Get-Member

`Get-Member` provides insight into the objects, properties, and methods associated with PowerShell commands. You can pipe any PowerShell command that produces object-based output to `Get-Member`. When you pipe the output of a command to `Get-Member`, it

reveals the structure of the object returned by the command, detailing its properties and methods.

- **Properties:** The attributes of an object.
- **Methods:** The actions you can perform on an object.

To illustrate this concept, consider a driver's license as an analogy. Like any object, a driver's license has properties, such as **eye color**, which typically includes `blue` and `brown` values. In contrast, methods represent actions you can perform on the object. For instance, **Revoke** is a method that the Department of Motor Vehicles can perform on a driver's license.

Properties

To retrieve details about the Windows Time service on your system using PowerShell, use the `Get-Service` cmdlet.

```
PowerShell
```

```
Get-Service -Name w32time
```

The results include the **Status**, **Name**, and **DisplayName** properties. The **Status** property indicates that the service is `Running`. The value for the **Name** property is `w32time`, and the value for the **DisplayName** property is `Windows Time`.

```
Output
```

Status	Name	DisplayName
-----	----	-----
Running	w32time	Windows Time

To list all available properties and methods for `Get-Service`, pipe it to `Get-Member`.

```
PowerShell
```

```
Get-Service -Name w32time | Get-Member
```

The results show the first line contains one piece of significant information. **TypeName** identifies the type of object returned, which in this example is a **System.ServiceProcess.ServiceController** object. This name is often abbreviated to the last part of the **TypeName**, such as **ServiceController**, in this example.

```
Output
```

TypeName: System.ServiceProcess.ServiceController

Name	MemberType	Definition
Name	AliasProperty	Name = ServiceName
RequiredServices	AliasProperty	RequiredServices = ServicesDepend...
Disposed	Event	System.EventHandler Disposed(Syst...
Close	Method	void Close()
Continue	Method	void Continue()
CreateObjRef	Method	System.Runtime.Remoting.ObjRef Cr...
Dispose	Method	void Dispose(), void IDisposable....
Equals	Method	bool Equals(System.Object obj)
ExecuteCommand	Method	void ExecuteCommand(int command)
GetHashCode	Method	int GetHashCode()
GetLifetimeService	Method	System.Object GetLifetimeService()
GetType	Method	type GetType()
InitializeLifetimeService	Method	System.Object InitializeLifetimeS...
Pause	Method	void Pause()
Refresh	Method	void Refresh()
Start	Method	void Start(), void Start(string[]...)
Stop	Method	void Stop()

Site	Property	System.ComponentModel.ISite Site ...
StartType	Property	System.ServiceProcess.ServiceStar...
Status	Property	System.ServiceProcess.ServiceCont...
ToString	ScriptMethod	System.Object ToString();

Notice when you piped `Get-Service` to `Get-Member`, there are more properties than are displayed by default. Although these additional properties aren't shown by default, you can select them by piping to `Select-Object` and using the `Property` parameter. The following example selects all properties by piping the results of `Get-Service` to `Select-Object` and specifying the `*` wildcard character as the value for the `Property` parameter.

PowerShell

```
Get-Service -Name w32time | Select-Object -Property *
```

By default, PowerShell returns four properties as a table and five or more as a list. However, some commands apply custom formatting to override the default number of properties displayed in a table. You can use `Format-Table` and `Format-List` to override these defaults manually.

Output

```
Name          : w32time
RequiredServices : {}
CanPauseAndContinue : False
CanShutdown      : True
CanStop         : True
DisplayName     : Windows Time
DependentServices : {}
MachineName    : .
ServiceName    : w32time
ServicesDependedOn : {}
ServiceHandle   :
Status         : Running
ServiceType    : Win32OwnProcess, Win32ShareProcess
StartType       : Manual
Site           :
Container      :
```

Specific properties can also be selected using a comma-separated list as the value of the **Property** parameter.

PowerShell

```
Get-Service -Name w32time |
  Select-Object -Property Status, Name, DisplayName, ServiceType
```

Output

Status	Name	DisplayName	ServiceType
Running	w32time	Windows Time	Win32OwnProcess, Win32ShareProcess

You can use wildcard characters when specifying property names with `Select-Object`.

In the following example, use `Can*` as one of the values for the **Property** parameter to return all the properties that start with `Can`. These include `CanPauseAndContinue`, `CanShutdown`, and `CanStop`.

PowerShell

```
Get-Service -Name w32time |  
    Select-Object -Property Status, DisplayName, Can*
```

Notice there are more properties listed than are displayed by default.

Output

```
Status          : Running  
DisplayName     : Windows Time  
CanPauseAndContinue : False  
CanShutdown     : True  
CanStop         : True
```

Methods

Methods are actions you can perform on an object. Use the **MemberType** parameter to narrow down the results of `Get-Member` to display only the methods for `Get-Service`.

PowerShell

```
Get-Service -Name w32time | Get-Member -MemberType Method
```

As you can see, there are several methods.

Output

```
TypeName: System.ServiceProcess.ServiceController  
  
Name           MemberType Definition  
---  
Close          Method    void Close()  
Continue       Method    void Continue()  
CreateObjRef   Method    System.Runtime.Remoting.ObjRef Creat...  
Dispose        Method    void Dispose(), void IDisposable.Dis...  
Equals         Method    bool Equals(System.Object obj)  
ExecuteCommand Method    void ExecuteCommand(int command)  
GetHashCode    Method    int GetHashCode()  
GetLifetimeService Method  System.Object GetLifetimeService()  
GetType        Method    type GetType()  
InitializeLifetimeService Method System.Object InitializeLifetimeServ...  
Pause          Method    void Pause()  
Refresh        Method    void Refresh()  
Start          Method    void Start(), void Start(string[] args)  
Stop           Method    void Stop()  
WaitForStatus  Method    void WaitForStatus(System.ServicePro...
```

You can use the **Stop** method to stop a Windows service. You must run this command from an elevated PowerShell session.

```
PowerShell
```

```
(Get-Service -Name w32time).Stop()
```

Query the status of the Windows Time service to confirm it's stopped.

```
PowerShell
```

```
Get-Service -Name w32time
```

```
Output
```

Status	Name	DisplayName
-----	-----	-----
Stopped	w32time	Windows Time

You might use methods sparingly, but you should be aware of them. Sometimes, you find `Get-*` commands without a corresponding `Set-*` command. Often, you can find a method to perform a `Set-*` action in this scenario. The `Get-SqlAgentJob` cmdlet in the **SqlServer** PowerShell module is an excellent example. No corresponding `Set-*` cmdlet exists, but you can use a method to complete the same task. For more information about the **SqlServer** PowerShell module and installation instructions, see the [SQL Server PowerShell overview](#).

Another reason to be aware of methods is some PowerShell users assume you can't make destructive changes with `Get-*` commands, but they can actually cause severe problems if misused.

A better option is to use a dedicated cmdlet if one exists to perform an action. For example, use the `Start-Service` cmdlet to start the Windows Time service.

By default, `Start-Service`, like the **Start** method of `Get-Service`, doesn't return any results. However, one of the benefits of using a cmdlet is that it often provides additional capabilities that aren't available with a method.

In the following example, use the **PassThru** parameter, which causes a cmdlet that doesn't typically produce output to generate output.

Since PowerShell doesn't participate in User Access Control (UAC), you must run commands that require elevation, such as `Start-Service`, from an elevated PowerShell

session.

PowerShell

```
Get-Service -Name w32time | Start-Service -PassThru
```

Output

Status	Name	DisplayName
-----	-----	-----
Running	w32time	Windows Time

ⓘ Note

When working with PowerShell cmdlets, it's important to avoid making assumptions about their output.

To retrieve information about the PowerShell process running on your lab environment computer, use the `Get-Process` cmdlet.

PowerShell

```
Get-Process -Name powershell
```

Output

Handles	NPM(K)	PM(K)	WS(K)	CPU(s)	Id	SI	ProcessName
-----	-----	-----	-----	-----	--	-	-----
710	31	55692	70580	0.72	9436	2	powershell

To determine the available properties, pipe `Get-Process` to `Get-Member`.

PowerShell

```
Get-Process -Name powershell | Get-Member
```

When using the `Get-Process` command, you might notice that some properties displayed by default are missing when you view the results of `Get-Member`. This behavior is because several of the values shown by default, such as `NPM(K)`, `PM(K)`, `WS(K)`, and `CPU(s)`, are calculated properties. You must pipe commands to `Get-Member` to determine their actual property names.

Output

TypeName: System.Diagnostics.Process

Name	MemberType	Definition
Handles	AliasProperty	Handles = HandleCount

You can't pipe a command to `Get-Member` that doesn't generate output. Because `Start-Service` doesn't produce output by default, attempting to pipe it to `Get-Member` results in an error.

PowerShell

```
Start-Service -Name w32time | Get-Member
```

ⓘ Note

To be piped to `Get-Member`, a command must produce object-based output.

Output

```
Get-Member : You must specify an object for the Get-Member cmdlet.  
At line:1 char:31  
+ Start-Service -Name w32time | Get-Member  
+  
+ CategoryInfo          : CloseError: (:) [Get-Member], InvalidOperationException  
Exception  
+ FullyQualifiedErrorId : NoObjectInGetMember,Microsoft.PowerShell.Commands.GetMemberCommand
```

To avoid this error, specify the `PassThru` parameter with `Start-Service`. As previously mentioned, adding the `PassThru` parameter causes a cmdlet that doesn't usually produce output to generate output.

PowerShell

```
Start-Service -Name w32time -PassThru | Get-Member
```

Output

TypeName: System.ServiceProcess.ServiceController

Name	MemberType	Definition
-----	-----	-----
Name	AliasProperty	Name = ServiceName

ToString	ScriptMethod	System.Object ToString();

`Out-Host` is designed to show output directly in the PowerShell host and doesn't produce object-based output. As a result, you can't pipe its output to `Get-Member`, which requires object-based input.

PowerShell

```
Get-Service -Name w32time | Out-Host | Get-Member
```

Output

Status	Name	DisplayName
Running	w32time	Windows Time

```
Get-Member : You must specify an object for the Get-Member cmdlet.
At line:1 char:40
+ Get-Service -Name w32time | Out-Host | Get-Member
+               ~~~~~
+ CategoryInfo          : CloseError: (:) [Get-Member], InvalidOperationException
Exception
+ FullyQualifiedErrorId : NoObjectInGetMember,Microsoft.PowerShell.Commands.GetMemberCommand
```

Get-Command

Knowing the type of object a command produces allows you to search for commands that accept that type of object as input.

```
PowerShell
```

```
Get-Command -ParameterType ServiceController
```

The following commands accept a **ServiceController** object via pipeline or parameter input.

```
Output
```

CommandType	Name	Version
Cmdlet	Get-Service	3.1.0.0
Cmdlet	Restart-Service	3.1.0.0
Cmdlet	Resume-Service	3.1.0.0
Cmdlet	Set-Service	3.1.0.0
Cmdlet	Start-Service	3.1.0.0
Cmdlet	Stop-Service	3.1.0.0
Cmdlet	Suspend-Service	3.1.0.0

Active Directory

ⓘ Note

As mentioned in the chapter prerequisites, ensure you have RSAT installed for this section. Additionally, your lab environment computer must be a member of your lab environment Active Directory domain.

To identify the commands added to the **ActiveDirectory** PowerShell module after you install RSAT, use `Get-Command` combined with the **Module** parameter. The following example lists all the commands available in the **ActiveDirectory** module.

```
PowerShell
```

```
Get-Command -Module ActiveDirectory
```

The **ActiveDirectory** PowerShell module added a total of 147 commands.

Have you observed the naming convention of these commands? The nouns in the command names are prefixed with *AD* to avoid potential naming conflicts with commands in other modules. This prefixing is a common practice among PowerShell modules.

```
Output
```

CommandType	Name	Version
Cmdlet	Add-ADCentralAccessPolicyMember	1.0.1.0
Cmdlet	Add-ADComputerServiceAccount	1.0.1.0
Cmdlet	Add-ADDomainControllerPasswordReplicationPolicy	1.0.1.0
Cmdlet	Add-ADFineGrainedPasswordPolicySubject	1.0.1.0
Cmdlet	Add-ADGroupMember	1.0.1.0
Cmdlet	Add-ADPrincipalGroupMembership	1.0.1.0
Cmdlet	Add-ADResourcePropertyListMember	1.0.1.0
Cmdlet	Clear-ADAccountExpiration	1.0.1.0
Cmdlet	Clear-ADClaimTransformLink	1.0.1.0
Cmdlet	Disable-ADAccount	1.0.1.0
...		

By default, the `Get-ADUser` cmdlet retrieves a limited set of properties for user objects and limits its output to the first 1,000 users. This constraint is a performance optimization designed to avoid overwhelming Active Directory with excessive data retrieval.

PowerShell

```
Get-ADUser -Identity mike | Get-Member -MemberType Properties
```

Even if you only have a basic understanding of Active Directory, you might recognize that a user account has more properties than those shown in the example.

Output

```
TypeName: Microsoft.ActiveDirectory.Management.ADUser
```

Name	MemberType	Definition
DistinguishedName	Property	System.String DistinguishedName {get;set;}
Enabled	Property	System.Boolean Enabled {get;set;}
GivenName	Property	System.String GivenName {get;set;}
Name	Property	System.String Name {get;}
ObjectClass	Property	System.String ObjectClass {get;set;}
ObjectGUID	Property	System.Nullable`1[[System.Guid, mscorelib, Ve...]
SamAccountName	Property	System.String SamAccountName {get;set;}
SID	Property	System.Security.Principal.SecurityIdentifier...
Surname	Property	System.String Surname {get;set;}
UserPrincipalName	Property	System.String UserPrincipalName {get;set;}

The `Get-ADUser` cmdlet includes a `Properties` parameter to specify additional properties beyond the defaults you want to retrieve. To return all properties, use the `*` wildcard character as the parameter value.

PowerShell

```
Get-ADUser -Identity mike -Properties * | Get-Member -MemberType Properties
```

Output

The default configuration for retrieving Active Directory user account properties is intentionally limited to avoid performance issues. Trying to return every property for every user account in your production Active Directory environment could severely degrade the performance of your domain controllers and network. Usually, you only need specific properties for certain users. However, returning all properties for a single user is reasonable when identifying the available properties.

It's not uncommon to run a command multiple times when prototyping it. If you anticipate running a resource-intensive query when prototyping a command, consider executing it once and storing the results in a variable. Then, you can work with the variable's contents more efficiently than repeatedly executing a resource-intensive query.

For example, the following command retrieves all properties for a user account and stores the results in a variable named `$Users`. Work with the contents of the `$Users` variable instead of running the `Get-ADUser` command multiple times. Remember, the variable's contents don't update automatically when a user's information changes in Active Directory.

PowerShell

```
$Users = Get-ADUser -Identity mike -Properties *
```

You can explore the available properties by piping the `$Users` variable to `Get-Member`.

PowerShell

```
$Users | Get-Member -MemberType Properties
```

To view specific properties such as `Name`, `LastLogonDate`, and `LastBadPasswordAttempt`, pipe the `$Users` variable to `Select-Object`. This method displays the desired properties and their values based on the contents of the `$Users` variable, eliminating the need for multiple queries to Active Directory. It's a more resource-efficient approach than repeatedly executing the `Get-ADUser` command.

```
PowerShell
```

```
$Users | Select-Object -Property Name, LastLogonDate, LastBadPasswordAttempt
```

When you query Active Directory, filter the data at the source using the **Properties** parameter of `Get-ADUser` to return only the necessary properties.

```
PowerShell
```

```
Get-ADUser -Identity mike -Properties LastLogonDate, LastBadPasswordAttempt
```

Output

```
DistinguishedName      : CN=Mike F. Robbins,CN=Users,DC=mikefrobbins,DC=com
Enabled                : True
GivenName               : Mike

```

Summary

In this chapter, you learned how to determine what type of object a command produces, what properties and methods are available for a command, and how to work with commands that limit the properties returned by default.

Review

1. What type of object does the `Get-Process` cmdlet produce?
2. How do you determine what the available properties are for a command?
3. What should you check for if a command exists to get something but not to set the same thing?
4. How can some commands that don't return output by default be made to generate output?
5. What should you consider doing when prototyping a command that produces a large amount of output?

Next steps

In the next chapter, you'll learn about one-liners and the pipeline.

Chapter 4 - One-Liners and the pipeline

Article • 01/08/2025

When I started learning PowerShell, I initially relied on the Graphical User Interface (GUI) for tasks that seemed too complex for simple PowerShell commands. However, as I continued to learn, I improved my skills and moved from basic one-liners to creating scripts, functions, and modules. It's important to remember that feeling overwhelmed by advanced examples online is normal. No one starts as an expert in PowerShell; we all start as beginners.

For those who primarily use the GUI for administrative tasks, install the management tools on your administrative workstation to remotely manage your servers. Whether your server uses a GUI or the Server Core OS installation, this approach is beneficial. It's a practical way to familiarize yourself with remote server management in preparation for performing administrative tasks with PowerShell.

As with the previous chapters, try these concepts in your lab environment.

One-Liners

A PowerShell one-liner is one continuous pipeline. It's a common misconception that a command on one physical line is a PowerShell one-liner, but this isn't always true.

For instance, consider the following example: the command extends over multiple physical lines, yet it's a PowerShell one-liner because it forms a continuous pipeline. Line-breaking a lengthy one-liner at the pipe symbol, a natural breaking point in PowerShell, is recommended to enhance readability and clarity. This strategic use of line breaks improves readability without disrupting the flow of the pipeline.

```
PowerShell

Get-Service |  
Where-Object CanPauseAndContinue -EQ $true |  
Select-Object -Property *
```

```
Output

```

Natural line breaks can occur at commonly used characters, including comma (,), and opening brackets ([]), braces ({ }), and parenthesis (()). Others that aren't so common include the semicolon (;), equals sign (=), and both opening single and double quotes (',"').

Using the backtick (`) or grave accent character as a line continuation is controversial. It's best to avoid it if possible. Using a backtick following a natural line break character is a common mistake. This redundancy is unnecessary and can clutter the code.

The commands in the following example execute correctly from the PowerShell console. However, attempting to run them in the console pane of the PowerShell Integrated Scripting Environment (ISE) results in an error. This difference occurs because, unlike the PowerShell console, the console pane of the ISE doesn't automatically anticipate the continuation of a command onto the next line. To prevent this issue, press `Shift + Enter` in the console pane of the ISE instead of `Enter` when you need to extend a command across multiple lines. This key combination signals to the ISE that the command is continuing on the following line, preventing the execution that leads to errors.

```
PowerShell

Get-Service -Name w32time |
    Select-Object -Property *

Output

Name          : w32time
RequiredServices : {}
CanPauseAndContinue : False
CanShutdown      : True
CanStop         : True
DisplayName     : Windows Time
DependentServices : {}
MachineName     : .
ServiceName     : w32time
ServicesDependedOn : {}
ServiceHandle    :
Status          : Running
ServiceType      : Win32OwnProcess, Win32ShareProcess
StartType        : Manual
Site            :
Container       :
```

This next example doesn't qualify as a PowerShell one-liner because it's not one continuous pipeline. Instead, it's two separate commands placed on a single line,

separated by a semicolon. This semicolon indicates the end of one command and the beginning of another.

PowerShell

```
$Service = 'w32time'; Get-Service -Name $Service
```

Output

Status	Name	DisplayName
-----	----	-----
Running	w32time	Windows Time

Many programming and scripting languages require a semicolon at the end of each line. However, in PowerShell, semicolons at the end of lines are unnecessary and not recommended. You should avoid them for cleaner and more readable code.

Filter Left

This chapter demonstrates how to filter the results of various commands.

It's a best practice in PowerShell to filter the results as early as possible in the pipeline. Achieving this involves applying filters using parameters on the initial command, usually at the beginning of the pipeline. This is commonly referred to as *filtering left*.

To illustrate this concept, consider the following example: Use the **Name** parameter of `Get-Service` to filter the results at the beginning of the pipeline, returning only the details for the Windows Time service. This method demonstrates efficient data retrieval, ensuring you only return the necessary and relevant information.

PowerShell

```
Get-Service -Name w32time
```

Output

Status	Name	DisplayName
-----	----	-----
Running	w32time	Windows Time

It's common to see online examples of a PowerShell command being piped to the `Where-Object` cmdlet to filter its results. This technique is inefficient if an earlier command in the pipeline has a parameter to perform the filtering.

PowerShell

```
Get-Service | Where-Object Name -EQ w32time
```

Output

Status	Name	DisplayName
-----	-----	-----
Running	W32Time	Windows Time

The first example demonstrates filtering directly at the source, returning results specifically for the Windows Time service. In contrast, the second example retrieves all services and then uses another command to filter the results. This might seem insignificant in small-scale scenarios, but consider a situation involving a large dataset, like Active Directory. It's inefficient to retrieve details for thousands of user accounts only to narrow them down to a small subset. Practice *filtering left* — applying filters as early as possible in the command sequence — even in seemingly trivial cases. This habit ensures efficiency in more complex scenarios where it becomes more important.

Command sequencing for effective filtering

There's a misconception that the order of commands in PowerShell is inconsequential, but this is a misunderstanding. The sequence in which you arrange commands, particularly when filtering, is important. For example, suppose you're using `Select-Object` to choose specific properties and `Where-Object` to filter. In that case, it's essential to apply the filtering first. Failing to do so means the necessary properties might not be available in the pipeline for filtering, leading to ineffective or erroneous results.

The following example fails to produce results because the `CanPauseAndContinue` property is absent when `Select-Object` is piped to `Where-Object`. This is because the `CanPauseAndContinue` property wasn't included in the selection made by `Select-Object`. Effectively, it's excluded or filtered out.

PowerShell

```
Get-Service |  
    Select-Object -Property DisplayName, Running, Status |  
    Where-Object CanPauseAndContinue
```

Reversing the order of `Select-Object` and `Where-Object` produces the desired results.

PowerShell

```
Get-Service |  
    Where-Object CanPauseAndContinue |  
    Select-Object -Property DisplayName, Status
```

Output

DisplayName	Status
Workstation	Running
Netlogon	Running
Hyper-V Heartbeat Service	Running
Hyper-V Data Exchange Service	Running
Hyper-V Remote Desktop Virtualization Service	Running
Hyper-V Guest Shutdown Service	Running
Hyper-V Volume Shadow Copy Requestor	Running
Web Threat Defense Service	Running
Web Threat Defense User Service_644de	Running
Windows Management Instrumentation	Running

The Pipeline

As seen in many examples throughout this book, you can often use the output of one command as input for another command. In Chapter 3, `Get-Member` was used to determine what type of object a command produces.

Chapter 3 also showed using the `ParameterType` parameter of `Get-Command` to determine what commands accepted that type of input. Depending on how thorough help for a command is, it might include an **INPUTS** and **OUTPUTS** section.

The **INPUTS** section indicates that you can pipe a `ServiceController` or a `String` object to the `Stop-Service` cmdlet.

PowerShell

```
help Stop-Service -Full
```

The following output is abbreviated to show the relevant portion of the help.

Output

...

INPUTS

`System.ServiceProcess.ServiceController`

You can pipe a service object to this cmdlet.

`System.String`

You can pipe a string that contains the name of a service to this cmdlet.

OUTPUTS

None

By default, this cmdlet returns no output.

`System.ServiceProcess.ServiceController`

When you use the `PassThru` parameter, this cmdlet returns a `ServiceController` object representing the service.

...

However, it doesn't specify which parameters accept this type of input. You can determine that information by checking the different parameters in the full version of the help for the `Stop-Service` cmdlet.

PowerShell

```
help Stop-Service -Full
```

Once again, only the relevant help is shown in the following results. Notice that the **DisplayName** parameter doesn't accept pipeline input. The **InputObject** parameter accepts pipeline input by value for `ServiceController` objects. The **Name** parameter accepts pipeline input by value for `String` objects and pipeline input by **property name**.

Output

...

`-DisplayName <System.String[]>`

Specifies the display names of the services to stop. Wildcard characters are permitted.

Required?	true
Position?	named
Default value	None
Accept pipeline input?	False
Accept wildcard characters?	true

`-InputObject <System.ServiceProcess.ServiceController[]>`

Specifies `ServiceController` objects that represent the services to stop. Enter a variable that contains the objects, or type a command or expression that gets the objects.

Required?	true
Position?	0
Default value	None
Accept pipeline input?	True (ByValue)
Accept wildcard characters?	false

```
-Name <System.String[]>
    Specifies the service names of the services to stop. Wildcard
    characters are permitted.

    Required?          true
    Position?         0
    Default value     None
    Accept pipeline input?   True (ByPropertyName, ByValue)
    Accept wildcard characters? true
    ...
```

When handling pipeline input, a parameter that accepts pipeline input both **by property name** and **by value** prioritizes **by value** binding first. If this method fails, it attempts to process pipeline input **by property name**. However, the term **by value** can be misleading. A more accurate description is **by type**.

For instance, if you pipe the output of a command that generates a **ServiceController** object to `Stop-Service`, this output is bound to the **InputObject** parameter. If the piped command produces a **String** object, it associates the output with the **Name** parameter. If you pipe output from a command that doesn't produce a **ServiceController** or **String** object, but does include a property named **Name**, `Stop-Service` binds the value of the **Name** property to its **Name** parameter.

Determine what type of output the `Get-Service` command produces.

PowerShell

```
Get-Service -Name w32time | Get-Member
```

`Get-Service` produces a **ServiceController** object type.

Output

```
TypeName: System.ServiceProcess.ServiceController
```

As shown in the help for `Stop-Service` cmdlet, the **InputObject** parameter accepts **ServiceController** objects through the pipeline **by value**. This implies that when you pipe the output of the `Get-Service` cmdlet to `Stop-Service`, the **ServiceController** objects produced by `Get-Service` bind to the **InputObject** parameter of `Stop-Service`.

PowerShell

```
Get-Service -Name w32time | Stop-Service
```

Now try string input. Pipe `w32time` to `Get-Member` to confirm that it's a string.

PowerShell

```
'w32time' | Get-Member
```

Output

```
TypeName: System.String
```

The PowerShell help documentation illustrates that when you pipe a string to `Stop-Service`, it binds to the `Name` parameter **by value**. Conduct a practical test to see this in action: pipe the string `w32time` to `Stop-Service`. This example demonstrates how `Stop-Service` processes the string `w32time` as the name of the service to stop. Execute the following command to observe this binding and command execution in action.

Notice that `w32time` is enclosed in single quotes. In PowerShell, it's a best practice to use single quotes for static strings, reserving double quotes for situations where the string contains variables that require expansion. Single quotes tell PowerShell to treat the content literally without parsing for variables. This approach not only ensures accuracy in how your script interprets the string but also enhances performance, as PowerShell expends less processing effort on strings within single quotes.

PowerShell

```
'w32time' | Stop-Service
```

Create a custom object to test pipeline input by property name for the `Name` parameter of `Stop-Service`.

PowerShell

```
$customObject = [pscustomobject]@{  
    Name = 'w32time'  
}
```

The contents of the `CustomObject` variable is a `PSCustomObject` object type and it contains a property named `Name`.

PowerShell

```
$customObject | Get-Member
```

Output

```
TypeName: System.Management.Automation.PSCustomObject
```

Name	MemberType	Definition
Equals	Method	bool Equals(System.Object obj)
GetHashCode	Method	int GetHashCode()
GetType	Method	type GetType()
ToString	Method	string ToString()
Name	NoteProperty	string Name=w32time

When working with variables in PowerShell, such as `$customObject` in this example, it's important to use double quotes if you need to enclose the variable in quotes. Double quotes allow for variable expansion — PowerShell evaluates the variable and uses its value. For example, if you enclose `$customObject` in double quotes and pipe it to `Get-Member`, PowerShell processes the value of `$customObject`. In contrast, using single quotes would result in piping the literal string `$customObject` to `Get-Member`, not the value of the variable. This distinction is important for scenarios where you need to evaluate the value of variables.

When piping the contents of the `$customObject` variable to the `Stop-Service` cmdlet, the binding to the **Name** parameter occurs by **property name** rather than **by value**. This is because `$customObject` is an object that contains a property named **Name**. In this scenario, PowerShell identifies the **Name** property within `$customObject` and uses its value for the **Name** parameter of `Stop-Service`.

Create another custom object using a different property name, such as **Service**.

PowerShell

```
$customObject = [pscustomobject]@{  
    Service = 'w32time'  
}
```

An error occurs while trying to stop the `w32time` service by piping `$customObject` to `Stop-Service`. The pipeline binding fails because `$customObject` doesn't produce a `ServiceController` or `String` object and doesn't contain a **Name** property.

PowerShell

```
$customObject | Stop-Service
```

Output

```
Stop-Service : Cannot find any service with service name
'@{Service=w32time}'.
At line:1 char:17
+ $customObject | Stop-Service
+
+ CategoryInfo          : ObjectNotFound: (@{Service=w32time}:String) [
Stop-Service], ServiceCommandException
+ FullyQualifiedErrorId : NoServiceFoundForGivenName,Microsoft.PowerShe
ll.Commands.StopServiceCommand
```

When the output property names of one command don't match the pipeline input requirements of another command, you can use `Select-Object` to rename the property names so they line up correctly.

In the following example, use `Select-Object` to rename the `Service` property to a property named `Name`.

At first glance, the syntax of this example might appear complex. However, it's essential to understand that more than copying and pasting code is required to learn the syntax. Instead, take the time to type out the code manually. This hands-on practice helps you remember the syntax, and it becomes more intuitive with repeated effort. Utilizing multiple monitors or split screen can also aid in the learning process. Display the example code on one screen while actively typing and experimenting with it on another. This setup makes it easier to follow along and enhances your understanding and retention of the syntax.

PowerShell

```
$customObject |
  Select-Object -Property @{Name='Name';Expression={$_['.Service}} |
  Stop-Service
```

There are instances where you might need to use a parameter that doesn't accept pipeline input. In such cases, you can still use the output of one command as the input for another. First, capture and save the display names of a few specific Windows services into a text file. This step allows you to use the saved data as input for another command.

PowerShell

```
'Background Intelligent Transfer Service', 'Windows Time' |
  Out-File -FilePath $env:TEMP\services.txt
```

You can use parentheses to pass the output of one command as input for a parameter to another command.

PowerShell

```
Stop-Service -DisplayName (Get-Content -Path $env:TEMP\services.txt)
```

This concept is like the order of operations in Algebra. Just as mathematical operations within parentheses are computed first, the command enclosed in parentheses is executed before the outer command.

PowerShellGet

PowerShellGet, a module included with PowerShell version 5.0 and higher, provides commands to discover, install, update, and publish PowerShell modules and other items in a NuGet repository. For those using PowerShell version 3.0 and above, **PowerShellGet** is also available as a separate download.

The [PowerShell Gallery](#) is an online repository hosted by Microsoft, designed as a central hub for sharing PowerShell modules, scripts, and other resources. While Microsoft hosts the PowerShell Gallery, the PowerShell community contributes most of the available modules and scripts. Given the source of these modules and scripts, exercise caution before integrating any code from the PowerShell Gallery into your environment. Review and test downloads from the PowerShell Gallery in an isolated test environment. This process ensures the code is secure and reliable, works as expected, and safeguards your environment from potential issues or vulnerabilities arising from unvetted code.

Many organizations opt to establish their own internal, private NuGet repository. This repository serves a dual purpose. First, it acts as a secure location for storing modules developed in-house, intended solely for internal use. Secondly, it provides a vetted collection of modules sourced externally, including those from public repositories. Companies typically undertake a thorough validation process before adding these external modules to the internal repository. This process is important to ensure the modules are free from malicious content and align with the security and operational standards of the company.

Use the `Find-Module` cmdlet that's part of the **PowerShellGet** module to find a module in the PowerShell Gallery that I wrote named **MrToolkit**.

PowerShell

```
Find-Module -Name MrToolkit
```

Output

```
NuGet provider is required to continue
PowerShellGet requires NuGet provider version '2.8.5.201' or newer to
interact with NuGet-based repositories. The NuGet provider must be available
in 'C:\Program Files\PackageManagement\ProviderAssemblies' or
'C:\Users\mikefrobbins\AppData\Local\PackageManagement\ProviderAssemblies'.
You can also install the NuGet provider by running 'Install-PackageProvider
-Name NuGet -MinimumVersion 2.8.5.201 -Force'. Do you want PowerShellGet to
install and import the NuGet provider now?
[Y] Yes [N] No [S] Suspend [?] Help (default is "Y"):
```

Version	Name	Repository	Description
-----	-----	-----	-----
1.3	MrToolkit	PSGallery	Misc PowerShell Tools

The first time you use one of the commands from the **PowerShellGet** module, you're prompted to install the NuGet provider.

To install the **MrToolkit** module, pipe the previous command to `Install-Module`.

PowerShell

```
Find-Module -Name MrToolkit | Install-Module -Scope CurrentUser
```

Output

```
Untrusted repository
You are installing the modules from an untrusted repository. If you trust
this repository, change its InstallationPolicy value by running the
Set-PSRepository cmdlet. Are you sure you want to install the modules from
'https://www.powershellgallery.com/api/v2'?
[Y] Yes [A] Yes to All [N] No [L] No to All [S] Suspend [?] Help
(default is "N"):
```

Since the PowerShell Gallery is an untrusted repository, it prompts you to approve the installation of the module.

Finding pipeline input the easy way

The **MrToolkit** module includes a function named `Get-MrPipelineInput`. This cmdlet is designed to provide users with a convenient method for identifying the parameters of a command capable of accepting pipeline input. Specifically, it reveals three key aspects:

- Which parameters of a command can receive pipeline input
- The type of object each parameter accepts
- Whether they accept pipeline input **by value** or **by property name**

This capability dramatically simplifies the process of understanding and utilizing the pipeline capabilities of PowerShell commands.

The information previously obtained by analyzing the help documentation can be determined using this function.

```
PowerShell

Get-MrPipelineInput -Name Stop-Service | Format-List

Output

ParameterName          : InputObject
ParameterType          : System.ServiceProcess.ServiceController[]
ValueFromPipeline      : True
ValueFromPipelineByPropertyName : False

ParameterName          : Name
ParameterType          : System.String[]
ValueFromPipeline      : True
ValueFromPipelineByPropertyName : True
```

Summary

In this chapter, you learned about the intricacies of PowerShell one-liners. You also learned that the physical line count of a command is irrelevant to its classification as a PowerShell one-liner. Additionally, you learned about key concepts such as filtering left, the pipeline, and **PowerShellGet**.

Review

1. What's a PowerShell one-liner?
2. What are some characters where natural line breaks can occur in PowerShell?
3. Why should you filter left?
4. What are the two ways that a PowerShell command can accept pipeline input?
5. Why shouldn't you trust commands found in the PowerShell Gallery?

- PowerShellGet: The BIG EASY way to discover, install, and update PowerShell modules ↗

Next steps

In the next chapter, you'll learn about formatting, aliases, providers, and comparison operators.

Chapter 5 - Formatting, aliases, providers, comparison

Article • 01/09/2025

Prerequisites

The `SqlServer` PowerShell module is required by some examples shown in this chapter. For more information about the `SqlServer` PowerShell module and installation instructions, see [SQL Server PowerShell overview](#). It's also used in subsequent chapters. Download and install it on your Windows lab environment computer.

Format Right

In Chapter 4, you learned to filter as far to the left as possible. The rule for manually formatting a command's output is similar to that rule, except it needs to occur as far to the right as possible.

The most common format commands are `Format-Table` and `Format-List`. `Format-Wide` and `Format-Custom` can also be used, but are less common.

As mentioned in Chapter 3, a command that returns more than four properties defaults to a list unless custom formatting is used.

```
PowerShell

Get-Service -Name w32time |
    Select-Object -Property Status, DisplayName, Can*
```

```
Output

Status : Running
DisplayName : Windows Time
CanPauseAndContinue : False
CanShutdown : True
CanStop : True
```

Use the `Format-Table` cmdlet to manually override the formatting and show the output in a table instead of a list.

```
PowerShell
```

```
Get-Service -Name w32time |  
    Select-Object -Property Status, DisplayName, Can* |  
    Format-Table
```

Output

Status	DisplayName	CanPauseAndContinue	CanShutdown	CanStop
-----	-----	-----	-----	-----
Running	Windows Time	False	True	True

The default output for `Get-Service` is three properties in a table.

PowerShell

```
Get-Service -Name w32time
```

Output

Status	Name	DisplayName
-----	-----	-----
Running	w32time	Windows Time

Use the `Format-List` cmdlet to override the default formatting and return the results in a list.

PowerShell

```
Get-Service -Name w32time | Format-List
```

Notice that simply piping `Get-Service` to `Format-List` made it return additional properties. This doesn't occur with every command because of how the format for that particular command is set up behind the scenes.

Output

Name	:	w32time
DisplayName	:	Windows Time
Status	:	Running
DependentServices	:	{}
ServicesDependedOn	:	{}
CanPauseAndContinue	:	False
CanShutdown	:	True
CanStop	:	True
ServiceType	:	Win32OwnProcess, Win32ShareProcess

The number one thing to be aware of with the format cmdlets is they produce format objects that are different than normal objects in PowerShell.

PowerShell

```
Get-Service -Name w32time | Format-List | Get-Member
```

Output

TypeName: Microsoft.PowerShell.Commands.Internal.Format.FormatStartData

Name	MemberType	Definition
-----	-----	-----
Equals	Method	bool Equals(System.Object)
GetHashCode	Method	int GetHashCode()
GetType	Method	type GetType()

GetType	Method	type GetType()
ToString	Method	string ToString()
ClassId2e4f51ef21dd47e99d3c952918aff9cd	Property	string ClassId2e4f51ef...
formatEntryInfo	Property	Microsoft.PowerShell.C...
outOfBand	Property	bool outOfBand {get;set;}
writeStream	Property	Microsoft.PowerShell.C...

```
TypeName: Microsoft.PowerShell.Commands.Internal.Format.GroupEndData
```

Name	MemberType	Definition
-----	-----	-----
Equals	Method	bool Equals(System.Object)
GetHashCode	Method	int GetHashCode()
GetType	Method	type GetType()
ToString	Method	string ToString()
ClassId2e4f51ef21dd47e99d3c952918aff9cd	Property	string ClassId2e4f51ef...
groupingEntry	Property	Microsoft.PowerShell.C...

```
TypeName: Microsoft.PowerShell.Commands.Internal.Format.FormatEndData
```

Name	MemberType	Definition
-----	-----	-----
Equals	Method	bool Equals(System.Object)
GetHashCode	Method	int GetHashCode()
GetType	Method	type GetType()
ToString	Method	string ToString()
ClassId2e4f51ef21dd47e99d3c952918aff9cd	Property	string ClassId2e4f51ef...
groupingEntry	Property	Microsoft.PowerShell.C...

What this means is format commands can't be piped to most other commands. They can be piped to some of the `Out-*` commands, but that's about it. This is why you want to perform any formatting at the very end of the line (format right).

Aliases

An alias in PowerShell is a shorter name for a command. PowerShell includes a set of built-in aliases and you can also define your own aliases.

The `Get-Alias` cmdlet is used to find aliases. If you already know the alias for a command, the `Name` parameter is used to determine what command the alias is associated with.

```
PowerShell
```

```
Get-Alias -Name gcm
```

```
Output
```

CommandType	Name	Version
-----	-----	-----
Alias	gcm -> Get-Command	

Multiple aliases can be specified for the value of the `Name` parameter.

PowerShell

```
Get-Alias -Name gcm, gm
```

Output

CommandType	Name	Version
-----	-----	-----
Alias	gcm -> Get-Command	
Alias	gm -> Get-Member	

You often see the **Name** parameter omitted since it's a positional parameter.

PowerShell

```
Get-Alias gm
```

Output

CommandType	Name	Version
-----	-----	-----
Alias	gm -> Get-Member	

If you want to find aliases for a command, you need to use the **Definition** parameter.

PowerShell

```
Get-Alias -Definition Get-Command, Get-Member
```

Output

CommandType	Name	Version
-----	-----	-----
Alias	gcm -> Get-Command	
Alias	gm -> Get-Member	

The **Definition** parameter can't be used positionally, so it must be specified.

Aliases can save you a few keystrokes, and they're fine when you type commands into the console. They shouldn't be used in scripts or any code that you're saving or sharing with others. As mentioned earlier in this book, using full cmdlet and parameter names is self-documenting and easier to understand.

Use caution when creating your own aliases because they only exist in your current PowerShell session on your computer.

Providers

A provider in PowerShell is an interface that allows file system-like access to a data store. There are several built-in providers in PowerShell.

```
PowerShell
Get-PSProvider
```

As you can see in the following results, there are built-in providers for the registry, aliases, environment variables, the file system, functions, variables, certificates, and WSMAN.

Output		
Name	Capabilities	Drives
Registry	ShouldProcess, Transactions	{HKLM, HKCU}
Alias	ShouldProcess	{Alias}
Environment	ShouldProcess	{Env}
FileSystem	Filter, ShouldProcess, Cr...	{C, D}
Function	ShouldProcess	{Function}
Variable	ShouldProcess	{Variable}

The actual drives that these providers use to expose their data store can be determined with the `Get-PSDrive` cmdlet. The `Get-PSDrive` cmdlet not only displays drives exposed by providers but also displays Windows logical drives, including drives mapped to network shares.

Output				
Name	Used (GB)	Free (GB)	Provider	Root
Alias			Alias	
C	18.56	107.62	FileSystem	C:\
Cert			Certificate	\
D			FileSystem	D:\
Env			Environment	

Function	Function
HKCU	Registry HKEY_CURRENT_USER
HKLM	Registry HKEY_LOCAL_MACHINE
Variable	Variable
WSMan	WSMan

Third-party modules such as the **ActiveDirectory** PowerShell module and the **SqlServer** PowerShell module both add their own PowerShell provider and PSDrive.

Import the **ActiveDirectory** and **SqlServer** PowerShell modules.

PowerShell

```
Import-Module -Name ActiveDirectory, SqlServer
```

Check to see if any additional PowerShell providers were added.

PowerShell

```
Get-PSPrinter
```

Notice that in the following set of results, two new PowerShell providers now exist, one for Active Directory and another one for SQL Server.

Output

Name	Capabilities	Drives
-----	-----	-----
Registry	ShouldProcess, Transactions	{HKLM, HKCU}
Alias	ShouldProcess	{Alias}
Environment	ShouldProcess	{Env}
FileSystem	Filter, ShouldProcess, Credentials	{C, A, D}
Function	ShouldProcess	{Function}
Variable	ShouldProcess	{Variable}
ActiveDirectory	Include, Exclude, Filter, Shoul...	{AD}
SqlServer	Credentials	{SQLSERVER}

A PSDrive for each of those modules was also added.

PowerShell

```
Get-PSDrive
```

Output

Name	Used (GB)	Free (GB)	Provider	Root
A			FileSystem	A:\
AD			ActiveDire...	//RootDSE/
Alias			Alias	
C	19.38	107.13	FileSystem	C:\
Cert			Certificate	\
D			FileSystem	D:\
Env			Environment	
Function			Function	
HKCU			Registry	HKEY_CURRENT_USER
HKLM			Registry	HKEY_LOCAL_MACHINE
SQLSERVER			SqlServer	SQLSERVER:\
Variable			Variable	
WSMan			WSMan	

PSDrives can be accessed just like a traditional file system.

PowerShell
<code>Get-ChildItem -Path Cert:\LocalMachine\CA</code>

Output
<pre>PSParentPath: Microsoft.PowerShell.Security\Certificate::LocalMachine\CA Thumbprint Subject ----- ----- FEE449EE0E3965A5246F000E87FDE2A065FD89D4 CN=Root Agency D559A586669B08F46A30A133F8A9ED3D038E2EA8 OU=www.verisign.com/CPS Incorp..... 109F1CAED645BB78B3EA2B94C0697C740733031C CN=Microsoft Windows Hardware C...</pre>

Comparison Operators

PowerShell contains various comparison operators that are used to compare values or find values that match certain patterns. The following table contains a list of comparison operators in PowerShell.

All the operators listed in the table are case-insensitive. To make them case-sensitive, place a `c` in front of the operator. For example, `-ceq` is the case-sensitive version of the equals (`-eq`) comparison operator.

[+] Expand table

Operator	Definition
-eq	Equal to
-ne	Not equal to
-gt	Greater than
-ge	Greater than or equal to
-lt	Less than
-le	Less than or equal to
-like	Match using the * wildcard character
-notlike	Doesn't match using the * wildcard character
-match	Matches the specified regular expression
-notmatch	Doesn't match the specified regular expression
-contains	Determines if a collection contains a specified value
-notcontains	Determines if a collection doesn't contain a specific value
-in	Determines if a specified value is in a collection
-notin	Determines if a specified value isn't in a collection
-replace	Replaces the specified value

Proper case "PowerShell" is equal to lower case "powershell" using the equals comparison operator.

PowerShell

```
'PowerShell' -eq 'powershell'
```

Output

True

It's not equal using the case-sensitive version of the equals comparison operator.

PowerShell

```
'PowerShell' -ceq 'powershell'
```

Output

False

The not equal comparison operator reverses the condition.

PowerShell

```
'PowerShell' -ne 'powershell'
```

Output

False

Greater than, greater than or equal to, less than, and less than or equal all work with string or numeric values.

PowerShell

```
5 -gt 5
```

Output

False

Using greater than or equal to instead of greater than with the previous example returns the **Boolean** true since five is equal to five.

PowerShell

```
5 -ge 5
```

Output

True

Based on the results from the previous two examples, you can probably guess how both less than and less than or equal to work.

PowerShell

```
5 -lt 10
```

Output

True

The `-like` and `-match` operators can be confusing, even for experienced PowerShell users. `-like` is used with the wildcard characters `*` and `?` to perform "like" matches.

PowerShell

```
'PowerShell' -like '*shell'
```

Output

True

The `-match` operator uses a regular expression to perform the matching.

PowerShell

```
'PowerShell' -match '^.*shell$'
```

Output

True

Use the range operator to store the numbers 1 through 10 in a variable.

PowerShell

```
$Numbers = 1..10
```

Determine if the `$Numbers` variable includes 15.

PowerShell

```
$Numbers -contains 15
```

Output

False

Determine if it includes the number 10.

PowerShell

```
$Numbers -contains 10
```

Output

```
True
```

The `-notcontains` operator reverses the logic to see if the `$Numbers` variable doesn't contain a value.

PowerShell

```
$Numbers -notcontains 15
```

The previous example returns the **Boolean** true because it's true that the `$Numbers` variable doesn't contain 15.

Output

```
True
```

It does, however, contain the number 10, so it's false when tested.

PowerShell

```
$Numbers -notcontains 10
```

Output

```
False
```

The `-in` comparison operator was first introduced in PowerShell version 3.0. It's used to determine if a value is *in* an array. The `$Numbers` variable is an array since it contains multiple values.

PowerShell

```
15 -in $Numbers
```

Output

```
False
```

In other words, `-in` performs the same test as the `contains` comparison operator except from the opposite direction.

```
PowerShell
```

```
10 -in $Numbers
```

```
Output
```

```
True
```

Fifteen isn't in the `$Numbers` array, so `false` is returned in the following example.

```
PowerShell
```

```
15 -in $Numbers
```

```
Output
```

```
False
```

Just like the `-contains` operator, `not` reverses the logic for the `-in` operator.

```
PowerShell
```

```
10 -notin $Numbers
```

The previous example returns `false` because the `$Numbers` array does include 10 and the condition tests to determine if it doesn't contain 10.

```
Output
```

```
False
```

Determine if fifteen isn't in the `$Numbers` array.

```
PowerShell
```

```
15 -notin $Numbers
```

15 is "not in" the `$Numbers` array so it returns the **Boolean** true.

Output

True

The `-replace` operator does just what you would think. It's used to replace something. Specifying one value replaces that value with nothing. In the following example, you replace "Shell" with nothing.

PowerShell

```
'PowerShell' -replace 'Shell'
```

Output

Power

If you want to replace a value with a different one, specify the new one after the pattern you want to replace. SQL Saturday in Baton Rouge is an event I try to speak at every year. In the following example, the word "Saturday" is replaced with the abbreviation "Sat".

PowerShell

```
'SQL Saturday - Baton Rouge' -replace 'saturday', 'Sat'
```

Output

SQL Sat - Baton Rouge

There are also methods like **Replace()** that can be used to replace things similar to how the replace operator works. However, the `-replace` operator is case-insensitive by default, and the **Replace()** method is case-sensitive.

PowerShell

```
'SQL Saturday - Baton Rouge'.Replace('saturday', 'Sat')
```

Notice that the word "Saturday" isn't replaced. This is because it's specified in a different case than the original.

Output

```
SQL Saturday - Baton Rouge
```

When the word "Saturday" is specified in the same case as the original, the `Replace()` method performs the replacement as expected.

PowerShell

```
'SQL Saturday - Baton Rouge'.Replace('Saturday', 'Sat')
```

Output

```
SQL Sat - Baton Rouge
```

Be careful when using methods to transform data because you can encounter unforeseen problems, such as failing the *Turkey Test*. For an example, see my blog article, [Using Pester to Test PowerShell Code with Other Cultures](#). I recommend using operators instead of methods whenever possible to avoid these types of problems.

While the comparison operators can be used, as shown in the previous examples, I typically use them with the `Where-Object` cmdlet to perform filtering.

Summary

You learned several topics in this chapter, including Formatting Right, Aliases, Providers, and Comparison Operators.

Review

1. Why is it necessary to perform formatting as far to the right as possible?
2. How do you determine what the actual cmdlet is for the `%` alias?
3. Why shouldn't you use aliases in scripts you save or code you share with others?
4. Perform a directory listing on the drives that are associated with the Registry provider.
5. What's one of the main benefits of using the replace operator instead of the replace method?

- [about_Arrays](#)

Next steps

In the next chapter, you'll learn about flow control, scripting, loops, and conditional logic.

Chapter 6 - Flow control

Article • 03/25/2025

Scripting

When you move from writing PowerShell one-liners to writing scripts, it sounds more complicated than it is. A script is nothing more than the same or similar commands you run interactively in the PowerShell console, except you save them as a `.ps1` file. There are some scripting constructs that you might use, such as a `foreach` loop instead of the `ForEach-Object` cmdlet. The differences can be confusing for beginners when considering that `foreach` is both a language keyword and an alias for the `ForEach-Object` cmdlet.

Looping

One of the best aspects of PowerShell is its scalability. Once you learn how to perform a task for a single item, applying the same action to hundreds of items is almost as straightforward. Loop through the items using one of the different types of loops in PowerShell.

ForEach-Object

`ForEach-Object` is a cmdlet for iterating through items in a pipeline, such as with PowerShell one-liners. `ForEach-Object` streams the objects through the pipeline.

Although the `Module` parameter of `Get-Command` accepts multiple string values, it only accepts them via pipeline input by property name. In the following scenario, if you want to pipe two string values to `Get-Command` for use with the `Module` parameter, you need to use the `ForEach-Object` cmdlet.

PowerShell

```
'ActiveDirectory', 'SQLServer' |  
    ForEach-Object {Get-Command -Module $_} |  
        Group-Object -Property ModuleName -NoElement |  
            Sort-Object -Property Count -Descending
```

Output

```
Count Name
-----
 147 ActiveDirectory
   82 SqlServer
```

In the previous example, `$_` is the current object. Beginning with PowerShell version 3.0, `$PSItem` can be used instead of `$_`. Most experienced PowerShell users prefer using `$_` since it's backward compatible and less to type.

When using the `foreach` keyword, you must store the items in memory before iterating through them, which could be difficult if you don't know how many items you're working with.

PowerShell

```
$ComputerName = 'DC01', 'WEB01'
foreach ($Computer in $ComputerName) {
    Get-ADComputer -Identity $Computer
}
```

Output

```
DistinguishedName : CN=DC01,OU=Domain Controllers,DC=mikefrobbins,DC=com
DNSHostName      : dc01.mikefrobbins.com
Enabled          : True
Name             : DC01
ObjectClass      : computer
ObjectGUID       : c38da20c-a484-469d-ba4c-bab3fb71ae8e
SamAccountName   : DC01$

UserPrincipalName :
```

Many times a loop such as `foreach` or `ForEach-Object` is necessary. Otherwise you receive an error message.

PowerShell

```
Get-ADComputer -Identity 'DC01', 'WEB01'
```

Output

```
Get-ADComputer : Cannot convert 'System.Object[]' to the type
'Microsoft.ActiveDirectory.Management.ADComputer' required by parameter
'Identity'. Specified method is not supported.
At line:1 char:26
+ Get-ADComputer -Identity 'DC01', 'WEB01'

+ CategoryInfo          : InvalidArgument: (:) [Get-ADComputer], Param
eterBindingException
+ FullyQualifiedErrorId : CannotConvertArgument,Microsoft.ActiveDirecto
ry.Management.Commands.GetADComputer
```

Other times, you can get the same results while eliminating the loop. Consult the cmdlet help to understand your options.

PowerShell

```
'DC01', 'WEB01' | Get-ADComputer
```

Output

```
DistinguishedName : CN=DC01,OU=Domain Controllers,DC=mikefrobbins,DC=com
DNSHostName      : dc01.mikefrobbins.com
Enabled          : True
Name             : DC01
ObjectClass      : computer
ObjectGUID       : c38da20c-a484-469d-ba4c-bab3fb71ae8e
SamAccountName   : DC01$
SID              : S-1-5-21-2989741381-570885089-3319121794-1001
UserPrincipalName : 

DistinguishedName : CN=WEB01,CN=Computers,DC=mikefrobbins,DC=com
DNSHostName      : web01.mikefrobbins.com
Enabled          : True
Name             : WEB01
ObjectClass      : computer
ObjectGUID       : 33aa530e-1e31-40d8-8c78-76a18b673c33
SamAccountName   : WEB01$
SID              : S-1-5-21-2989741381-570885089-3319121794-1107
UserPrincipalName :
```

As you can see in the previous examples, the **Identity** parameter for `Get-ADComputer` only accepts a single value when provided via parameter input. However, by using the

pipeline, you can send multiple values to the command because the values are processed one at a time.

For

A `for` loop iterates while a specified condition is true. I don't use the `for` loop often, but it has uses.

PowerShell

```
for ($i = 1; $i -lt 5; $i++) {  
    Write-Output "Sleeping for $i seconds"  
    Start-Sleep -Seconds $i  
}
```

Output

```
Sleeping for 1 seconds  
Sleeping for 2 seconds  
Sleeping for 3 seconds  
Sleeping for 4 seconds
```

In the previous example, the loop iterates four times by starting with the number one and continuing as long as the counter variable `$i` is less than 5. It sleeps for a total of 10 seconds.

Do

There are two different `do` loops in PowerShell: `do until` and `do while`. `do until` runs until the specified condition is false.

The following example is a numbers game that continues until the value you guess equals the same number that the `Get-Random` cmdlet generated.

PowerShell

```
$number = Get-Random -Minimum 1 -Maximum 10  
do {  
    $guess = Read-Host -Prompt "What's your guess?"  
    if ($guess -lt $number) {  
        Write-Output 'Too low!'  
    } elseif ($guess -gt $number) {  
        Write-Output 'Too high!'  
    }  
}
```

```
}
```

```
until ($guess -eq $number)
```

Output

```
What's your guess?: 1
Too low!
What's your guess?: 2
Too low!
What's your guess?: 3
```

`Do While` is the opposite. It runs as long as the specified condition is evaluated as true.

PowerShell

```
$number = Get-Random -Minimum 1 -Maximum 10
do {
    $guess = Read-Host -Prompt "What's your guess?"
    if ($guess -lt $number) {
        Write-Output 'Too low!'
    } elseif ($guess -gt $number) {
        Write-Output 'Too high!'
    }
}
while ($guess -ne $number)
```

Output

```
What's your guess?: 1
Too low!
What's your guess?: 2
Too low!
What's your guess?: 3
Too low!
What's your guess?: 4
```

The same results are achieved with a `Do While` loop by reversing the test condition to not equals.

`do` loops always run at least once because the condition is evaluated at the end of the loop.

While

Like the `do while` loop, a `while` loop runs as long as the specified condition is true. The difference, however, is that a `while` loop evaluates the condition at the top of the loop

before any code is run. So, it doesn't run if the condition is evaluated as false.

The following example calculates what day Thanksgiving Day is on in the United States. It's always on the fourth Thursday of November. The loop starts with the 22nd day of November and adds a day, while the day of the week isn't equal to Thursday. If the 22nd is a Thursday, the loop doesn't run at all.

PowerShell

```
$date = Get-Date -Date 'November 22'  
while ($date.DayOfWeek -ne 'Thursday') {  
    $date = $date.AddDays(1)  
}  
Write-Output $date
```

Output

```
Thursday, November 23, 2017 12:00:00 AM
```

break, continue, and return

The `break` keyword is designed to exit a loop and is often used with the `switch` statement. In the following example, `break` causes the loop to end after the first iteration.

PowerShell

```
for ($i = 1; $i -lt 5; $i++) {  
    Write-Output "Sleeping for $i seconds"  
    Start-Sleep -Seconds $i  
    break  
}
```

Output

```
Sleeping for 1 seconds
```

The `continue` keyword is designed to skip to the next iteration of a loop.

The following example outputs the numbers 1, 2, 4, and 5. It skips number 3 and continues with the next iteration of the loop. Like `break`, `continue` breaks out of the loop except only for the current iteration. Execution continues with the next iteration instead of breaking out of the loop altogether and stopping.

PowerShell

```
while ($i -lt 5) {  
    $i += 1  
    if ($i -eq 3) {  
        continue  
    }  
    Write-Output $i  
}
```

Output

```
1  
2  
4  
5
```

The `return` keyword is designed to exit out of the existing scope.

Notice in the following example that `return` outputs the first result and then exits out of the loop.

PowerShell

```
$number = 1..10  
foreach ($n in $number) {  
    if ($n -ge 4) {  
        return $n  
    }  
}
```

Output

```
4
```

A more thorough explanation of the `result` statement can be found in one of my blog articles: [The PowerShell return keyword ↴](#).

Summary

In this chapter, you learned about the different types of loops that exist in PowerShell.

Review

1. What's the difference between the `ForEach-Object` cmdlet and the `foreach` statement?
2. What's the primary advantage of using a `while` loop instead of a `do while` or `do until` loop?
3. How do the `break` and `continue` statements differ?

Chapter 7 - Working with WMI

Article • 03/24/2025

WMI and CIM

Windows PowerShell ships by default with cmdlets for working with other technologies, such as Windows Management Instrumentation (WMI). The WMI cmdlets are deprecated and aren't available in PowerShell 6+, but are covered here as you might encounter them in older scripts running on Windows PowerShell. For new development, use the CIM cmdlets instead.

Several native WMI cmdlets exist in PowerShell without you having to install any other software or modules. `Get-Command` can be used to determine what WMI cmdlets exist in Windows PowerShell. The following results are from a Windows 11 system running PowerShell version 5.1. Your results might differ depending on the PowerShell version you're running.

PowerShell

```
Get-Command -Noun WMI*
```

Output

CommandType	Name	Version
Cmdlet	Get-WmiObject	3.1.0.0
Cmdlet	Invoke-WmiMethod	3.1.0.0
Cmdlet	Register-WmiEvent	3.1.0.0
Cmdlet	Remove-WmiObject	3.1.0.0
Cmdlet	Set-WmiInstance	3.1.0.0

The Common Information Model (CIM) cmdlets were introduced in PowerShell 3.0 and are grouped within a dedicated module. To list all available CIM cmdlets, use the `Get-Command` cmdlet with the **Module** parameter, as shown in the following example.

PowerShell

```
Get-Command -Module CimCmdlets
```

Output

CommandType	Name	Version
Cmdlet	Export-BinaryMiLog	1.0.0.0
Cmdlet	Get-CimAssociatedInstance	1.0.0.0
Cmdlet	Get-CimClass	1.0.0.0
Cmdlet	Get-CimInstance	1.0.0.0
Cmdlet	Get-CimSession	1.0.0.0
Cmdlet	Import-BinaryMiLog	1.0.0.0
Cmdlet	Invoke-CimMethod	1.0.0.0
Cmdlet	New-CimInstance	1.0.0.0
Cmdlet	New-CimSession	1.0.0.0
Cmdlet	New-CimSessionOption	1.0.0.0
Cmdlet	Register-CimIndicationEvent	1.0.0.0
Cmdlet	Remove-CimInstance	1.0.0.0
Cmdlet	Remove-CimSession	1.0.0.0
Cmdlet	Set-CimInstance	1.0.0.0

The CIM cmdlets still allow you to work with WMI, so don't be confused when someone states: "*When I query WMI with the PowerShell CIM cmdlets*".

As previously mentioned, WMI is a separate technology from PowerShell, and you're just using the CIM cmdlets to access WMI. You might find an old VBScript that uses WMI Query Language (WQL) to query WMI, such as in the following example.

VB

```

strComputer = "."
Set objWMIService = GetObject("winmgmts:" _
& "{impersonationLevel=impersonate}!\" & strComputer & "\root\CIMV2")

Set colBIOS = objWMIService.ExecQuery _
("Select * from Win32_BIOS")

For each objBIOS in colBIOS
    Wscript.Echo "Manufacturer: " & objBIOS.Manufacturer
    Wscript.Echo "Name: " & objBIOS.Name
    Wscript.Echo "Serial Number: " & objBIOS.SerialNumber
    Wscript.Echo "SMBIOS Version: " & objBIOS.SMBIOSBIOSVersion
    Wscript.Echo "Version: " & objBIOS.Version
Next

```

You can take the WQL query from the VBScript and use it with the `Get-CimInstance` cmdlet without any modifications.

PowerShell

```
Get-CimInstance -Query 'Select * from Win32_BIOS'
```

Output

```
SMBIOSBIOSVersion : 090006
Manufacturer       : American Megatrends Inc.
Name               : Intel(R) Xeon(R) CPU E3-1505M v5 @ 2.80GHz
SerialNumber       : 3810-1995-1654-4615-2295-2755-89
Version            : VIRTUAL - 4001628
```

The previous example isn't how I typically query WMI with PowerShell. But it works and allows you to easily migrate existing Visual Basic scripts to PowerShell. When writing a one-liner to query WMI, I use the following syntax.

PowerShell

```
Get-CimInstance -ClassName Win32_BIOS
```

Output

```
SMBIOSBIOSVersion : 090006
Manufacturer       : American Megatrends Inc.
Name               : Intel(R) Xeon(R) CPU E3-1505M v5 @ 2.80GHz
SerialNumber       : 3810-1995-1654-4615-2295-2755-89
Version            : VIRTUAL - 4001628
```

If you only want the serial number, pipe the output to `Select-Object` and specify only the `SerialNumber` property.

PowerShell

```
Get-CimInstance -ClassName Win32_BIOS | 
    Select-Object -Property SerialNumber
```

Output

```
SerialNumber
-----
3810-1995-1654-4615-2295-2755-89
```

By default, when querying WMI, several properties that are never used are retrieved behind the scenes. It doesn't matter much when querying WMI on the local computer. But once you start querying remote computers, it's not only extra processing time to return that information but also more unnecessary information to send across the network. `Get-CimInstance` has a `Property` parameter that limits the information retrieved, making the WMI query more efficient.

PowerShell

```
Get-CimInstance -ClassName Win32_BIOS -Property SerialNumber |  
    Select-Object -Property SerialNumber
```

Output

```
SerialNumber  
-----  
3810-1995-1654-4615-2295-2755-89
```

The previous results returned an object. To return a string, use the **ExpandProperty** parameter.

PowerShell

```
Get-CimInstance -ClassName Win32_BIOS -Property SerialNumber |  
    Select-Object -ExpandProperty SerialNumber
```

Output

```
3810-1995-1654-4615-2295-2755-89
```

You could also use the dotted syntax style to return a string, eliminating the need to pipe to `Select-Object`.

PowerShell

```
(Get-CimInstance -ClassName Win32_BIOS -Property SerialNumber).SerialNumber
```

Output

```
3810-1995-1654-4615-2295-2755-89
```

Query Remote Computers with the CIM cmdlets

You should still be running PowerShell as a local admin and domain user. When you try to query information from a remote computer using the `Get-CimInstance` cmdlet, you receive an access denied error message.

PowerShell

```
Get-CimInstance -ComputerName dc01 -ClassName Win32_BIOS
```

Output

```
Get-CimInstance : Access is denied.  
At line:1 char:1  
+ Get-CimInstance -ComputerName dc01 -ClassName Win32_BIOS  
+ ~~~~~  
+ CategoryInfo          : PermissionDenied: (root\cimv2:Win32_BIOS:String) [Get-CimInstance], CimException  
+ FullyQualifiedErrorId : HRESULT 0x80070005,Microsoft.Management.Infrastructure.CimCmdlets.GetCimInstanceCommand  
+ PSComputerName        : dc01
```

Many people have security concerns regarding PowerShell, but you have the same permissions in PowerShell as in the GUI. No more and no less. The problem in the previous example is that the user running PowerShell doesn't have rights to query WMI information from the DC01 server. You could relaunch PowerShell as a domain administrator since `Get-CimInstance` doesn't have a **Credential** parameter. But that isn't a good idea because anything you run from PowerShell would run as a domain admin. Depending on the situation, that scenario could be dangerous from a security standpoint.

Using the principle of least privilege, elevate to your domain admin account on a per-command basis using the **Credential** parameter if a command has one. `Get-CimInstance` doesn't have a **Credential** parameter, so the solution in this scenario is to create a **CimSession** first. Then, use the **CimSession** instead of a computer name to query WMI on the remote computer.

PowerShell

```
$CimSession = New-CimSession -ComputerName dc01 -Credential (Get-Credential)
```

Output

```
cmdlet Get-Credential at command pipeline position 1  
Supply values for the following parameters:  
Credential
```

The CIM session was stored in a variable named `$cimSession`. Notice that you also specify the `Get-Credential` cmdlet in parentheses so that it executes first, prompting for alternate credentials, before creating the new session. I show you another more efficient

way to specify alternate credentials later in this chapter, but it's important to understand this basic concept before making it more complicated.

You can now use the CIM session created in the previous example with the `Get-CimInstance` cmdlet to query the BIOS information from WMI on the remote computer.

PowerShell

```
Get-CimInstance -CimSession $CimSession -ClassName Win32_BIOS
```

Output

```
SMBIOSBIOSVersion : 090006
Manufacturer       : American Megatrends Inc.
Name               : Intel(R) Xeon(R) CPU E3-1505M v5 @ 2.80GHz
SerialNumber       : 0986-6980-3916-0512-6608-8243-13
Version            : VIRTUAL - 4001628
PSComputerName     : dc01
```

There are several other benefits to using CIM sessions instead of just specifying a computer name. When you run multiple queries to the same computer, using a CIM session is more efficient than using the computer name for each query. Creating a CIM session only sets up the connection once. Then, multiple queries use that same session to retrieve information. Using the computer name requires the cmdlets to set up and tear down the connection with each query.

The `Get-CimInstance` cmdlet uses the WSMAN protocol by default, which means the remote computer needs PowerShell version 3.0 or higher to connect. It's actually not the PowerShell version that matters, it's the stack version. The stack version can be determined using the `Test-WSMan` cmdlet. It needs to be version 3.0, which you find with PowerShell version 3.0 and higher.

PowerShell

```
Test-WSMan -ComputerName dc01
```

Output

```
wsmid          : http://schemas.dmtf.org/wbem/wsman/identity/1/wsmanidentit
                  y.xsd
ProtocolVersion : http://schemas.dmtf.org/wbem/wsman/1/wsman.xsd
ProductVendor   : Microsoft Corporation
ProductVersion  : OS: 0.0.0 SP: 0.0 Stack: 3.0
```

The older WMI cmdlets use the DCOM protocol, which is compatible with older versions of Windows. However, the firewall typically blocks DCOM on newer versions of Windows. The `New-CimSessionOption` cmdlet allows you to create a DCOM protocol connection for use with `New-CimSession`. This option allows the `Get-CimInstance` cmdlet to communicate with versions of Windows as old as Windows Server 2000. This ability also means that PowerShell isn't required on the remote computer when using the `Get-CimInstance` cmdlet with a CimSession configured to use the DCOM protocol.

Create the DCOM protocol option using the `New-CimSessionOption` cmdlet and store it in a variable.

PowerShell

```
$DCOM = New-CimSessionOption -Protocol Dcom
```

For efficiency, you can store your domain administrator or elevated credentials in a variable so you don't have to constantly enter them for each command.

PowerShell

```
$Cred = Get-Credential
```

Output

```
cmdlet Get-Credential at command pipeline position 1
Supply values for the following parameters:
Credential
```

I have a server named SQL03 that runs Windows Server 2008 (non-R2). It's the newest Windows Server operating system that doesn't have PowerShell installed by default.

Create a `CimSession` to SQL03 using the DCOM protocol.

PowerShell

```
$CimSession = New-CimSession -ComputerName sql03 -SessionOption $DCOM -
Credential $Cred
```

Notice in the previous command that you specify the variable named `$Cred` as the value for the `Credential` parameter instead of manually entering your credentials again.

The output of the query is the same regardless of the underlying protocol.

PowerShell

```
Get-CimInstance -CimSession $CimSession -ClassName Win32_BIOS
```

Output

```
SMBIOSBIOSVersion : 090006
Manufacturer       : American Megatrends Inc.
Name               : Intel(R) Xeon(R) CPU E3-1505M v5 @ 2.80GHz
SerialNumber       : 7237-7483-8873-8926-7271-5004-86
Version            : VIRTUAL - 4001628
PSComputerName    : sql03
```

The `Get-CimSession` cmdlet is used to see what CimSessions are currently connected and what protocols they use.

PowerShell

```
Get-CimSession
```

Output

```
Id      : 1
Name    : CimSession1
InstanceId : 80742787-e38e-41b1-a7d7-fa1369cf1402
ComputerName : dc01
Protocol   : WSMAN

Id      : 2
Name    : CimSession2
InstanceId : 8fcabd81-43cf-4682-bd53-ccce1e24aecb
ComputerName : sql03
Protocol   : DCOM
```

Retrieve and store the previously created CimSessions in a variable named `$CimSession`.

PowerShell

```
$CimSession = Get-CimSession
```

Query both computers with one command, one using the WSMAN protocol and the other with DCOM.

PowerShell

```
Get-CimInstance -CimSession $CimSession -ClassName Win32_BIOS
```

Output

```
SMBIOSBIOSVersion : 090006
Manufacturer      : American Megatrends Inc.
Name              : Intel(R) Xeon(R) CPU E3-1505M v5 @ 2.80GHz
SerialNumber      : 0986-6980-3916-0512-6608-8243-13
Version           : VIRTUAL - 4001628
PSComputerName    : dc01

SMBIOSBIOSVersion : 090006
Manufacturer      : American Megatrends Inc.
Name              : Intel(R) Xeon(R) CPU E3-1505M v5 @ 2.80GHz
SerialNumber      : 7237-7483-8873-8926-7271-5004-86
Version           : VIRTUAL - 4001628
PSComputerName    : sql03
```

One of my blog articles on WMI and CIM cmdlets features a PowerShell function that automatically detects whether to use WSMan or DCOM and then sets up the appropriate CIM session for you. For more information, see [PowerShell Function to Create CimSessions to Remote Computers with Fallback to Dcom](#).

When you finish with the CIM sessions, remove them with the `Remove-CimSession` cmdlet. To remove all CIM sessions, pipe `Get-CimSession` to `Remove-CimSession`.

PowerShell

```
Get-CimSession | Remove-CimSession
```

Summary

In this chapter, you learned about using PowerShell to work with WMI on local and remote computers. You also learned how to use the CIM cmdlets to work with remote computers using the WSMan and DCOM protocols.

Review

1. What's the difference in the WMI and CIM cmdlets?
2. By default, what protocol does the `Get-CimInstance` cmdlet use?
3. What are some benefits of using a CIM session instead of specifying a computer name with `Get-CimInstance`?

4. How do you specify an alternate protocol other than the default one for use with
`Get-CimInstance`?
5. How do you close or remove CIM sessions?

Chapter 8 - PowerShell remoting

Article • 03/26/2025

PowerShell offers several ways to run commands against remote computers. In the last chapter, you explored how to remotely query WMI using the CIM cmdlets. PowerShell also includes several cmdlets that feature a built-in **ComputerName** parameter.

As shown in the following example, you can use `Get-Command` with the **ParameterName** parameter to identify cmdlets that include a **ComputerName** parameter.

```
PowerShell

Get-Command -ParameterName ComputerName

Output

CommandType Name          Version Source
----- ----
Cmdlet      Add-Computer   3.1.0.0 Microsoft.PowerShell.Management
Cmdlet      Clear-EventLog 3.1.0.0 Microsoft.PowerShell.Management
Cmdlet      Connect-PSSession 3.0.0.0 Microsoft.PowerShell.Core
Cmdlet      Enter-PSSession 3.0.0.0 Microsoft.PowerShell.Core
Cmdlet      Get-EventLog    3.1.0.0 Microsoft.PowerShell.Management
Cmdlet      Get-HotFix     3.1.0.0 Microsoft.PowerShell.Management
Cmdlet      Get-Process    3.1.0.0 Microsoft.PowerShell.Management
Cmdlet      Get-PSSession   3.0.0.0 Microsoft.PowerShell.Core
Cmdlet      Get-Service    3.1.0.0 Microsoft.PowerShell.Management
Cmdlet      Get-WmiObject  3.1.0.0 Microsoft.PowerShell.Management
Cmdlet      Invoke-Command 3.0.0.0 Microsoft.PowerShell.Core
Cmdlet      Invoke-WmiMethod 3.1.0.0 Microsoft.PowerShell.Management
Cmdlet      Limit-EventLog 3.1.0.0 Microsoft.PowerShell.Management
Cmdlet      New-EventLog   3.1.0.0 Microsoft.PowerShell.Management
Cmdlet      New-PSSession  3.0.0.0 Microsoft.PowerShell.Core
Cmdlet      Receive-Job    3.0.0.0 Microsoft.PowerShell.Core
Cmdlet      Receive-PSSession 3.0.0.0 Microsoft.PowerShell.Core
Cmdlet      Register-WmiEvent 3.1.0.0 Microsoft.PowerShell.Management
Cmdlet      Remove-Computer 3.1.0.0 Microsoft.PowerShell.Management
Cmdlet      Remove-EventLog 3.1.0.0 Microsoft.PowerShell.Management
Cmdlet      Remove-PSSession 3.0.0.0 Microsoft.PowerShell.Core
Cmdlet      Remove-WmiObject 3.1.0.0 Microsoft.PowerShell.Management
Cmdlet      Rename-Computer 3.1.0.0 Microsoft.PowerShell.Management
Cmdlet      Restart-Computer 3.1.0.0 Microsoft.PowerShell.Management
Cmdlet      Send-MailMessage 3.1.0.0 Microsoft.PowerShell.Utility
Cmdlet      Set-Service    3.1.0.0 Microsoft.PowerShell.Management
Cmdlet      Set-WmiInstance 3.1.0.0 Microsoft.PowerShell.Management
Cmdlet      Show-EventLog   3.1.0.0 Microsoft.PowerShell.Management
Cmdlet      Stop-Computer   3.1.0.0 Microsoft.PowerShell.Management
```

```
Cmdlet      Test-Connection    3.1.0.0 Microsoft.PowerShell.Management  
Cmdlet      Write-EventLog     3.1.0.0 Microsoft.PowerShell.Management
```

Commands such as `Get-Process` and `Get-HotFix` include a **ComputerName** parameter, but this approach isn't the long-term direction Microsoft recommends for running commands against remote systems. Even when you find a command with a **ComputerName** parameter, it often lacks a **Credential** parameter, making it difficult to specify alternate credentials. Running PowerShell from an elevated session doesn't guarantee success, as a network firewall can block the request between your system and the remote computer.

To use the PowerShell remoting commands demonstrated in this chapter, PowerShell remoting must be enabled on the remote computer. You can enable it by running the `Enable-PSRemoting` cmdlet.

PowerShell

```
Enable-PSRemoting
```

Output

```
WinRM has been updated to receive requests.  
WinRM service type changed successfully.  
WinRM service started.
```

```
WinRM has been updated for remote management.  
WinRM firewall exception enabled.
```

One-to-one remoting

If you want an interactive remote session, one-to-one remoting is what you want. This type of remoting is provided via the `Enter-PSSession` cmdlet.

Store your domain admin credentials in the `$Cred` variable. This approach allows you to enter your credentials once and reuse them on a per-command basis as long as your current PowerShell session remains active.

PowerShell

```
$Cred = Get-Credential
```

Establish a one-to-one PowerShell remoting session to the domain controller named dc01.

PowerShell

```
Enter-PSSession -ComputerName dc01 -Credential $Cred
```

Notice the PowerShell prompt is preceded by `[dc01]`. This prefix indicates you're in an interactive session with the remote computer named dc01. Any commands you run now execute on dc01, not your local machine.

Output

```
[dc01]: PS C:\Users\Administrator\Documents>
```

Remember that you can only access the PowerShell commands and modules installed on the remote computer. If you installed other modules locally, they aren't available in the remote session.

When connected via a one-to-one interactive remoting session, it's as if you're sitting directly at the remote machine.

PowerShell

```
[dc01]: Get-Process | Get-Member
```

Output

```
TypeName: System.Diagnostics.Process
```

Name	MemberType	Definition
Handles	AliasProperty	Handles = HandleCount
Name	AliasProperty	Name = ProcessName

When you finish working with the remote computer, run the `Exit-PSSession` cmdlet to end the remote session.

PowerShell

```
[dc01]: Exit-PSSession
```

One-to-many remoting

While you might occasionally need to perform tasks interactively on a remote computer, PowerShell remoting becomes more powerful when you simultaneously execute commands across multiple remote systems. Use the `Invoke-Command` cmdlet to run commands on one or more remote computers at the same time.

In the following example, you query three servers for the status of the Windows Time service. The `Get-Service` cmdlet is placed inside the script block of `Invoke-Command`, meaning it executes on each remote computer.

PowerShell

```
Invoke-Command -ComputerName dc01, sql02, web01 {
    Get-Service -Name W32time
} -Credential $Cred
```

The results are returned to your local session as deserialized objects.

Output

Status	Name	DisplayName	PSComputerName
Running	W32time	Windows Time	web01
Start...	W32time	Windows Time	dc01
Running	W32time	Windows Time	sql02

To confirm the returned objects are deserialized, pipe the output to `Get-Member`.

PowerShell

```
Invoke-Command -ComputerName dc01, sql02, web01 {
    Get-Service -Name W32time
} -Credential $Cred | Get-Member
```

Output

TypeName: Deserialized.System.ServiceProcess.ServiceController

Name	MemberType	Definition
GetType	Method	type GetType()
ToString	Method	string ToString(), string ToString(strin...
Name	NoteProperty	string Name=W32time
PSComputerName	NoteProperty	string PSComputerName=dc01
PSShowComputerName	NoteProperty	bool PSShowComputerName=True
RequiredServices	NoteProperty	Deserialized.System.ServiceProcess.Servi...
RunspaceId	NoteProperty	guid RunspaceId=5ed06925-8037-43ef-9072-...
CanPauseAndContinue	Property	System.Boolean {get;set;}
CanShutdown	Property	System.Boolean {get;set;}
CanStop	Property	System.Boolean {get;set;}
Container	Property	{get;set;}
DependentServices	Property	Deserialized.System.ServiceProcess.Servi...
DisplayName	Property	System.String {get;set;}
MachineName	Property	System.String {get;set;}
ServiceHandle	Property	System.String {get;set;}
ServiceName	Property	System.String {get;set;}
ServicesDependedOn	Property	Deserialized.System.ServiceProcess.Servi...
ServiceType	Property	System.String {get;set;}
Site	Property	{get;set;}
StartType	Property	System.String {get;set;}
Status	Property	System.String {get;set;}

Notice that most methods are missing from deserialized objects. The methods are missing because these objects aren't live. They're inert snapshots of the object's state when you execute the command against the remote computer. For example, you can't start or stop a service using a deserialized object since it no longer has access to the required methods.

However, this doesn't mean you can't use methods like `Stop()` with `Invoke-Command`.

The key is that you must call the method within the remote session.

To demonstrate, stop the Windows Time service on all three remote servers by invoking the `Stop()` method remotely.

PowerShell

```
Invoke-Command -ComputerName dc01, sql02, web01 {
    (Get-Service -Name W32time).Stop()
} -Credential $Cred

Invoke-Command -ComputerName dc01, sql02, web01 {
    Get-Service -Name W32time
} -Credential $Cred
```

Output

Status	Name	DisplayName	PSComputerName
Stopped	W32time	Windows Time	web01
Stopped	W32time	Windows Time	dc01
Stopped	W32time	Windows Time	sql02

As mentioned in an earlier chapter, if there's a cmdlet available to accomplish a task, it's preferable to use it rather than calling a method directly. For example, use the `Stop-Service` cmdlet instead of the `Stop()` method to stop a service.

In the previous example, the `Stop()` method is used to make a point. Some people mistakenly believe that you can't use methods with PowerShell remoting. While it's true that you can't call methods on deserialized objects returned to your local session, you can, however, invoke them within the remote session.

PowerShell sessions

In the final example from the previous section, you ran two commands using the `Invoke-Command` cmdlet. This scenario resulted in two separate sessions being established and torn down. One for each command.

Like CIM sessions, a persistent PowerShell session allows you to run multiple commands against a remote computer without the overhead of creating a new session for each command.

Create a PowerShell session to each of the three computers you're working with in this chapter, DC01, SQL02, and WEB01.

```
PowerShell
```

```
$Session = New-PSSession -ComputerName dc01, sql02, web01 -Credential $Cred
```

Now, use the `$Session` variable to start the Windows Time service by calling its method and then verify the service status.

```
PowerShell
```

```
Invoke-Command -Session $Session {((Get-Service -Name W32time).Start())}
Invoke-Command -Session $Session {Get-Service -Name W32time}
```

```
Output
```

Status	Name	DisplayName	PSComputerName
Running	W32time	Windows Time	web01
Start...	W32time	Windows Time	dc01
Running	W32time	Windows Time	sql02

Once you create the session with alternate credentials, you don't need to specify those credentials again for each command.

Be sure to remove the sessions when you finish using them.

```
PowerShell
```

```
Get-PSSession | Remove-PSSession
```

Summary

In this chapter, you learned the fundamentals of PowerShell remoting, including running commands interactively on a single remote computer and executing commands across multiple systems using one-to-many remoting. You also explored the advantages of using persistent PowerShell sessions when running multiple commands against the same remote computer.

Review

1. How do you enable PowerShell remoting?
2. What PowerShell command do you use to start an interactive session with a remote computer?
3. What's one benefit of using a PowerShell remoting session instead of specifying the computer name with each command?
4. Can you use a PowerShell session in a one-to-one interactive remoting scenario?
5. What's the difference between the objects returned by cmdlets run locally and objects returned when the same cmdlets are executed on remote computers using `Invoke-Command`?

Chapter 9 - Functions

Article • 01/23/2025

PowerShell one-liners and scripts that have to be modified often are good candidates to turn into reusable functions.

Write functions whenever possible because they're more tool-oriented. You can add the functions to a script module, put that module in a location defined in the `$env:PSModulePath`, and call the functions without needing to locate where you saved the functions. Using the **PowerShellGet** module, it's easy to share your PowerShell modules in a NuGet repository. **PowerShellGet** ships with PowerShell version 5.0 and higher. It's also available as a separate download for PowerShell version 3.0 and higher.

Don't overcomplicate things. Keep it simple and use the most straightforward way to accomplish a task. Avoid aliases and positional parameters in any code that you reuse. Format your code for readability. Don't hardcode values; use parameters and variables. Don't write unnecessary code even if it doesn't hurt anything. It adds unnecessary complexity. Attention to detail goes a long way when writing any PowerShell code.

Naming

When naming your functions in PowerShell, use a [Pascal case](#) name with an approved verb and a singular noun. To obtain a list of approved verbs in PowerShell, run `Get-Verb`. The following example sorts the results of `Get-Verb` by the **Verb** property.

```
PowerShell
Get-Verb | Sort-Object -Property Verb
```

The **Group** property gives you an idea of how the verbs are meant to be used.

```
Output
Verb      Group
-----
Add       Common
Approve   Lifecycle
Assert    Lifecycle
Backup    Data
Block     Security
Checkpoint Data
Clear     Common
Close     Common
```

It's important to use an approved verb for your PowerShell functions. Modules that contain functions with unapproved verbs generate a warning message when they're imported into a PowerShell session. That warning message makes your functions look unprofessional. Unapproved verbs also limit the discoverability of your functions.

A simple function

A function in PowerShell is declared with the `function` keyword followed by the function name and then an opening and closing curly brace (`{ }`). The code executed by the function is contained within those curly braces.

```
function Get-Version {
    $PSVersionTable.PSVersion
}
```

The function shown in the following example is a simple example that returns the version of PowerShell.

PowerShell

```
Get-Version
```

Output

Major	Minor	Build	Revision
-----	-----	-----	-----
5	1	14393	693

When you use a generic name for your functions, such as `Get-Version`, it could cause naming conflicts. Default commands added in the future or commands that others might write could conflict with them. Prefix the noun portion of your function names to help prevent naming conflicts. For example: `<ApprovedVerb>-<Prefix><SingularNoun>`.

The following example uses the prefix `PS`.

PowerShell

```
function Get-PSVersion {
    $PSVersionTable.PSVersion
}
```

Other than the name, this function is identical to the previous one.

PowerShell

```
Get-PSVersion
```

Output

Major	Minor	Build	Revision
-----	-----	-----	-----
5	1	14393	693

You can still have a name conflict even when you add a prefix to the noun. I like to prefix my function nouns with my initials. Develop a standard and stick to it.

PowerShell

```
function Get-MrPSVersion {  
    $PSVersionTable.PSVersion  
}
```

This function is no different than the previous two, except for using a more unique name to try to prevent naming conflicts with other PowerShell commands.

PowerShell

```
Get-MrPSVersion
```

Output

Major	Minor	Build	Revision
5	1	14393	693

Once loaded into memory, you can see functions on the **Function** PSDrive.

PowerShell

```
Get-ChildItem -Path Function:\Get-*Version
```

Output

CommandType	Name	Version
Function	Get-Version	
Function	Get-PSVersion	
Function	Get-MrPSVersion	

If you want to remove these functions from your current session, remove them from the **Function** PSDrive or close and reopen PowerShell.

PowerShell

```
Get-ChildItem -Path Function:\Get-*Version | Remove-Item
```

Verify that the functions were indeed removed.

```
PowerShell
```

```
Get-ChildItem -Path Function:\Get-*Version
```

If the functions were loaded as part of a module, you can unload the module to remove them.

```
PowerShell
```

```
Remove-Module -Name <ModuleName>
```

The `Remove-Module` cmdlet removes PowerShell modules from memory in your current PowerShell session. It doesn't remove them from your system or disk.

Parameters

Don't statically assign values. Use parameters and variables instead. When naming your parameters, use the same name as the default cmdlets for your parameter names whenever possible.

In the following function, notice that I used `ComputerName` and not `Computer`, `ServerName`, or `Host` for the parameter name. Using `ComputerName` standardizes the parameter name to match the parameter name and case like the default cmdlets.

```
PowerShell
```

```
function Test-MrParameter {
    param (
        $ComputerName
    )
    Write-Output $ComputerName
}
```

The following function queries all commands on your system and returns the number with specific parameter names.

```
PowerShell
```

```
function Get-MrParameterCount {
    param (
        [string[]]$ParameterName
    )
}
```

```

foreach ($Parameter in $ParameterName) {
    $Results = Get-Command -ParameterName $Parameter -ErrorAction
    SilentlyContinue

    [pscustomobject]@{
        ParameterName      = $Parameter
        NumberOfCmdlets   = $Results.Count
    }
}
}

```

As you can see in the following results, 39 commands that have a **ComputerName** parameter. There aren't any commands with parameters such as **Computer**, **ServerName**, **Host**, or **Machine**.

PowerShell

```
Get-MrParameterCount -ParameterName ComputerName, Computer, ServerName,
                      Host, Machine
```

Output

ParameterName	NumberOfCmdlets
ComputerName	39
Computer	0
ServerName	0
Host	0
Machine	0

Use the same case for your parameter names as the default cmdlets. For example, use `ComputerName`, not `computername`. This naming scheme helps people familiar with PowerShell discover your functions and look and feel like the default cmdlets.

The `param` statement allows you to define one or more parameters. A comma (,) separates the parameter definitions. For more information, see [about_Functions_Advanced_Parameters](#).

Advanced functions

Turning a function into an advanced function in PowerShell is simple. One of the differences between a function and an advanced function is that advanced functions have common parameters that are automatically added. Common parameters include parameters such as **Verbose** and **Debug**.

Start with the `Test-MrParameter` function that was used in the previous section.

PowerShell

```
function Test-MrParameter {  
  
    param (  
        $ComputerName  
    )  
  
    Write-Output $ComputerName  
  
}
```

There are a couple of different ways to see the common parameters. One is by viewing the syntax with `Get-Command`.

PowerShell

```
Get-Command -Name Test-MrParameter -Syntax
```

Notice the `Test-MrParameter` function doesn't have any common parameters.

Output

```
Test-MrParameter [[ -ComputerName] <Object>]
```

Another is to drill down into the parameters property of `Get-Command`.

PowerShell

```
(Get-Command -Name Test-MrParameter).Parameters.Keys
```

Output

```
ComputerName
```

Add the `CmdletBinding` attribute to turn the function into an advanced function.

PowerShell

```
function Test-MrCmdletBinding {  
  
    [CmdletBinding()] # Turns a regular function into an advanced function  
    param (  
        $ComputerName  
    )  
}
```

```
)  
  
    Write-Output $ComputerName  
  
}
```

When you specify `CmdletBinding`, the common parameters are added automatically. `CmdletBinding` requires a `param` block, but the `param` block can be empty.

PowerShell

```
Get-Command -Name Test-MrCmdletBinding -Syntax
```

Output

```
Test-MrCmdletBinding [[-ComputerName] <Object>] [<CommonParameters>]
```

Drilling down into the `parameters` property of `Get-Command` shows the actual parameter names, including the common ones.

PowerShell

```
(Get-Command -Name Test-MrCmdletBinding).Parameters.Keys
```

Output

```
ComputerName
Verbose
Debug
ErrorAction
WarningAction
InformationAction
ErrorVariable
WarningVariable
InformationVariable
OutVariable
OutBuffer
PipelineVariable
```

SupportsShouldProcess

The `SupportsShouldProcess` attribute adds the `WhatIf` and `Confirm` risk mitigation parameters. These parameters are only needed for commands that make changes.

PowerShell

```
function Test-MrSupportsShouldProcess {  
  
    [CmdletBinding(SupportsShouldProcess)]  
    param (  
        $ComputerName  
    )  
  
    Write-Output $ComputerName  
  
}
```

Notice that there are now **WhatIf** and **Confirm** parameters.

PowerShell

```
Get-Command -Name Test-MrSupportsShouldProcess -Syntax
```

Output

```
Test-MrSupportsShouldProcess [[-ComputerName] <Object>] [-WhatIf] [-Confirm]  
[<CommonParameters>]
```

Once again, you can also use `Get-Command` to return a list of the actual parameter names, including the common, ones along with **WhatIf** and **Confirm**.

PowerShell

```
(Get-Command -Name Test-MrSupportsShouldProcess).Parameters.Keys
```

Output

```
ComputerName  
Verbose  
Debug  
ErrorAction  
WarningAction  
InformationAction  
ErrorVariable  
WarningVariable  
InformationVariable  
OutVariable  
OutBuffer  
PipelineVariable  
WhatIf  
Confirm
```

Parameter validation

Validate input early on. Don't allow your code to continue on a path when it can't complete without valid input.

Always specify a datatype for the variables used for parameters. In the following example, **String** is specified as the datatype for the **ComputerName** parameter. This validation limits it to only allow a single computer name to be specified for the **ComputerName** parameter.

PowerShell

```
function Test-MrParameterValidation {  
  
    [CmdletBinding()]  
    param (  
        [string]$ComputerName  
    )  
  
    Write-Output $ComputerName  
  
}
```

An error is generated if more than one computer name is specified.

PowerShell

```
Test-MrParameterValidation -ComputerName Server01, Server02
```

Output

```
Test-MrParameterValidation : Cannot process argument transformation on  
parameter 'ComputerName'. Cannot convert value to type System.String.  
At line:1 char:42  
+ Test-MrParameterValidation -ComputerName Server01, Server02  
+                                         ~~~~~~  
+ CategoryInfo          : InvalidData: (:) [Test-MrParameterValidation]  
, ParameterBindingArgumentTransformationException  
+ FullyQualifiedErrorId : ParameterArgumentTransformationError,Test-MrP  
arameterValidation
```

The problem with the current definition is that it's valid to omit the value of the **ComputerName** parameter, but a value is required for the function to complete successfully. This scenario is where the **Mandatory** parameter attribute is beneficial.

The syntax used in the following example is compatible with PowerShell version 3.0 and higher. `[Parameter(Mandatory=$true)]` could be specified to make the function compatible with PowerShell version 2.0 or higher.

PowerShell

```
function Test-MrParameterValidation {  
  
    [CmdletBinding()]  
    param (  
        [Parameter(Mandatory)]  
        [string]$ComputerName  
    )  
  
    Write-Output $ComputerName  
  
}
```

Now that the **ComputerName** is required, if one isn't specified, the function prompts for one.

PowerShell

```
Test-MrParameterValidation
```

Output

```
cmdlet Test-MrParameterValidation at command pipeline position 1  
Supply values for the following parameters:  
ComputerName:
```

If you want to allow more than one value for the **ComputerName** parameter, use the **String** datatype but add square brackets (`[]`) to the datatype to allow an array of strings.

PowerShell

```
function Test-MrParameterValidation {  
  
    [CmdletBinding()]  
    param (  
        [Parameter(Mandatory)]  
        [string[]]$ComputerName  
    )  
  
    Write-Output $ComputerName
```

```
}
```

Maybe you want to specify a default value for the `ComputerName` parameter if one isn't specified. The problem is that default values can't be used with mandatory parameters. Instead, use the `ValidateNotNullOrEmpty` parameter validation attribute with a default value.

Even when setting a default value, try not to use static values. In the following example, `$env:COMPUTERNAME` is used as the default value, which is automatically translated to the local computer name if a value isn't provided.

PowerShell

```
function Test-MrParameterValidation {  
  
    [CmdletBinding()]  
    param (  
        [ValidateNotNullOrEmpty()]  
        [string[]]$ComputerName = $env:COMPUTERNAME  
    )  
  
    Write-Output $ComputerName  
  
}
```

Verbose output

Inline comments are useful if you're writing complex code, but users don't see them unless they look at the code.

The function in the following example has an inline comment in the `foreach` loop. While this particular comment might not be difficult to locate, imagine if the function contained hundreds of lines of code.

PowerShell

```
function Test-MrVerboseOutput {  
  
    [CmdletBinding()]  
    param (  
        [ValidateNotNullOrEmpty()]  
        [string[]]$ComputerName = $env:COMPUTERNAME  
    )  
  
    foreach ($Computer in $ComputerName) {  
        #Attempting to perform an action on $Computer <--- Don't use  
    }  
}
```

```
#inline comments like this, use Write-Verbose instead.  
Write-Output $Computer  
}  
}
```

A better option is to use `Write-Verbose` instead of inline comments.

PowerShell

```
function Test-MrVerboseOutput {  
  
    [CmdletBinding()]  
    param (  
        [ValidateNotNullOrEmpty()]  
        [string[]]$ComputerName = $env:COMPUTERNAME  
    )  
  
    foreach ($Computer in $ComputerName) {  
        Write-Verbose -Message "Attempting to perform an action on  
$Computer"  
        Write-Output $Computer  
    }  
}
```

The verbose output isn't displayed when the function is called without the `Verbose` parameter.

PowerShell

```
Test-MrVerboseOutput -ComputerName Server01, Server02
```

The verbose output is displayed when the function is called with the `Verbose` parameter.

PowerShell

```
Test-MrVerboseOutput -ComputerName Server01, Server02 -Verbose
```

Pipeline input

Extra code is necessary when you want your function to accept pipeline input. As mentioned earlier in this book, commands can accept pipeline input **by value** (by type) or **by property name**. You can write your functions like the native commands so they accept either one or both of these input types.

To accept pipeline input **by value**, specify the `ValueFromPipeline` parameter attribute for that particular parameter. You can only accept pipeline input **by value** from one parameter of each datatype. If you have two parameters that accept string input, only one of them can accept pipeline input **by value**. If you specified **by value** for both of the string parameters, the input wouldn't know which parameter to bind to. This scenario is another reason I call this type of pipeline input *by type* instead of **by value**.

Pipeline input is received one item at a time, similar to how items are handled in a `foreach` loop. A `process` block is required to process each item if your function accepts an array as input. If your function only accepts a single value as input, a `process` block isn't necessary but is recommended for consistency.

PowerShell

```
function Test-MrPipelineInput {  
  
    [CmdletBinding()]  
    param (  
        [Parameter(Mandatory,  
                  ValueFromPipeline)]  
        [string[]]$ComputerName  
    )  
  
    process {  
        Write-Output $ComputerName  
    }  
  
}
```

Accepting pipeline input **by property name** is similar, except you specify it with the `ValueFromPipelineByPropertyName` parameter attribute, and it can be specified for any number of parameters regardless of datatype. The key is the output of the command being piped in must have a property name that matches the name of the parameter or a parameter alias of your function.

PowerShell

```
function Test-MrPipelineInput {  
  
    [CmdletBinding()]  
    param (  
        [Parameter(Mandatory,  
                  ValueFromPipelineByPropertyName)]  
        [string[]]$ComputerName  
    )  
  
    process {  
        Write-Output $ComputerName  
    }  

```

```
}
```

```
}
```

`begin` and `end` blocks are optional. `begin` is specified before the `process` block and is used to perform any initial work before the items are received from the pipeline. Values that are piped in aren't accessible in the `begin` block. The `end` block is specified after the `process` block and is used for cleanup after all items piped in are processed.

Error handling

The function shown in the following example generates an unhandled exception when a computer can't be contacted.

```
PowerShell
```

```
function Test-MrErrorHandler {
    [CmdletBinding()]
    param (
        [Parameter(Mandatory,
                   ValueFromPipeline,
                   ValueFromPipelineByPropertyName)]
        [string[]]$ComputerName
    )

    process {
        foreach ($Computer in $ComputerName) {
            Test-WSMan -ComputerName $Computer
        }
    }
}
```

There are a couple of different ways to handle errors in PowerShell. `Try/Catch` is the more modern way to handle errors.

```
PowerShell
```

```
function Test-MrErrorHandler {
    [CmdletBinding()]
    param (
        [Parameter(Mandatory,
                   ValueFromPipeline,
                   ValueFromPipelineByPropertyName)]
        [string[]]$ComputerName
    )
}
```

```

process {
    foreach ($Computer in $ComputerName) {
        try {
            Test-WSMan -ComputerName $Computer
        }
        catch {
            Write-Warning -Message "Unable to connect to Computer:
$Computer"
        }
    }
}

```

Although the function shown in the previous example uses error handling, it generates an unhandled exception because the command doesn't generate a terminating error. Only terminating errors are caught. Specify the **ErrorAction** parameter with **Stop** as its value to turn a nonterminating error into a terminating one.

PowerShell

```

function Test-MrErrorHandler {
    [CmdletBinding()]
    param (
        [Parameter(Mandatory,
                   ValueFromPipeline,
                   ValueFromPipelineByPropertyName)]
        [string[]]$ComputerName
    )

    process {
        foreach ($Computer in $ComputerName) {
            try {
                Test-WSMan -ComputerName $Computer -ErrorAction Stop
            }
            catch {
                Write-Warning -Message "Unable to connect to Computer:
$Computer"
            }
        }
    }
}

```

Don't modify the global `$ErrorActionPreference` variable unless absolutely necessary. If you change it in a local scope, it reverts to the previous value when you exit that scope.

If you're using something like .NET directly from within your PowerShell function, you can't specify the **ErrorAction** parameter on the command itself. You can change the `$ErrorActionPreference` variable just before you call the .NET method.

Comment-based help

Adding help to your functions is considered a best practice. Help allows people you share them with to know how to use them.

```
PowerShell

function Get-MrAutoStoppedService {

    <#
    .SYNOPSIS
        Returns a list of services that are set to start automatically, are not
        currently running, excluding the services that are set to delayed start.

    .DESCRIPTION
        Get-MrAutoStoppedService is a function that returns a list of services
        from the specified remote computer(s) that are set to start
        automatically, are not currently running, and it excludes the services
        that are set to start automatically with a delayed startup.

    .PARAMETER ComputerName
        The remote computer(s) to check the status of the services on.

    .PARAMETER Credential
        Specifies a user account that has permission to perform this action. The
        default is the current user.

    .EXAMPLE
        Get-MrAutoStoppedService -ComputerName 'Server1', 'Server2'

    .EXAMPLE
        'Server1', 'Server2' | Get-MrAutoStoppedService

    .EXAMPLE
        Get-MrAutoStoppedService -ComputerName 'Server1' -Credential (Get-
        Credential)

    .INPUTS
        String

    .OUTPUTS
        PSCustomObject

    .NOTES
        Author: Mike F. Robbins
        Website: https://mikefrobbins.com
        Twitter: @mikefrobbins
```

```
#>

[CmdletBinding()]
param (
)

#Function Body

}
```

When you add comment-based help to your functions, help can be retrieved for them like the default built-in commands.

All the syntax for writing a function in PowerShell can seem overwhelming for someone getting started. If you can't remember the syntax for something, open a second instance of the PowerShell Integrated Scripting Environment (ISE) on a separate monitor and view the "Cmdlet (advanced function) - Complete" snippet while typing in the code for your functions. Snippets can be accessed in the PowerShell ISE using the **Ctrl** + **J** key combination.

Summary

In this chapter, you learned the basics of writing functions in PowerShell, including how to:

- Create advanced functions
- Use parameter validation
- Use verbose output
- Support pipeline input
- Handle errors
- Create comment-based help

Review

1. How do you obtain a list of approved verbs in PowerShell?
2. How do you turn a PowerShell function into an advanced function?
3. When should **WhatIf** and **Confirm** parameters be added to your PowerShell functions?
4. How do you turn a nonterminating error into a terminating one?
5. Why should you add comment-based help to your functions?

- Video: PowerShell Toolmaking with Advanced Functions and Script Modules ↗

Chapter 10 - Script modules

Article • 03/27/2025

If you find yourself using the same PowerShell one-liners or scripts often, turning them into reusable tools is even more important. Packaging your functions in a script module gives them a more professional feel and makes them easier to support and share with others.

Dot-sourcing functions

One thing we didn't cover in the previous chapter is dot-sourcing functions. When you define a function in a script but not part of a module, the only way to load it into memory is by dot-sourcing its `.ps1` file.

For example, save the following function in a file named `Get-MrPSVersion.ps1`.

```
PowerShell

function Get-MrPSVersion {
    $PSVersionTable
}
```

When you run the script, it appears that nothing happens.

```
PowerShell

.\Get-MrPSVersion.ps1
```

Attempting to call the function results in an error because it isn't loaded into memory.

```
PowerShell

Get-MrPSVersion
```

Output

```
Get-MrPSVersion : The term 'Get-MrPSVersion' is not recognized as the name
of a cmdlet, function, script file, or operable program. Check the spelling
of the name, or if a path was included, verify that the path is correct and
try again.
At line:1 char:1
+ Get-MrPSVersion
+ ~~~~~~
```

```
+ CategoryInfo          : ObjectNotFound: (Get-MrPSVersion:String) [],
CommandNotFoundException
+ FullyQualifiedErrorId : CommandNotFoundException
```

You can confirm whether functions are loaded into memory by verifying their existence on the **Function:** PSDrive.

PowerShell

```
Get-ChildItem -Path Function:\Get-MrPSVersion
```

Output

```
Get-ChildItem : Cannot find path 'Get-MrPSVersion' because it does not
exist.
At line:1 char:1
+ Get-ChildItem -Path Function:\Get-MrPSVersion
+ ~~~~~
+ CategoryInfo          : ObjectNotFound: (Get-MrPSVersion:String) [Get
-ChildItem], ItemNotFoundException
+ FullyQualifiedErrorId : PathNotFound,Microsoft.PowerShell.Commands.Ge
tChildItemCommand
```

The issue with running the script that defines the function is that it loads it into the **Script** scope. Once the script finishes executing, PowerShell discards that scope along with the function.

To keep the function available after the script runs, it needs to be loaded into the **Global** scope. You can accomplish this by dot-sourcing the script file. You can use a relative path for this purpose.

PowerShell

```
. .\Get-MrPSVersion.ps1
```

You can also use the full path to the script when dot-sourcing it.

PowerShell

```
. C:\Demo\Get-MrPSVersion.ps1
```

If part of the path is stored in a variable, you can combine it with the rest of the path. There's no need to use string concatenation to do this.

PowerShell

```
$Path = 'C:\'  
. $Path\Get-MrPSVersion.ps1
```

Now, if you check the **Function** PSDrive, you see the `Get-MrPSVersion` function is available.

PowerShell

```
Get-ChildItem -Path Function:\Get-MrPSVersion
```

Output

CommandType	Name	Version
-----	-----	-----
Function	Get-MrPSVersion	

Script modules

In PowerShell, a script module is simply a `.psm1` file that contains one or more functions, just like a regular script, but with a different file extension.

How do you create a script module? You might assume with a command named something like `New-Module`. That assumption is a reasonable guess, but that command actually creates a dynamic module, not a script module.

This scenario is a good reminder to always read the help documentation, even when a command name looks exactly like what you need.

PowerShell

```
help New-Module
```

Output

NAME

 New-Module

SYNOPSIS

 Creates a new dynamic module that exists only in memory.

SYNTAX

```
    New-Module [-Name] <System.String> [-ScriptBlock]  
                  <System.Management.Automation.ScriptBlock> [-ArgumentList]
```

```
<System.Object[]>] [-AsCustomObject] [-Cmdlet <System.String[]>]
[-Function <System.String[]>] [-ReturnResult] [<CommonParameters>]
```

DESCRIPTION

The `New-Module` cmdlet creates a dynamic module from a script block. The members of the dynamic module, such as functions and variables, are immediately available in the session and remain available until you close the session.

Like static modules, by default, the cmdlets and functions in a dynamic module are exported and the variables and aliases are not. However, you can use the `Export-ModuleMember` cmdlet and the parameters of `New-Module` to override the defaults.

You can also use the `AsCustomObject` parameter of `New-Module` to return

the dynamic module as a custom object. The members of the module, such as functions, are implemented as script methods of the custom object instead of being imported into the session.

Dynamic modules exist only in memory, not on disk. Like all modules, the members of dynamic modules run in a private module scope that is a child of the global scope. `Get-Module` cannot get a dynamic module, but `Get-Command` can get the exported members.

To make a dynamic module available to `Get-Module`, pipe a `New-Module` command to `Import-Module`, or pipe the module object that `New-Module` returns to `Import-Module`. This action adds the dynamic module to the `Get-Module` list, but it does not save the module to disk or make it persistent.

REMARKS

To see the examples, type: "Get-Help New-Module -Examples".
For more information, type: "Get-Help New-Module -Detailed".
For technical information, type: "Get-Help New-Module -Full".
For online help, type: "Get-Help New-Module -Online"

The previous chapter mentioned that functions should use approved verbs. Otherwise, PowerShell generates a warning when the module is imported.

The following example uses the `New-Module` cmdlet to create a dynamic module in memory, specifically to demonstrate what happens when you don't use an approved

verb.

PowerShell

```
New-Module -Name MyModule -ScriptBlock {  
  
    function Return-MrOsVersion {  
        Get-CimInstance -ClassName Win32_OperatingSystem |  
            Select-Object -Property @{Label='OperatingSystem';Expression=  
{$_.Caption}}  
    }  
  
    Export-ModuleMember -Function Return-MrOsVersion  
  
} | Import-Module
```

Output

```
WARNING: The names of some imported commands from the module 'MyModule'  
include  
unapproved verbs that might make them less discoverable. To find the  
commands with  
unapproved verbs, run the Import-Module command again with the Verbose  
parameter. For a  
list of approved verbs, type Get-Verb.
```

Although you used the `New-Module` cmdlet in the previous example, as mentioned before, it's not the command for creating script modules in PowerShell.

To create a script module, save your functions in a `.psm1` file. For example, save the following two functions in a file named `MyScriptModule.psm1`.

PowerShell

```
function Get-MrPSVersion {  
    $PSVersionTable  
}  
  
function Get-MrComputerName {  
    $env:COMPUTERNAME  
}
```

Try to run one of the functions.

PowerShell

```
Get-MrComputerName
```

When you call the function, you receive an error saying PowerShell can't find it. Like before, checking the **Function**: PSDrive confirms that it isn't loaded into memory.

Output

```
Get-MrComputerName : The term 'Get-MrComputerName' is not recognized as the
name of a cmdlet, function, script file, or operable program. Check the
spelling of the name, or if a path was included, verify that the path is
correct and try again.
At line:1 char:1
+ Get-MrComputerName
+ ~~~~~
+ CategoryInfo          : ObjectNotFound: (Get-MrComputerName:String) [ ]
, CommandNotFoundException
+ FullyQualifiedErrorId : CommandNotFoundException
```

To make the function available, you can manually import the `MyScriptModule.psm1` file using the `Import-Module` cmdlet.

PowerShell

```
Import-Module C:\MyScriptModule.psm1
```

PowerShell introduced module autoloading in version 3. To take advantage of this feature, the script module must be saved in a folder with the same base name as the `.psm1` file. That folder must be located in one of the directories specified in the `$env:PSModulePath` environment variable.

PowerShell

```
$env:PSModulePath
```

The output of `$env:PSModulePath` is difficult to read.

Output

```
C:\Users\mike-ladm\Documents\WindowsPowerShell\Modules;C:\Program Files\Wind
owsPowerShell\Modules;C:\Windows\system32\WindowsPowerShell\v1.0\Modules;C:\
Program Files (x86)\Microsoft SQL Server\130\Tools\PowerShell\Modules\
```

To make the results more readable, split the paths on the semicolon path separator so each one appears on its own line.

PowerShell

```
$env:PSModulePath -split ';'
```

The first three paths in the list are the default module locations. SQL Server Management Studio added the last path when you installed it.

Output

```
C:\Users\mike-ladm\Documents\WindowsPowerShell\Modules
C:\Program Files\WindowsPowerShell\Modules
C:\Windows\system32\WindowsPowerShell\v1.0\Modules
C:\Program Files (x86)\Microsoft SQL Server\130\Tools\PowerShell\Modules\
```

For module autoloading to work, you must place the `MyScriptModule.psm1` file must in a folder named `MyScriptModule`, and that folder must reside directly inside one of the paths listed in

```
$env:PSModulePath.
```

Not all those paths are equally useful. For example, the current user path on my system isn't the first one in the list. That's because I sign in to Windows with a different account than the one I use to run PowerShell. So, it doesn't point to my user's documents folder.

The second path is the `AllUsers` path, which is where I store all of my modules.

The third path points to `C:\Windows\System32`, a protected system location. Only Microsoft should be placing modules there, as it falls under the operating system's directory structure.

Once you place the `.psm1` file in an appropriate folder within one of these paths, PowerShell automatically loads the module the first time you call one of its commands.

Module manifests

Every module should include a module manifest, which is a `.psd1` file containing metadata about the module. While the `.psd1` extension is used for manifests, not all `.psd1` files are module manifests. You can also use them for other purposes, such as defining environment data in a DSC configuration.

You can create a module manifest using the `New-ModuleManifest` cmdlet. The only required parameter is `Path`, but for the module to work correctly, you must also specify the `RootModule` parameter.

It's a best practice to include values like **Author** and **Description**, especially if you plan to publish your module to a NuGet repository using **PowerShellGet**. These fields are required in that scenario.

One quick way to tell if a module lacks a manifest is to check its version.

```
PowerShell  
  
Get-Module -Name MyScriptModule
```

A version number of `0.0` is a clear sign that the module lacks a manifest.

```
Output  
  
ModuleType Version Name ExportedCommands  
---- - - - -  
Script 0.0 MyScriptModule {Get-MrComputer...}
```

You should include all recommended details when creating a module manifest to ensure your module is well-documented and ready for sharing or publishing.

```
PowerShell  
  
$moduleManifestParams = @{  
    Path =  
    "$env:ProgramFiles\WindowsPowerShell\Modules\MyScriptModule\MyScriptModule.p  
sd1"  
    RootModule = 'MyScriptModule'  
    Author = 'Mike F. Robbins'  
    Description = 'MyScriptModule'  
    CompanyName = 'mikefrobbins.com'  
}  
  
New-ModuleManifest @moduleManifestParams
```

If you omit any values when initially creating the module manifest, you can add or update it later using the `Update-ModuleManifest` cmdlet. Avoid recreating the manifest with `New-ModuleManifest` once you create it, as doing so generates a new GUID.

Defining public and private functions

Sometimes, your module might include helper functions you don't want to expose to users. These private functions are used internally by other functions in the module but aren't exposed to users. There are a few ways to handle this scenario.

If you're not following best practices and only have a `.psm1` file without a proper module structure, your only option is to control visibility using the `Export-ModuleMember` cmdlet. This option lets you explicitly define which functions should be exposed directly from within the `.psm1` script module file, keeping everything else private by default.

In the following example, only the `Get-MrPSVersion` function is exposed to users of your module, while the `Get-MrComputerName` function remains accessible internally to other functions within the module.

```
PowerShell

function Get-MrPSVersion {
    $PSVersionTable
}

function Get-MrComputerName {
    $env:COMPUTERNAME
}

Export-ModuleMember -Function Get-MrPSVersion
```

Determine what commands are available publicly in the `MyScriptModule` module.

```
PowerShell

Get-Command -Module MyScriptModule
```

Output									
<table border="1"><thead><tr><th> CommandType</th><th>Name</th><th> Version</th></tr><tr><th>-----</th><th>---</th><th>-----</th></tr></thead><tbody><tr><td> Function</td><td>Get-MrPSVersion</td><td> 1.0</td></tr></tbody></table>	CommandType	Name	Version	-----	---	-----	Function	Get-MrPSVersion	1.0
CommandType	Name	Version							
-----	---	-----							
Function	Get-MrPSVersion	1.0							

If you add a module manifest to your module, it's a best practice to explicitly list the functions you want to export in the `FunctionsToExport` section. This option gives you control over what you expose to users from the `.psd1` module manifest file.

```
PowerShell

FunctionsToExport = 'Get-MrPSVersion'
```

You don't need to use both `Export-ModuleMember` in the `.psm1` file and the `FunctionsToExport` section in the module manifest. Either approach is enough on its own.

Summary

In this chapter, you learned how to turn your functions into a script module in PowerShell. You also explored best practices for creating script modules, including the importance of adding a module manifest to define metadata and manage exported commands.

Review

1. How do you create a script module in PowerShell?
2. Why is it important to use approved verbs for your function names?
3. How do you create a module manifest in PowerShell?
4. What are the two ways to export only specific functions from a module?
5. What conditions must be met for a module to autoload when you run one of its commands?

Optimizing your shell experience

Article • 12/01/2022

PowerShell is a command-line shell and a scripting language used for automation.

[Wikipedia](#) includes the following description of a shell:

A shell manages the user-system interaction by prompting users for input, interpreting their input, and then handling output from the underlying operating system (much like a read-eval-print loop or [REPL](#)).

Similar to other shells like `bash` or `cmd.exe`, PowerShell allows you to run any command available on your system, not just PowerShell commands.

PowerShell commands are known as *cmdlets* (pronounced command-lets). Cmdlets are PowerShell commands, not stand-alone executables. PowerShell commands can't be run in other shells without running PowerShell first.

Features of the PowerShell command-line interface

PowerShell is a modern command shell that includes the best features of other popular shells. Unlike most shells that only accept and return text, PowerShell accepts and returns .NET objects. The shell has several features that you can use to optimize your interactive user experience.

- Robust command-line [history](#)
- [Tab completion](#) and [command prediction](#)
- Supports command and parameter [aliases](#)
- [Pipeline](#) for chaining commands
- In-console [help](#) system, similar to Unix `man` pages

Running commands in the shell

Article • 01/23/2025

PowerShell is a command-line shell and a scripting language used for automation. Similar to other shells, like `bash` on Linux or the Windows Command Shell (`cmd.exe`), PowerShell lets you run any command available on your system, not just PowerShell commands.

Types of commands

For any shell in any operating system there are three types of commands:

- **Shell language keywords** are part of the shell's scripting language.
 - Examples of `bash` keywords include: `if`, `then`, `else`, `elif`, and `fi`.
 - Examples of `cmd.exe` keywords include: `dir`, `copy`, `move`, `if`, and `echo`.
 - Examples of PowerShell keywords include: `for`, `foreach`, `try`, `catch`, and `trap`.
- **OS-native commands** are executable files installed in the operating system. The executables can be run from any command-line shell, like PowerShell. This includes script files that may require other shells to work properly. For example, if you run a Windows batch script (`.cmd` file) in PowerShell, PowerShell runs `cmd.exe` and passes in the batch file for execution.
- **Shell environment-specific commands** are commands defined in external files that can only be used within the runtime environment of the shell. These include scripts and functions, or they can be specially compiled modules that add commands to the shell runtime. In PowerShell, these commands are known as *cmdlets* (pronounced "command-lets").

Running native commands

Any native command can be run from the PowerShell command line. Usually you run the command exactly as you would in `bash` or `cmd.exe`. The following example shows running the `grep` command in `bash` on Ubuntu Linux.

Bash

```
sdwheeler@circumflex:~$ grep sdwheeler /etc/passwd
sdwheeler:x:1000:1000:,,,:/home/sdwheeler:/bin/bash
sdwheeler@circumflex:~$ pwsh
PowerShell 7.2.6
Copyright (c) Microsoft Corporation.

https://aka.ms/powershell
Type 'help' to get help.
```

After starting PowerShell on Ubuntu, you can run the same command from the PowerShell command line:

```
PowerShell

PS /home/sdwheeler> grep sdwheeler /etc/passwd
sdwheeler:x:1000:1000:,,,:/home/sdwheeler:/bin/bash
```

Passing arguments to native commands

Most shells include features for using variables, evaluating expressions, and handling strings. But each shell does these things differently. In PowerShell, all parameters start with a hyphen (-) character. In cmd.exe, most parameters use a slash (/) character. Other command-line tools may not have a special character for parameters.

Each shell has its own way of handling and evaluating strings on the command line. When running native commands in PowerShell that expect strings to be quoted in a specific way, you may need adjust how you pass those strings.

For more information, see the following articles:

- [about_Parsing](#)
- [about_Quoting_Rules](#)

PowerShell 7.2 introduced a new experimental feature `PSNativeCommandArgumentPassing` that improved native command handling. For more information, see [\\$PSNativeCommandArgumentPassing](#).

Handling output and errors

PowerShell also has several more output streams than other shells. The bash and cmd.exe shells have `stdout` and `stderr`. PowerShell has six output streams. For more information, see [about_Redirection](#) and [about_Output_Streams](#).

In general, the output sent to `stdout` by a native command is sent to the `Success` stream in PowerShell. Output sent to `stderr` by a native command is sent to the `Error` stream in PowerShell.

When a native command has a non-zero exit code, `$?` is set to `$false`. If the exit code is zero, `$?` is set to `$true`.

However, this changed in PowerShell 7.2. Error records redirected from native commands, like when using redirection operators (`2>&1`), aren't written to PowerShell's `$Error` variable and the preference variable `$ErrorActionPreference` doesn't affect the redirected output.

Many native commands write to `stderr` as an alternative stream for additional information. This behavior can cause confusion in PowerShell when looking through errors and the additional output information can be lost if `$ErrorActionPreference` is set to a state that mutes the output.

PowerShell 7.3 added a new experimental feature

`PSNativeCommandErrorActionPreference` that allows you to control whether output to `stderr` is treated as an error. For more information, see [\\$PSNativeCommandUseErrorActionPreference](#).

Running PowerShell commands

As previously noted, PowerShell commands are known as cmdlets. Cmdlets are collected into PowerShell modules that can be loaded on demand. Cmdlets can be written in any compiled .NET language or using the PowerShell scripting language itself.

PowerShell commands that run other commands

The PowerShell `call operator` (`&`) lets you run commands that are stored in variables and represented by strings or script blocks. You can use this to run any native command or PowerShell command. This is useful in a script when you need to dynamically construct the command-line parameters for a native command. For more information, see the [call operator](#).

The `Start-Process` cmdlet can be used to run native commands, but should only be used when you need to control how the command is executed. The cmdlet has parameters to support the following scenarios:

- Run a command using different credentials
- Hide the console window created by the new process

- Redirect `stdin`, `stdout`, and `stderr` streams
- Use a different working directory for the command

The following example runs the native command `sort.exe` with redirected input and output streams.

```
PowerShell

$processOptions = @{
    FilePath = "sort.exe"
    RedirectStandardInput = "TestSort.txt"
    RedirectStandardOutput = "Sorted.txt"
    RedirectStandardError = "SortError.txt"
    UseNewEnvironment = $true
}
Start-Process @processOptions
```

For more information, see [Start-Process](#).

On Windows, the `Invoke-Item` cmdlet performs the default action for the specified item. For example, it runs an executable file or opens a document file using the application associated with the document file type. The default action depends on the type of item and is resolved by the PowerShell provider that provides access to the item.

The following example opens the PowerShell source code repository in your default web browser.

```
PowerShell

Invoke-Item https://github.com/PowerShell/PowerShell
```

For more information, see [Invoke-Item](#).

Using tab-completion in the shell

Article • 02/08/2023

PowerShell provides completions on input to provide hints, enable discovery, and speed up input entry. Command names, parameter names, argument values and file paths can all be completed by pressing the `Tab` key.

The `Tab` key is the default key binding on Windows. `PSReadLine` also provides a `MenuComplete` function that's bound to `Ctrl + Space`. The `MenuComplete` function displays a list of matching completions below the command line.

These keybindings can be changed using `PSReadLine` cmdlets or the application that's hosting PowerShell. Keybindings can be different on non-Windows platforms. For more information, see [about_PSReadLine_Functions](#).

Built-in tab completion features

PowerShell has enabled tab completion for many aspects of the command line experience.

Filename completion

To fill in a filename or path from the available choices automatically, type part of the name and press the `Tab` key. PowerShell automatically expands the name to the first match that it finds. Pressing the `Tab` key again cycles through all the available choices with each key press.

Command and parameter name completion

The tab expansion of cmdlet names is slightly different. To use tab expansion on a cmdlet name, type the entire first part of the name (the verb) and the hyphen that follows it. You can fill in more of the name for a partial match. For example, if you type `get-co` and then press the `Tab` key, PowerShell automatically expands this to the `Get-Command` cmdlet (notice that it also changes the case of letters to their standard form). If you press `Tab` key again, PowerShell replaces this with the only other matching cmdlet name, `Get-Content`. Tab completion also works to resolve PowerShell aliases and native executables.

The following graphic shows examples of tab and menu completion.

A screenshot of a Windows PowerShell window. The title bar says "C:\Program Files\PowerShell\". The command line shows "PS D:\temp> |". The rest of the window is blank.

Other tab completion enhancements

Each new version of PowerShell includes improvements to tab completion that fix bugs and improve usability.

PowerShell 7.0

- Tab completion resolves variable assignments that are enums or are type constrained
- Tab completion expands abbreviated cmdlets and functions. For example, `i-psdf<tab>` returns `Import-PowerShellDataFile`

PowerShell 7.2

- Fix tab completion for unlocalized `about*` topics
- Fix splatting being treated as positional parameter in completions
- Add completions for Comment-based Help keywords
- Add completion for `#Requires` statements
- Add tab completion for `View` parameter of `Format-*` cmdlets
- Add support for class-based argument completers

PowerShell 7.3

- Fix tab completion within the script block specified for the `ValidateScriptAttribute`
- Added tab completion for loop labels after `break` and `continue`
- Improve Hashtable completion in multiple scenarios

- Parameter splatting
- **Arguments** parameter for `Invoke-CimMethod`
- **FilterHashtable** parameter for `Get-WinEvent`
- **Property** parameter for the CIM cmdlets
- Removes duplicates from member completion scenarios
- Support forward slashes in network share (UNC path) completion
- Improve member auto completion
- Prioritize `ValidateSet` completions over enums for parameters
- Add type inference support for generic methods with type parameters
- Improve type inference and completions
 - Allows methods to be shown in completion results for `ForEach-Object -MemberName`
 - Prevents completion on expressions that return **void** like (`[void]("")`)
 - Allows non-default Class constructors to show up when class completion is based on the AST

Other ways to enhance tab completion of command parameters

Built-in tab expansion is controlled by the internal function `TabExpansion` or `TabExpansion2`. It's possible to create functions or modules that replace the default behavior of these functions. You can find examples in the PowerShell Gallery by searching for the [TabExpansion ↗](#) keyword.

Using the `ValidateSet` or `ArgumentCompletions` attributes with parameters

The `ArgumentCompletions` attribute allows you to add tab completion values to a specific parameter. The `ArgumentCompletions` attribute is similar to `ValidateSet`. Both attributes takes a list of values to be presented when the user presses `Tab` after the parameter name. However, unlike `ValidateSet`, the values aren't validated.

For more information, see:

- [ArgumentCompletions](#)
- [ValidateSet](#)

Using the `ArgumentCompleter` attribute or `Register-ArgumentCompleter` with parameters

An argument completer is a script block or function that provides dynamic tab completion for parameter values.

The `ArgumentCompleter` attribute allows you to register a function that provides tab completion values for the parameter. The argument completer function must be available to the function containing the parameter with the `ArgumentCompleter` attribute. Usually, the function is defined in the same script or module.

For more information, see [ArgumentCompleter](#).

The `Register-ArgumentCompleter` cmdlet registers a script block as an argument completer function at run time for any command you specify. This allows you to define argument completers outside of the script or module or for native commands. For more information, see [Register-ArgumentCompleter](#).

Predictive IntelliSense in PSReadLine

PSReadLine 2.1.0 introduced the **Predictive IntelliSense** feature. Predictive IntelliSense provides suggestions for full commands based on items from your **PSReadLine** history.

PSReadLine 2.2.2 extends the power of Predictive IntelliSense by adding support for plug-in modules that use advanced logic to provide suggestions for full commands. The **Az.Tools.Predictor** module was the first plug-in for Predictive IntelliSense. It uses Machine Learning to predict what Azure PowerShell command you want to run and the parameters you want to use.

For more information, see [Using predictors](#).

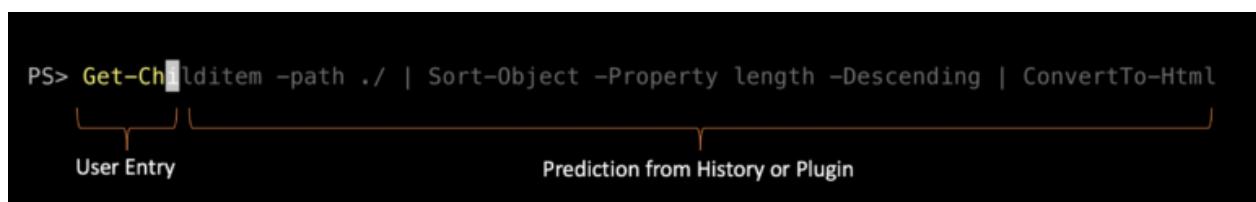

Using predictors in PSReadLine

Article • 01/11/2024

PSReadLine 2.1.0 introduced the **Predictive IntelliSense** feature. Predictive IntelliSense provides suggestions for full commands based on items from your **PSReadLine** history. PSReadLine 2.2.2 extends the power of Predictive IntelliSense by adding support for plug-in modules that use advanced logic to provide suggestions for full commands. The latest version, **PSReadLine** 2.2.6, enables predictions by default.

Using Predictive IntelliSense

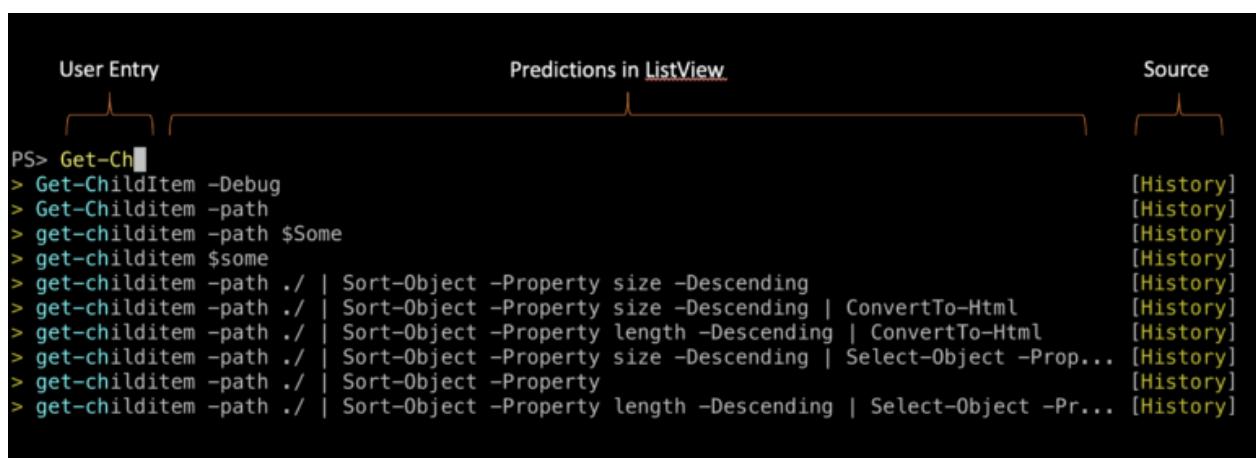

When Predictive IntelliSense is enabled, the prediction suggestion appears as colored text following the user's cursor. The suggestions from Predictive IntelliSense help new and experienced users of PowerShell discover, edit, and execute full commands based on matching predictions. Suggestions can come from the user's history and additional domain specific plugins.

A screenshot of a PowerShell window. The command entered is "PS> Get-Ch~~ilditem~~ -path ./ | Sort-Object -Property length -Descending | ConvertTo-Html". A red bracket labeled "User Entry" covers the part of the command before the cursor. A blue bracket labeled "Prediction from History or Plugin" covers the part of the command after the cursor, specifically the word "ilditem".

The previous image shows the default `InlineView` of the suggestion. Pressing `RightArrow` key accepts an inline suggestion. After accepting the suggestion, you can edit the command line before hitting `Enter` to run the command.

PSReadLine also offers a `ListView` presentation of the suggestions.

A screenshot of a PowerShell window showing the `ListView` view of Predictive IntelliSense. The command entered is "PS> Get-Ch~~ilditem~~". Below it, a list of suggestions is shown in a table:

User Entry	Predictions in <code>ListView</code>	Source
Get-Ch ilditem	Get-ChildItem -Debug	[History]
	Get-ChildItem -path	[History]
	get-childitem -path \$Some	[History]
	get-childitem \$some	[History]
	get-childitem -path ./ Sort-Object -Property size -Descending	[History]
	get-childitem -path ./ Sort-Object -Property size -Descending ConvertTo-Html	[History]
	get-childitem -path ./ Sort-Object -Property length -Descending ConvertTo-Html	[History]
	get-childitem -path ./ Sort-Object -Property size -Descending Select-Object -Prop...	[History]
	get-childitem -path ./ Sort-Object -Property	[History]
	get-childitem -path ./ Sort-Object -Property length -Descending Select-Object -Pr...	[History]

When in the list view, you can use the arrow keys to scroll through the available suggestions. List view also shows the source of the prediction.

`PSReadLine` defaults to `InlineView`. You can switch between `InlineView` and `ListView` by pressing the `F2` key. You can also use the `PredictionViewStyle` parameter of `Set-PSReadLineOption` to change the view.

Managing Predictive IntelliSense

To use Predictive IntelliSense you must have a newer version of `PSReadLine` installed. For best results, install the latest version of the module.

To install `PSReadLine` using `PowerShellGet`:

```
PowerShell  
  
Install-Module -Name PSReadLine
```

Or install using the new `PowerShellGet v3` module:

```
PowerShell  
  
Install-PSResource -Name PSReadLine
```

`PSReadLine` can be installed in Windows PowerShell 5.1 or in PowerShell 7 or higher. To use predictor plug-ins you must be running in PowerShell 7.2 or higher. Windows PowerShell 5.1 can use the history-based predictor.

In `PSReadLine` 2.2.6, Predictive IntelliSense is enabled by default depending on the following conditions:

- If Virtual Terminal (VT) is supported and `PSReadLine` running in PowerShell 7.2 or higher, `PredictionSource` is set to `HistoryAndPlugin`
- If VT is supported and `PSReadLine` running in PowerShell older than 7.2, `PredictionSource` is set to `History`
- If VT isn't supported, `PredictionSource` is set to `None`.

Use the following command to see the current setting:

```
PowerShell  
  
Get-PSReadLineOption | Select-Object -Property PredictionSource
```

You can change the prediction source using the `Set-PSReadLineOption` cmdlet with the `PredictionSource` parameter. The `PredictionSource` can be set to:

- `None`
- `History`
- `Plugin`
- `HistoryAndPlugin`

ⓘ Note

History-based predictions come from the history maintained by `PSReadLine`. That history is more comprehensive than the session-based history you can see using `Get-History`. For more information, see **Command history** section of [about_PSReadLine](#).

Setting the prediction color

By default, predictions appear in light grey text on the same line the user is typing. To support accessibility needs, you can customize the prediction color. Colors are defined using ANSI escape sequences. You can use `$PSStyle` to compose ANSI escape sequences.

PowerShell

```
Set-PSReadLineOption -Colors @{ InlinePrediction = $PSStyle.Background.Blue }
```

Or you can create your own. The default light-grey prediction text color can be restored using the following ANSI escape sequence.

PowerShell

```
Set-PSReadLineOption -Colors @{ InlinePrediction = "`e[38;5;238m" }
```

For more information about setting prediction color and other `PSReadLine` settings, see [Set-PSReadLineOption](#).

Changing keybindings

`PSReadLine` contains functions to navigate and accept predictions. For example:

- `AcceptSuggestion` - Accept the current inline suggestion
- `AcceptNextSuggestionWord` - Accept the next word of the inline suggestion

- `AcceptSuggestion` is built within `ForwardChar`, which is bound to `RightArrow` by default
- `AcceptNextSuggestionWord` is built within the function `ForwardWord`, which can be bound to `Ctrl + f`

You can use the `Set-PSReadLineKeyHandler` cmdlet to change key bindings.

PowerShell

```
Set-PSReadLineKeyHandler -Chord "Ctrl+f" -Function ForwardWord
```

With this binding, pressing `Ctrl + f` accepts the next word of an inline suggestion when the cursor is at the end of current editing line. You can bind other keys to `AcceptSuggestion` and `AcceptNextSuggestionWord` for similar functionalities. For example, you may want to make `RightArrow` accept the next word of the inline suggestion, instead of the whole suggestion line.

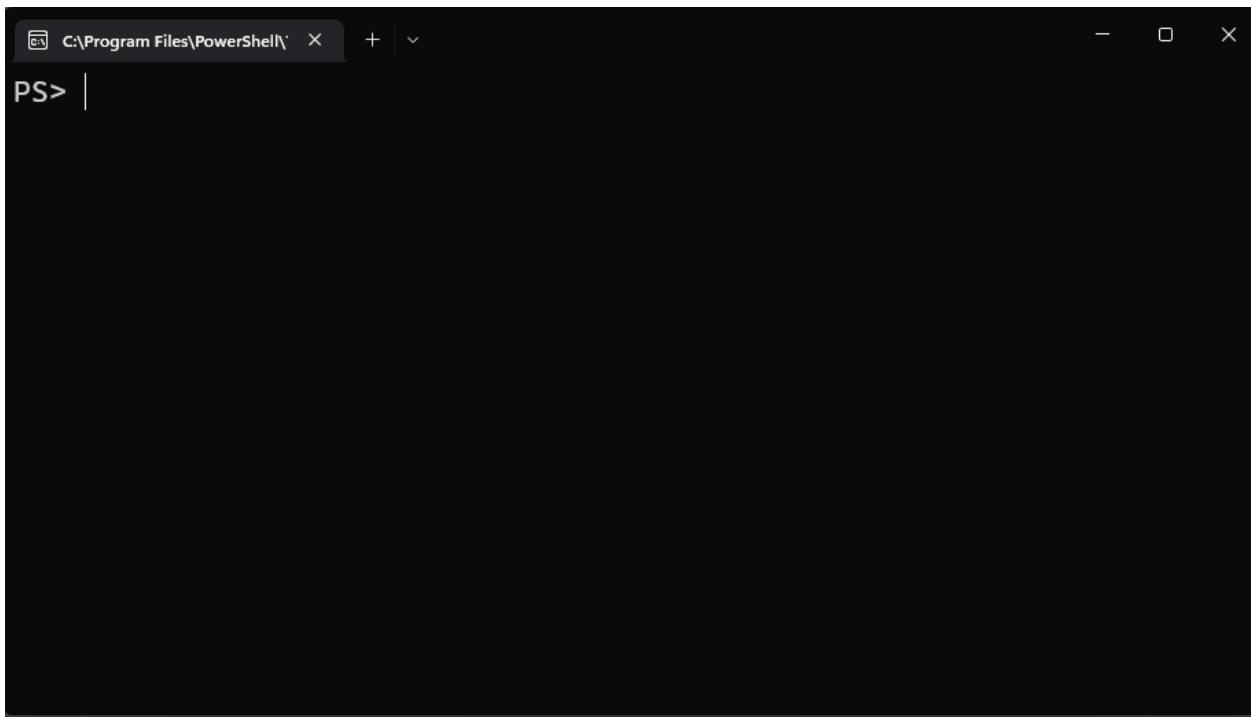

PowerShell

```
Set-PSReadLineKeyHandler -Chord "RightArrow" -Function ForwardWord
```

Using other predictor plug-ins

The `Az.Tools.Predictor` module was the first plug-in for Predictive IntelliSense. It uses Machine Learning to predict what Azure PowerShell command you want to run and the parameters you want to use. For more information and installation instructions, see [Announcing General Availability of Az.Tools.Predictor](#).

The `CompletionPredictor` module adds an IntelliSense experience for anything that can be tab-completed in PowerShell. With `PSReadLine` set to `InlineView`, you get the normal tab completion experience. When you switch to `ListView`, you get the IntelliSense experience. You can install the [CompletionPredictor](#) module from the PowerShell Gallery.

As previously noted, `ListView` shows you the source of the prediction. If you have multiple plug-ins installed the predictions are grouped by source with `History` listed first followed by each plug-in in the order that they were loaded.

Creating your own predictor module

You can write your own predictor using C# to create a compiled PowerShell module. The module must implement the

`System.Management.Automation.Subsystem.Prediction.ICommandPredictor` interface. This interface declares the methods used to query for prediction results and provide feedback.

For more information, see [How to create a command-line predictor](#).

Using dynamic help

Article • 03/27/2023

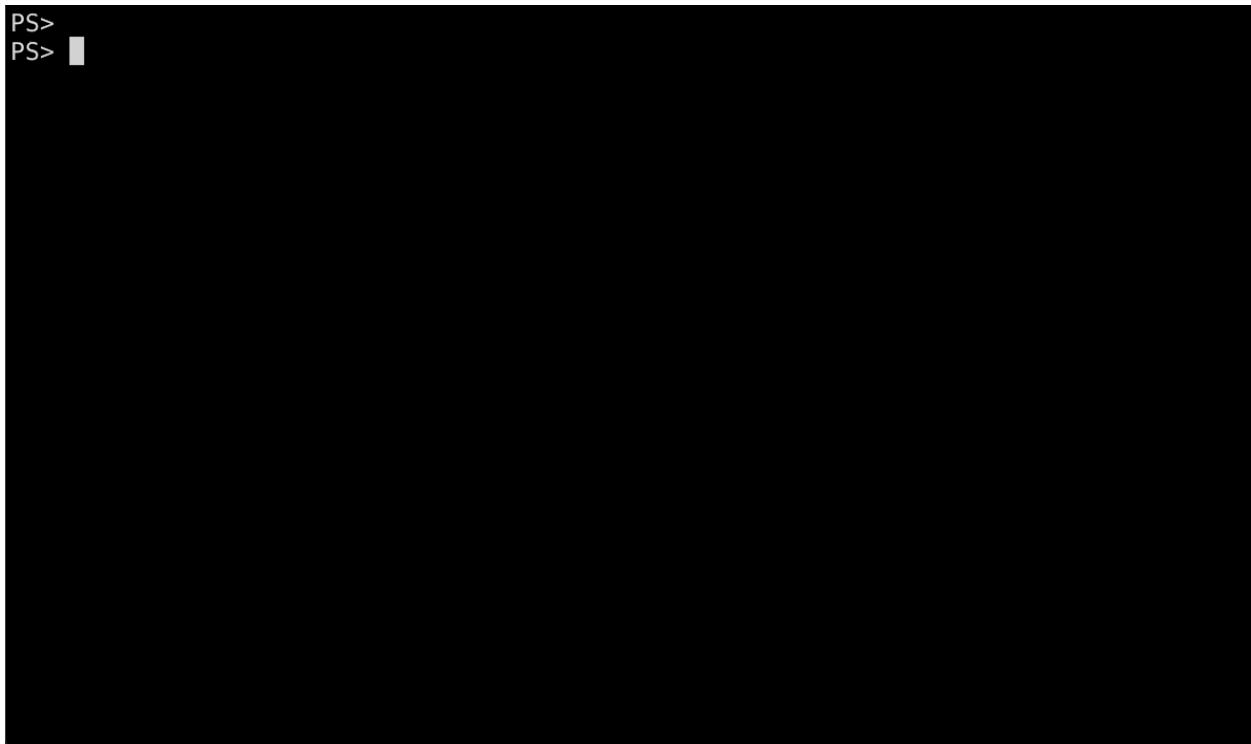

Dynamic Help provides just-in-time help that allows you to stay focused on your work without losing your place typing on the command line.

Getting cmdlet help

Dynamic Help provides a view of full cmdlet help shown in an alternative screen buffer.

PSReadLine maps the function `ShowCommandHelp` to the `F1` key.

- When the cursor is at the end of a fully expanded cmdlet name, pressing `F1` displays the help for that cmdlet.
- When the cursor is at the end of a fully expanded parameter name, pressing `F1` displays the help for the cmdlet beginning at the parameter.

The pager in **PSReadLine** allows you to scroll the displayed help using the up and down arrow keys. Pressing `Q` exits the alternative screen buffer and returns to the current cursor position on the command line on the primary screen.

Getting focused parameter help

Pressing `Alt + H` provides dynamic help for parameters. The help is shown below the current command line similar to [MenuComplete](#). The cursor must be at the end of the

fully expanded parameter name when you press the `Alt + h` key.

```
PS>
PS> Get-ChildItem -path█
-Path <System.String[]>

DESC: Specifies a path to one or more locations. Wildcards are accepted. The default
location is the current directory ('.').
Required: false, Position: 0, Default Value: Current directory, Pipeline Input: True
(ByPropertyName, ByValue), WildCard: true
```

Selecting arguments on the command line

To quickly select and edit the arguments of a cmdlet without disturbing your syntax using `Alt + a`. Based on the cursor position, it searches from the current cursor position and stops when it finds any arguments on the command line.

```
PS>
PS> get-childitem -path ./ | Sort-Object -Property length -Descending | format-table
-AutoSize█
```

Choosing keybindings

Not all keybindings work for all operating systems and terminal applications. For example, keybindings for the `Alt` key don't work on macOS by default. On Linux, `Ctrl + [` is the same as `Escape`. And `Ctrl + Spacebar` generates a `Control + 2` key sequence instead of the `Control + Spacebar` sequence expected.

To work around these quirks, map the PSReadLine function to an available key combination. For example:

```
Set-PSReadLineKeyHandler -Chord 'Ctrl+l' -Function ShowParameterHelp  
Set-PSReadLineKeyHandler -Chord 'Ctrl+k' -Function SelectCommandArgument
```

For more information about keybindings and workarounds, see [Using PSReadLine key handlers](#).

Using aliases

Article • 07/23/2024

An alias is an alternate name or shorthand name for a cmdlet or for a command element, such as a function, script, file, or executable file. You can run the command using the alias instead of the executable name.

Managing command aliases

PowerShell provides cmdlets for managing command aliases. The following command shows the cmdlets that manage aliases.

PowerShell

```
Get-Command -Noun Alias
```

Output

CommandType	Name	Version	Source
Cmdlet	Export-Alias	7.0.0.0	Microsoft.PowerShell.Utility
Cmdlet	Get-Alias	7.0.0.0	Microsoft.PowerShell.Utility
Cmdlet	Import-Alias	7.0.0.0	Microsoft.PowerShell.Utility
Cmdlet	New-Alias	7.0.0.0	Microsoft.PowerShell.Utility
Cmdlet	Remove-Alias	7.0.0.0	Microsoft.PowerShell.Utility
Cmdlet	Set-Alias	7.0.0.0	Microsoft.PowerShell.Utility

For more information, see [about_Aliases](#).

Use the [Get-Alias](#) cmdlet to list the aliases available in your environment. To list the aliases for a single cmdlet, use the **Definition** parameter and specify the executable name.

PowerShell

```
Get-Alias -Definition Get-ChildItem
```

Output

CommandType	Name
Alias	dir -> Get-ChildItem
Alias	gci -> Get-ChildItem
Alias	ls -> Get-ChildItem

To get the definition of a single alias, use the `Name` parameter.

PowerShell

```
Get-Alias -Name gci
```

Output

CommandType	Name
Alias	gci -> Get-ChildItem

To create an alias, use the `Set-Alias` command. You can create aliases for cmdlets, functions, scripts, and native executables files.

PowerShell

```
Set-Alias -Name np -Value Notepad.exe
Set-Alias -Name cmpo -Value Compare-Object
```

Compatibility aliases in Windows

PowerShell has several aliases that allow **Unix** and `cmd.exe` users to use familiar commands in Windows. The following table show common commands, the related PowerShell cmdlet, and the PowerShell alias:

[] Expand table

Windows Command Shell	Unix command	PowerShell cmdlet	PowerShell alias
<code>cd</code> , <code>chdir</code>	<code>cd</code>	<code>Set-Location</code>	<code>sl</code> , <code>cd</code> , <code>chdir</code>
<code>cls</code>	<code>clear</code>	<code>Clear-Host</code>	<code>cls</code> <code>clear</code>
<code>copy</code>	<code>cp</code>	<code>Copy-Item</code>	<code>cpi</code> , <code>cp</code> , <code>copy</code>
<code>del</code> , <code>erase</code> , <code>rd</code> , <code>rmdir</code>	<code>rm</code>	<code>Remove-Item</code>	<code>ri</code> , <code>del</code> , <code>erase</code> , <code>rd</code> , <code>rm</code> , <code>rmdir</code>
<code>dir</code>	<code>ls</code>	<code>Get-ChildItem</code>	<code>gci</code> , <code>dir</code> , <code>ls</code>
<code>echo</code>	<code>echo</code>	<code>Write-Output</code>	<code>write</code> <code>echo</code>
<code>md</code>	<code>mkdir</code>	<code>New-Item</code>	<code>ni</code>
<code>move</code>	<code>mv</code>	<code>Move-Item</code>	<code>mi</code> , <code>move</code> , <code>mi</code>

Windows Command Shell	Unix command	PowerShell cmdlet	PowerShell alias
popd	popd	Pop-Location	popd
	pwd	Get-Location	gl, pwd
pushd	pushd	Push-Location	pushd
ren	mv	Rename-Item	rni, ren
type	cat	Get-Content	gc, cat, type

! Note

The aliases in this table are Windows-specific. Some aliases aren't available on other platforms. This is to allow the native command to work in a PowerShell session. For example, `ls` isn't defined as a PowerShell alias on macOS or Linux so that the native command is run instead of `Get-ChildItem`.

Creating alternate names for commands with parameters

You can assign an alias to a cmdlet, script, function, or executable file. Unlike some Unix shells, you cannot assign an alias to a command with parameters. For example, you can assign an alias to the `Get-EventLog` cmdlet, but you cannot assign an alias to the `Get-EventLog -LogName System` command. You must create a function that contains the command with parameters.

For more information, see [about_Aliases](#).

Parameter aliases and shorthand names

PowerShell also provides ways to create shorthand names for parameters. Parameter aliases are defined using the `Alias` attribute when you declare the parameter. These can't be defined using the `*-Alias` cmdlets.

For more information, see the [Alias attribute](#) documentation.

In addition to parameter aliases, PowerShell lets you specify the parameter name using the fewest characters needed to uniquely identify the parameter. For example, the `Get-ChildItem` cmdlet has the `Recurse` and `ReadOnly` parameters. To uniquely identify the `Recurse` parameter

you only need to provide `-Rec`. If you combine that with the command alias, `Get-ChildItem -Recurse` can be shortened to `dir -Rec`.

Don't use aliases in scripts

Aliases are a convenience feature to be used interactively in the shell. You should always use the full command and parameter names in your scripts.

- Aliases can be deleted or redefined in a profile script
- Any aliases you define may not be available to the user of your scripts
- Aliases make your code harder to read and maintain

Customizing your shell environment

Article • 02/26/2025

A PowerShell profile is a script that runs when PowerShell starts. You can use the profile to customize the environment. You can:

- Add aliases, functions, and variables
- Load modules
- Create PowerShell drives
- Run arbitrary commands
- Change preference settings

Putting these settings in your profile ensures that they're available whenever you start PowerShell on your system.

ⓘ Note

To run scripts in Windows, the PowerShell execution policy needs to be set to `RemoteSigned` at a minimum. Execution policies don't apply to macOS and Linux. For more information, see [about_Execution_Policy](#).

The `$PROFILE` variable

The `$PROFILE` automatic variable stores the paths to the PowerShell profiles that are available in the current session.

There are four possible profiles available to support different user scopes and different PowerShell hosts. The fully qualified paths for each profile script are stored in the following member properties of `$PROFILE`.

- `AllUsersAllHosts`
- `AllUsersCurrentHost`
- `CurrentUserAllHosts`
- `CurrentUserCurrentHost`

You can create profile scripts that run for all users or just one user, the `CurrentUser`.

`CurrentUser` profiles are stored under the user's home directory path. The location varies depending on the operating system and the version of PowerShell you use.

By default, referencing the `$PROFILE` variable returns the path to the "Current User, Current Host" profile. The other profiles path can be accessed through the properties of

the `$PROFILE` variable. The following command shows the default profile locations on Windows.

PowerShell

```
PS> $PROFILE | Select-Object *
AllUsersAllHosts      : C:\Program Files\PowerShell\7\profile.ps1
AllUsersCurrentHost   : C:\Program
Files\PowerShell\7\Microsoft.PowerShell_profile.ps1
CurrentUserAllHosts    : C:\Users\username\Documents\PowerShell\profile.ps1
CurrentUserCurrentHost :
C:\Users\username\Documents\PowerShell\Microsoft.PowerShell_profile.ps1
Length                : 69
```

The following command shows the default profile locations on Ubuntu Linux.

PowerShell

```
$PROFILE | Select-Object *
AllUsersAllHosts      : /opt/microsoft/powershell/7/profile.ps1
AllUsersCurrentHost   :
/opt/microsoft/powershell/7/Microsoft.PowerShell_profile.ps1
CurrentUserAllHosts    : /home/username/.config/powershell/profile.ps1
CurrentUserCurrentHost :
/home/username/.config/powershell/Microsoft.PowerShell_profile.ps1
Length                : 67
```

There are also profiles that run for all PowerShell hosts or specific hosts. The profile script for each PowerShell host has a name unique for that host. For example, the filename for the standard Console Host on Windows or the default terminal application on other platforms is `Microsoft.PowerShell_profile.ps1`. For Visual Studio Code (VS Code), the filename is `Microsoft.VSCode_profile.ps1`.

For more information, see [about_Profiles](#).

How to create your personal profile

When you first install PowerShell on a system, the profile script files and the directories they belong to don't exist. The following command creates the "Current User, Current Host" profile script file if it doesn't exist.

PowerShell

```
if (!(Test-Path -Path $PROFILE)) {
  New-Item -ItemType File -Path $PROFILE -Force
```

```
}
```

The **Force** parameter of `New-Item` cmdlet creates the necessary folders when they don't exist. After you create the script file, you can use your favorite editor to customize your shell environment.

Adding customizations to your profile

The previous articles talked about using [tab completion](#), [command predictors](#), and [aliases](#). These articles showed the commands used to load the required modules, create custom completers, define key bindings, and other settings. These are the kinds of customizations that you want to have available in every PowerShell interactive session. The profile script is the place for these settings.

The simplest way to edit your profile script is to open the file in your favorite code editor. For example, the following command opens the profile in [VS Code](#).

```
PowerShell
```

```
code $PROFILE
```

You could also use `notepad.exe` on Windows, `vi` on Linux, or any other text editor.

The following profile script has examples for many of the customizations mentioned in the previous articles. You can use any of these settings in your own profile.

```
PowerShell
```

```
## Map PSDrives to other registry hives
if (!(Test-Path HKCR:)) {
    $null = New-PSDrive -Name HKCR -PSProvider Registry -Root HKEY_CLASSES_ROOT
    $null = New-PSDrive -Name HKU -PSProvider Registry -Root HKEY_USERS
}

## Customize the prompt
function prompt {
    $identity = [Security.Principal.WindowsIdentity]::GetCurrent()
    $principal = [Security.Principal.WindowsPrincipal] $identity
    $adminRole = [Security.Principal.WindowsBuiltInRole]::Administrator

    $prefix = if (Test-Path Variable:/PSDebugContext) { '[DBG]: ' } else {
        ''
    }
    if ($principal.IsInRole($adminRole)) {
        $prefix = "[ADMIN]:$prefix"
    }
}
```

```

$body = 'PS ' + $PWD.path
$suffix = $($if ($NestedPromptLevel -ge 1) { '>>' }) + '> '
"${prefix}${body}${suffix}"
}

## Create $PSSStyle if running on a version older than 7.2
## - Add other ANSI color definitions as needed

if ($PSVersionTable.PSVersion.ToString() -lt '7.2.0') {
    # define escape char since ``e`` may not be supported
    $esc = [char]0x1b
    $PSSStyle = [pscustomobject]@{
        Foreground = @{
            Magenta = "${esc}[35m"
            BrightYellow = "${esc}[93m"
        }
        Background = @{
            BrightBlack = "${esc}[100m"
        }
    }
}

## Set PSReadLine options and keybindings
$PSROptions = @{
    ContinuationPrompt = ' '
    Colors = @{
        Operator = $PSSStyle.Foreground.Magenta
        Parameter = $PSSStyle.Foreground.Magenta
        Selection = $PSSStyle.Background.BrightBlack
        InLinePrediction = $PSSStyle.Foreground.BrightYellow +
$PSSStyle.Background.BrightBlack
    }
}
Set-PSReadLineOption @PSROptions
Set-PSReadLineKeyHandler -Chord 'Ctrl+f' -Function ForwardWord
Set-PSReadLineKeyHandler -Chord 'Enter' -Function ValidateAndAcceptLine

## Add argument completer for the dotnet CLI tool
$scriptblock = {
    param($wordToComplete, $commandAst, $cursorPosition)
    dotnet complete --position $cursorPosition $commandAst.ToString() |
    ForEach-Object {
        [System.Management.Automation.CompletionResult]::new($_, $_,
'ParameterValue', $_)
    }
}
Register-ArgumentCompleter -Native -CommandName dotnet -ScriptBlock
$scriptblock

```

This profile script provides examples for the following customization:

- Adds two new **PSDrives** for the other root registry hives.
- Creates a **customized prompt** that changes if you're running in an elevated session.

- Configures **PSReadLine** and adds key binding. The color settings use the **\$PSSStyle** feature to define the ANSI color settings.
- Adds tab completion for the **dotnet CLI** tool. The tool provides parameters to help resolve the command-line arguments. The script block for **Register-ArgumentCompleter** uses that feature to provide the tab completion.

Using PSReadLine key handlers

Article • 03/29/2023

The **PSReadLine** module provides key handlers that map **PSReadLine** functions to keyboard chords. Keyboard chords are a sequence of one or more keystrokes that are pressed at the same time. For example, the chord `Ctrl + Spacebar` is the combination of the `Ctrl` and `Spacebar` keys pressed at the same time. A **PSReadLine** function is a predefined action that can be performed on a command line. For example, the `MenuComplete` function allows you to choose from a list of options from a menu complete the input on the command line.

PSReadLine has several predefined key handlers that are bound by default. You can also define your own custom key handlers. Run the following command to list the key handlers that are currently defined.

```
PowerShell
```

```
Get-PSReadLineKeyHandler
```

You can also get a list of all unbound **PSReadLine** functions that are available to be bound to a key chord.

```
PowerShell
```

```
Get-PSReadLineKeyHandler -Unbound
```

You can use the `Set-PSReadLineKeyHandler` cmdlet to bind a function to a key handler. The following command binds the `MenuComplete` function to the chord `Ctrl + Spacebar`.

```
PowerShell
```

```
Set-PSReadLineKeyHandler -Chord 'Ctrl+Spacebar' -Function MenuComplete
```

Finding key names and chord bindings

The names of the keys in the chord are defined by the `[System.ConsoleKey]` enumeration. For more information, see [System.ConsoleKey](#) documentation. For example, the name of the `2` key in `[System.ConsoleKey]` is `D2`, whereas the name of the `2` key on the numeric keypad is `NumPad2`. You can use the `[System.Console]::ReadKey()` method to find the name of the key you pressed.

PowerShell

```
[System.Console]::ReadKey()
```

The following output shows the information returned by the `ReadKey()` method for the `Ctrl+2` key chord.

Output

KeyChar	Key	Modifiers
	D2	Control

For the **PSReadLine** key handler cmdlets, this chord is represented as `Ctrl+D2`. The following example binds this chord to a function.

PowerShell

```
Set-PSReadLineKeyHandler -Chord 'Ctrl+D2' -Function MenuComplete
```

You can bind multiple chords to a single function. By default, the `BackwardDeleteChar` function is bound to two chords.

PowerShell

```
Get-PSReadLineKeyHandler -Chord Backspace, Ctrl+h
```

Output

Key	Function	Description
Backspace	BackwardDeleteChar	Delete the character before the cursor
Ctrl+h	BackwardDeleteChar	Delete the character before the cursor

① Note

The **Chord** parameter is **case-sensitive**. Meaning, you can create different bindings for `Ctrl+x` and `Ctrl+X`.

On Windows, you can also use the `Alt+?` key chord to show the function bound to the next key chord you enter. When you type `Alt+?` you see the following prompt:

Output

what-is-key:

When you hit the `Backspace` key you get the following response:

Output

Backspace: BackwardDeleteChar - Delete the character before the cursor

Key handlers on non-Windows computers

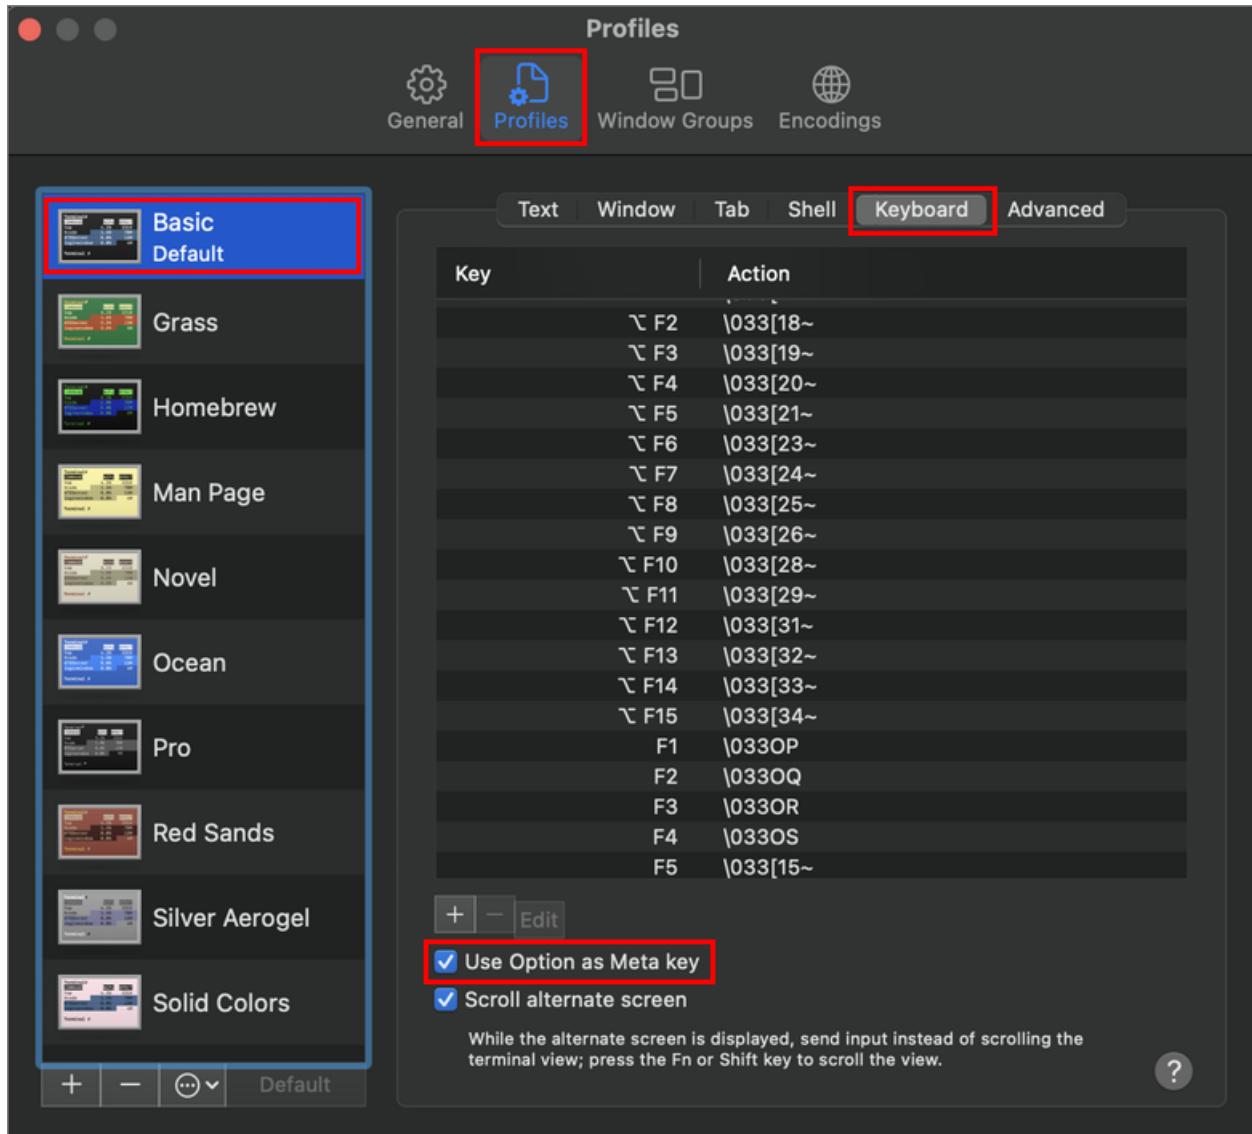

The key codes generated by your keyboard can be different depending on the operating system and terminal application you are using.

macOS

The Macintosh keyboard doesn't have an `Alt` key like Windows and Linux systems. Instead, it has the `⌥ Option` key. macOS uses this key differently than the `Alt` key on other systems. However, you can configure the terminal and iTerm2 applications on macOS to treat it as an `Alt` key.

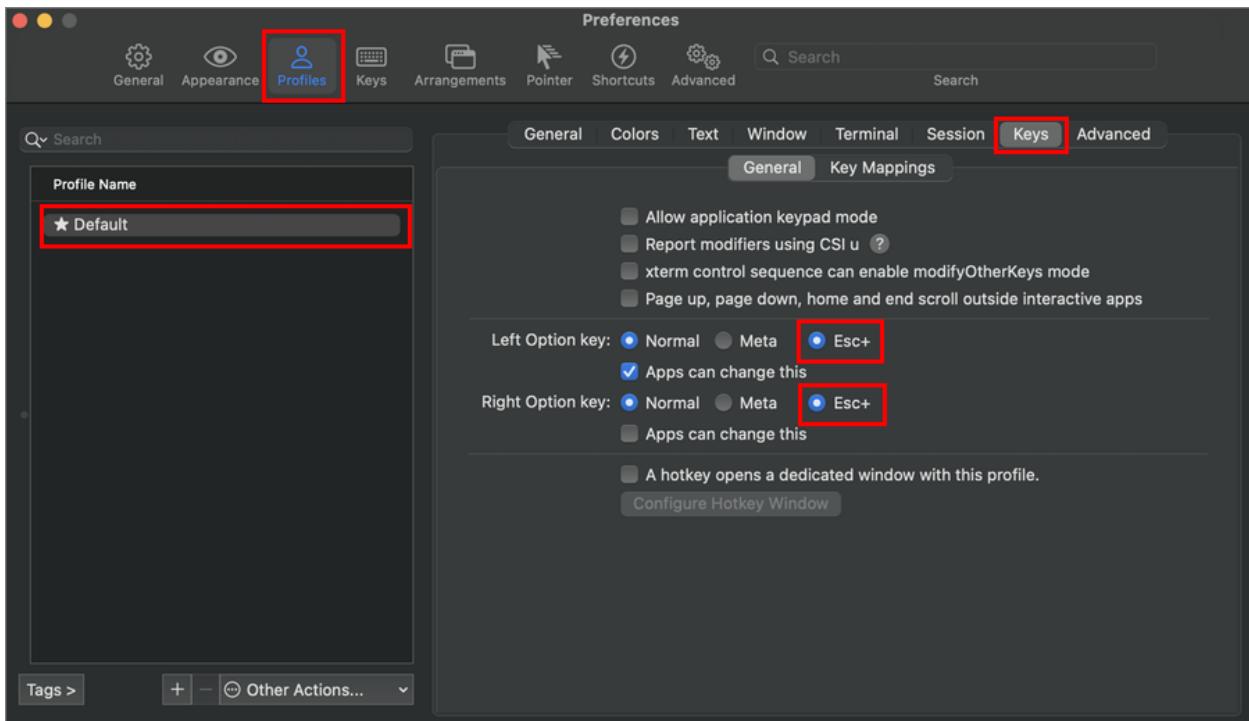

Configuring the Terminal application

Open the **Settings** window from the App bar in Terminal.app. Select **Profiles** and choose the profile you want to configure. Select the **Keyboard** tab of the configuration options. Below the list of keys, select the **Use Option as Meta Key** setting. This setting allows the `⌥ Option` key to act as `Alt` in the Terminal application.

Configuring the iTerm2 application

Open the **Settings** window from the App Bar in iTerm.app. Select **Profiles** and choose the profile you want to configure. Select the **Keys** tab of the configuration options. Select the **Esc+ option** for both the **Left Option Key** and **Right Option Key** settings. This setting allows the **Option** key to act as **Alt** in the iTerm application.

ⓘ Note

The exact steps may vary depending on the versions of macOS and the terminal applications. These examples were captured on macOS Ventura 13.2.1 and iTerm2 v3.4.16.

Linux

On Linux platforms, the key code generated can be different than other systems. For example:

- `Ctrl`+`[` is the same as `Escape`
- `Ctrl`+`Spacebar` generates the key codes for `Ctrl`+`D2`. If you want to map a function `Ctrl`+`Spacebar` you must use the chord `Ctrl+D2`.

PowerShell

```
Set-PSReadLineKeyHandler -Chord 'Ctrl+D2' -Function MenuComplete
```

Use the `.ReadKey()` method to verify the key codes generated by your keyboard.

Commonly used key handlers

Here are a few commonly used key handlers that are bound by default on Windows. Note that the key binding may be different on non-Windows platforms.

MenuComplete

Complete the input by selecting from a menu of possible completion values.

Default chord: `Ctrl+Spacebar`

The following example shows the menu of possible completions for commands beginning with `select`.

```
Output

PS C:\> select<Ctrl+Spacebar>
select          Select-Object          Select-PSFPropertyValue
Select-Xml
Select-AzContext   Select-PSFConfig      Select-PSMDBuildProject
Select-AzSubscription  Select-PSFObject     Select-String

Select-Object
```

Use the arrow keys to select the completion you want. Press the `Enter` key to complete the input. As you move through the selections, help for the selected command is displayed below the menu.

ClearScreen

This function clears the screen similar to the `cls` or `clear` commands.

Default chord: `Ctrl+l`

SelectCommandArgument

Selects the next argument on the command line.

Default chord: `Alt+a`

You may have command in your history that you want to run again with different parameter values. You can use the chord to cycle through each parameter and change the value as needed.

```
New-AzVM -ResourceGroupName myRGName -Location eastus -Name myVM
```

Pressing `Alt+a` selects the next parameter argument in turn: `myRGName`, `eastus`, `myVM`.

GotoBrace

Moves the cursor to the matching brace.

Default chord: `Ctrl+]`

This function moves your cursor to the closing brace that matches the brace at the current cursor position on the command line. The function works for brackets (`[]`), braces (`{}`), and parentheses, (`()`).

DigitArgument

Start or accumulate a numeric argument used to repeat a keystroke the specified number of times.

Default chord: `Alt+0` through `Alt+9`

For example, typing `Alt + 4 + #` enters `####` on the command line.

Configuring a light colored theme

Article • 03/07/2023

The default colors for both PowerShell and **PSReadLine** are selected for a dark background terminal. However, some users may choose to use a light background with dark text. Since most of the default colors don't set the background, using light foreground colors on a light background produces unreadable text.

PSReadLine allows you to define colors for 18 different syntax elements. You can view the current settings using the `Get-PSReadLineOption` cmdlet.

Output

```
EditMode : Windows
AddToHistoryHandler :
System.Func`2[System.String,System.Object]
HistoryNoDuplicates : True
HistorySavePath :
C:\Users\user1\AppData\Roaming\Microsoft\Wind...
HistorySaveStyle : SaveIncrementally
HistorySearchCaseSensitive : False
HistorySearchCursorMovesToEnd : False
MaximumHistoryCount : 4096
ContinuationPrompt : >>
ExtraPromptLineCount : 0
PromptText : {> }
BellStyle : Audible
DingDuration : 50
DingTone : 1221
CommandsToValidateScriptBlockArguments : {ForEach-Object, %, Invoke-Command, icm...}
CommandValidationHandler :
CompletionQueryItems : 100
MaximumKillRingCount : 10
ShowToolTips : True
ViModeIndicator : None
WordDelimiters : ;:,.[]{}()\/|^\&*-+='"--_
AnsiEscapeTimeout : 100
PredictionSource : HistoryAndPlugin
PredictionViewStyle : InlineView
CommandColor : ``e[93m"
CommentColor : ``e[32m"
ContinuationPromptColor : ``e[37m"
DefaultTokenColor : ``e[37m"
EmphasisColor : ``e[96m"
ErrorColor : ``e[91m"
InlinePredictionColor : ``e[38;5;238m"
KeywordColor : ``e[92m"
ListPredictionColor : ``e[33m"
ListPredictionSelectedColor : ``e[48;5;238m"
```

```

MemberColor           : ``e[97m"
NumberColor          : ``e[97m"
OperatorColor        : ``e[90m"
ParameterColor       : ``e[90m"
SelectionColor       : ``e[30;47m"
StringColor          : ``e[36m"
TypeColor            : ``e[37m"
VariableColor        : ``e[92m"

```

The color settings are stored as strings containing ANSI escape sequences that change the color in your terminal. Using the `Set-PSReadLineOption` cmdlet you can change the colors to values that work better for a light-colored background.

Defining colors for a light theme

The PowerShell ISE can be configured to use a light theme for both the editor and console panes. You can also view and change the colors that the ISE uses for various syntax and output types. You can use these color choices to define a similar theme for `PSReadLine`.

The following hashtable defines colors for `PSReadLine` that mimic the colors in the PowerShell ISE.

PowerShell

```

$ISETheme = @{
    Command           = $PSStyle.Foreground.FromRGB(0x0000FF)
    Comment          = $PSStyle.Foreground.FromRGB(0x006400)
    ContinuationPrompt = $PSStyle.Foreground.FromRGB(0x0000FF)
    Default          = $PSStyle.Foreground.FromRGB(0x0000FF)
    Emphasis          = $PSStyle.Foreground.FromRGB(0x287BF0)
    Error             = $PSStyle.Foreground.FromRGB(0xE50000)
    InlinePrediction = $PSStyle.Foreground.FromRGB(0x93A1A1)
    Keyword           = $PSStyle.Foreground.FromRGB(0x00008b)
    ListPrediction   = $PSStyle.Foreground.FromRGB(0x06DE00)
    Member            = $PSStyle.Foreground.FromRGB(0x000000)
    Number            = $PSStyle.Foreground.FromRGB(0x800080)
    Operator           = $PSStyle.Foreground.FromRGB(0x757575)
    Parameter          = $PSStyle.Foreground.FromRGB(0x000080)
    String             = $PSStyle.Foreground.FromRGB(0x8b0000)
    Type               = $PSStyle.Foreground.FromRGB(0x008080)
    Variable           = $PSStyle.Foreground.FromRGB(0xff4500)
    ListPredictionSelected = $PSStyle.Background.FromRGB(0x93A1A1)
    Selection          = $PSStyle.Background.FromRGB(0x00BFFF)
}

```

 Note

In PowerShell 7.2 and higher you can use the `FromRGB()` method of `$PSSStyle` to create the ANSI escape sequences for the colors you want.

For more information about `$PSSStyle`, see [about_ANSI_Terminals](#).

For more information about ANSI escape sequences, see the [ANSI escape code](#) article in Wikipedia.

Setting the color theme in your profile

To have the color settings you want in every PowerShell session, you must add the configuration settings to your PowerShell profile script. For an example, see [Customizing your shell environment](#)

Add the `$ISETheme` variable and the following `Set-PSReadLineOption` command to your profile.

```
PowerShell
```

```
Set-PSReadLineOption -Colors $ISETheme
```

Beginning in PowerShell 7.2, PowerShell adds colorized output to the default console experience. The colors used are defined in the `$PSSStyle` variable and are designed for a dark background. The following settings work better for a light background terminal.

```
PowerShell
```

```
$PSSStyle.Formatting.FormatAccent      = ``e[32m"
$PSSStyle.Formatting.TableHeader       = ``e[32m"
$PSSStyle.Formatting.ErrorAccent       = ``e[36m"
$PSSStyle.Formatting.Error            = ``e[31m"
$PSSStyle.Formatting.Warning          = ``e[33m"
$PSSStyle.Formatting.Verbose          = ``e[33m"
$PSSStyle.Formatting.Debug             = ``e[33m"
$PSSStyle.Progress.Style              = ``e[33m"
$PSSStyle.FileInfo.Directory          =
$PSSStyle.Background.FromRgb(0x2f6aff) +
                                         $PSSStyle.Foreground.BrightWhite
$PSSStyle.FileInfo.SymbolicLink        = ``e[36m"
$PSSStyle.FileInfo.Executable          = ``e[95m"
$PSSStyle.FileInfo.Extension['.ps1']   = ``e[36m"
$PSSStyle.FileInfo.Extension['.ps1xml'] = ``e[36m"
$PSSStyle.FileInfo.Extension['.psd1']   = ``e[36m"
$PSSStyle.FileInfo.Extension['.psm1']   = ``e[36m"
```

Choosing colors for accessibility

The ISE color theme may not work for users with color-blindness or other conditions that limit their ability to see colors.

The [World Wide Web Consortium \(W3C\)](#) has recommendations for using colors for accessibility. The Web Content Accessibility Guidelines (WCAG) 2.1 recommends that "visual presentation of text and images of text has a contrast ratio of at least 4.5:1." For more information, see [Success Criterion 1.4.3 Contrast \(Minimum\)](#).

The [Contrast Ratio](#) website provides a tool that lets you pick foreground and background colors and measure the contrast. You can use this tool to find color combinations that work best for you.

Improve the accessibility of output in PowerShell

Article • 09/12/2024

Most terminal environments only display raw text. Users that rely on screen readers are faced with tedious narration when consuming large amounts of raw text because the raw output doesn't have the accessibility metadata to characterize the format of the content.

There are two ways to improve the accessibility of the output in PowerShell:

- Output the data in a way that it can be viewed in another tool that supports screen reading technologies.
- Reduce the amount of output displayed in the terminal by filtering and selecting the data you want and output the text in a more readable format.

Display the data in a tool outside of the terminal

For large amounts of data, rather than output to the host, consider writing output in a format that can be viewed in another tool that supports screen reading technologies. You might need to save the data to a file in a format that can be opened in another application.

Out-GridView command on Windows

For small to moderate size output, use the `Out-GridView` command. The output is rendered using Windows Presentation Foundation (WPF) in tabular form, much like a spreadsheet. The GridView control allows you to sort, filter, and search the data, which reduces the amount of data that needs to be read. The GridView control is also accessible to screen readers. The **Narrator** tool built into Windows is able to read the GridView details, including column names and row count.

The following example shows how to display a list of services in a GridView control.

PowerShell

```
Get-Service | Out-GridView
```

The `Out-GridView` command is only available in PowerShell on Windows.

Character Separated Value (CSV) format

Spreadsheet applications such as **Microsoft Excel** support CSV files. The following example shows how to save the output of a command to a CSV file.

PowerShell

```
Get-Service | Export-Csv -Path .\myFile.csv  
Invoke-Item .\myFile.csv
```

The `Invoke-Item` command opens the file in the default application for CSV files, which is usually Microsoft Excel.

HyperText Markup Language (HTML) format

HTML files can be viewed by web browsers such as **Microsoft Edge**. The following example shows how to save the output of a command to an HTML file.

PowerShell

```
Get-Service | ConvertTo-HTML | Out-File .\myFile.html  
Invoke-Item .\myFile.html
```

The `Invoke-Item` command opens the file in your default web browser.

Reduce the amount of output

One way to improve the accessibility of the output is to reduce the amount of output displayed in the terminal. PowerShell has several commands that can help you filter and select the data you want.

Select and filter data

Rather than returning a large mount of data, use commands such as `Select-Object`, `Sort-Object`, and `Where-Object` to reduce the amount of output. The following example gets the list of services on the computer.

Each of the following commands improves the output in a different way:

- The `-ErrorAction SilentlyContinue` parameter suppresses error messages that might be generated if the user doesn't have permission to view some services.
- The `Where-Object` command reduces the number of items returned by filtering the list to only show services that are running and have `event` in the description.
- The `Select-Object` command selects only the service name and display name.
- The `Format-List` command displays the output in list format, which provides a better narration experience for screen readers.

PowerShell

```
Get-Service -ErrorAction SilentlyContinue |
    Where-Object {$_.Status -eq 'Running' -and $_.Description -match
    'event'} |
        Select-Object Name, DisplayName |
            Format-List
```

Reformat the output with calculated properties

The default property names of .NET objects output by PowerShell can be verbose and confusing. You can use calculated properties to change the property names and values to something easier to understand when read by a narrator technology.

The following example shows how to get the top five processes by memory usage and display the process name and memory usage in megabytes.

PowerShell

```
Get-Process |
    Sort-Object WorkingSet -Descending |
        Select-Object -First 5 -Property ProcessName,
            @{n="MemoryMB"; e={'{0:N2}' -f ($_.WorkingSet/1Mb)}} |
                Format-List
```

By default, `Get-Process` displays the `WorkingSet` as the number of bytes of memory used. Without formatting, it can be difficult to understand the magnitude of the number. The calculated property converts the number of bytes to megabytes and formats the number with commas and limits the value to two decimal places.

Output

```
ProcessName : vmmemWSL
MemoryMB   : 1,217.69

ProcessName : Memory Compression
MemoryMB   : 780.45
```

```
ProcessName : Code  
MemoryMB    : 726.43
```

```
ProcessName : OUTLOOK  
MemoryMB   : 460.16
```

```
ProcessName : msedgewebview2  
MemoryMB   : 428.94
```

Everything you wanted to know about arrays

Article • 06/20/2024

Arrays are a fundamental language feature of most programming languages. They're a collection of values or objects that are difficult to avoid. Let's take a close look at arrays and everything they have to offer.

ⓘ Note

The [original version](#) of this article appeared on the blog written by [@KevinMarquette](#). The PowerShell team thanks Kevin for sharing this content with us. Please check out his blog at [PowerShellExplained.com](#).

What is an array?

I'm going to start with a basic technical description of what arrays are and how they are used by most programming languages before I shift into the other ways PowerShell makes use of them.

An array is a data structure that serves as a collection of multiple items. You can iterate over the array or access individual items using an index. The array is created as a sequential chunk of memory where each value is stored right next to the other.

I'll touch on each of those details as we go.

Basic usage

Because arrays are such a basic feature of PowerShell, there is a simple syntax for working with them in PowerShell.

Create an array

An empty array can be created by using `@()`

PowerShell

```
PS> $data = @()
PS> $data.Count
```

We can create an array and seed it with values just by placing them in the `@()` parentheses.

PowerShell

```
PS> $data = @('Zero', 'One', 'Two', 'Three')
PS> $data.Count
4

PS> $data
Zero
One
Two
Three
```

This array has 4 items. When we call the `$data` variable, we see the list of our items. If it's an array of strings, then we get one line per string.

We can declare an array on multiple lines. The comma is optional in this case and generally left out.

PowerShell

```
$data = @(
    'Zero'
    'One'
    'Two'
    'Three'
)
```

I prefer to declare my arrays on multiple lines like that. Not only does it get easier to read when you have multiple items, it also makes it easier to compare to previous versions when using source control.

Other syntax

It's commonly understood that `@()` is the syntax for creating an array, but comma-separated lists work most of the time.

PowerShell

```
$data = 'Zero', 'One', 'Two', 'Three'
```

Write-Output to create arrays

One cool little trick worth mentioning is that you can use `Write-Output` to quickly create strings at the console.

```
PowerShell
```

```
$data = Write-Output Zero One Two Three
```

This is handy because you don't have to put quotes around the strings when the parameter accepts strings. I would never do this in a script but it's fair game in the console.

Accessing items

Now that you have an array with items in it, you may want to access and update those items.

Offset

To access individual items, we use the brackets `[]` with an offset value starting at 0. This is how we get the first item in our array:

```
PowerShell
```

```
PS> $data = 'Zero', 'One', 'Two', 'Three'  
PS> $data[0]  
Zero
```

The reason why we use zero here is because the first item is at the beginning of the list so we use an offset of 0 items to get to it. To get to the second item, we would need to use an offset of 1 to skip the first item.

```
PowerShell
```

```
PS> $data[1]  
One
```

This would mean that the last item is at offset 3.

```
PowerShell
```

```
PS> $data[3]
```

```
Three
```

Index

Now you can see why I picked the values that I did for this example. I introduced this as an offset because that is what it really is, but this offset is more commonly referred to as an index. An index that starts at `0`. For the rest of this article I will call the offset an index.

Special index tricks

In most languages, you can only specify a single number as the index and you get a single item back. PowerShell is much more flexible. You can use multiple indexes at once. By providing a list of indexes, we can select several items.

```
PowerShell
```

```
PS> $data[0,2,3]
```

```
Zero
```

```
Two
```

```
Three
```

The items are returned based on the order of the indexes provided. If you duplicate an index, you get that item both times.

```
PowerShell
```

```
PS> $data[3,0,3]
```

```
Three
```

```
Zero
```

```
Three
```

We can specify a sequence of numbers with the built-in `..` operator.

```
PowerShell
```

```
PS> $data[1..3]
```

```
One
```

```
Two
```

```
Three
```

This works in reverse too.

PowerShell

```
PS> $data[3..1]
Three
Two
One
```

You can use negative index values to offset from the end. So if you need the last item in the list, you can use `-1`.

PowerShell

```
PS> $data[-1]
Three
```

One word of caution here with the `..` operator. The sequence `0..-1` and `-1..0` evaluate to the values `0,-1` and `-1,0`. It's easy to see `$data[0..-1]` and think it would enumerate all items if you forget this detail. `$data[0..-1]` gives you the same value as `$data[0,-1]` by giving you the first and last item in the array (and none of the other values). Here is a larger example:

PowerShell

```
PS> $a = 1,2,3,4,5,6,7,8
PS> $a[2..-1]
3
2
1
8
```

This is the same as:

PowerShell

```
PS> $a[2,1,0,-1]
3
2
1
8
```

Out of bounds

In most languages, if you try to access an index of an item that is past the end of the array, you would get some type of error or an exception. PowerShell silently returns

nothing.

```
PowerShell
```

```
PS> $null -eq $data[9000]
True
```

Cannot index into a null array

If your variable is `$null` and you try to index it like an array, you get a `System.Management.Automation.RuntimeException` exception with the message `Cannot index into a null array.`.

```
PowerShell
```

```
PS> $empty = $null
PS> $empty[0]
Error: Cannot index into a null array.
```

So make sure your arrays are not `$null` before you try to access elements inside them.

Count

Arrays and other collections have a `Count` property that tells you how many items are in the array.

```
PowerShell
```

```
PS> $data.Count
4
```

PowerShell 3.0 added a `Count` property to most objects. you can have a single object and it should give you a count of `1`.

```
PowerShell
```

```
PS> $date = Get-Date
PS> $date.Count
1
```

Even `$null` has a `Count` property except it returns `0`.

```
PowerShell
```

```
PS> $null.Count  
0
```

There are some traps here that I will revisit when I cover checking for `$null` or empty arrays later on in this article.

Off-by-one errors

A common programming error is created because arrays start at index 0. Off-by-one errors can be introduced in two ways.

The first is by mentally thinking you want the second item and using an index of `2` and really getting the third item. Or by thinking that you have four items and you want last item, so you use the count to access the last item.

```
PowerShell
```

```
$data[ $data.Count ]
```

PowerShell is perfectly happy to let you do that and give you exactly what item exists at index 4: `$null`. You should be using `$data.Count - 1` or the `-1` that we learned about above.

```
PowerShell
```

```
PS> $data[ $data.Count - 1 ]  
Three
```

This is where you can use the `-1` index to get the last element.

```
PowerShell
```

```
PS> $data[ -1 ]  
Three
```

Lee Dailey also pointed out to me that we can use `$data.GetUpperBound(0)` to get the max index number.

```
PowerShell
```

```
PS> $data.GetUpperBound(0)  
3
```

```
PS> $data[ $data.GetUpperBound(0) ]  
Three
```

The second most common way is when iterating the list and not stopping at the right time. I'll revisit this when we talk about using the `for` loop.

Updating items

We can use the same index to update existing items in the array. This gives us direct access to update individual items.

```
PowerShell
```

```
$data[2] = 'dos'  
$data[3] = 'tres'
```

If we try to update an item that is past the last element, then we get an `Index was outside the bounds of the array.` error.

```
PowerShell
```

```
PS> $data[4] = 'four'  
Index was outside the bounds of the array.  
At line:1 char:1  
+ $data[4] = 'four'  
+ ~~~~~~  
+ CategoryInfo          : OperationStopped: () [], IndexOutOfRangeException  
+ FullyQualifiedErrorId : System.IndexOutOfRangeException
```

I'll revisit this later when I talk about how to make an array larger.

Iteration

At some point, you might need to walk or iterate the entire list and perform some action for each item in the array.

Pipeline

Arrays and the PowerShell pipeline are meant for each other. This is one of the simplest ways to process over those values. When you pass an array to a pipeline, each item inside the array is processed individually.

```
PowerShell
```

```
PS> $data = 'Zero', 'One', 'Two', 'Three'  
PS> $data | ForEach-Object {"Item: [$PSItem]"}  
Item: [Zero]  
Item: [One]  
Item: [Two]  
Item: [Three]
```

If you have not seen `$PSItem` before, just know that it's the same thing as `$_.` You can use either one because they both represent the current object in the pipeline.

ForEach loop

The `foreach` loop works well with collections. Using the syntax: `foreach (<variable> in <collection>)`

PowerShell

```
foreach ( $node in $data )  
{  
    "Item: [$node]"  
}
```

ForEach method

I tend to forget about this one but it works well for simple operations. PowerShell allows you to call `ForEach()` on a collection.

PowerShell

```
PS> $data.ForEach({"Item: [$PSItem]"}  
Item: [Zero]  
Item: [One]  
Item: [Two]  
Item: [Three]
```

The `ForEach()` takes a parameter that is a script block. You can drop the parentheses and just provide the script block.

PowerShell

```
$data.ForEach{"Item: [$PSItem]"}  
Item: [Zero]  
Item: [One]  
Item: [Two]  
Item: [Three]
```

This is a lesser known syntax but it works just the same. This `ForEach` method was added in PowerShell 4.0.

For loop

The `for` loop is used heavily in most other languages but you don't see it much in PowerShell. When you do see it, it's often in the context of walking an array.

PowerShell

```
for ( $index = 0; $index -lt $data.Count; $index++)
{
    "Item: [{0}]" -f $data[$index]
}
```

The first thing we do is initialize an `$index` to `0`. Then we add the condition that `$index` must be less than `$data.Count`. Finally, we specify that every time we loop that we must increase the index by `1`. In this case `$index++` is short for `$index = $index + 1`. The [format operator](#) (`-f`) is used to insert the value of `$data[$index]` in the output string.

Whenever you're using a `for` loop, pay special attention to the condition. I used `$index -lt $data.Count` here. It's easy to get the condition slightly wrong to get an off-by-one error in your logic. Using `$index -le $data.Count` or `$index -lt ($data.Count - 1)` are ever so slightly wrong. That would cause your result to process too many or too few items. This is the classic off-by-one error.

Switch loop

This is one that is easy to overlook. If you provide an array to a [switch statement](#), it checks each item in the array.

PowerShell

```
$data = 'Zero', 'One', 'Two', 'Three'
switch( $data )
{
    'One'
    {
        'Tock'
    }
    'Three'
    {
        'Tock'
    }
    Default
```

```
{  
    'Tick'  
}  
}
```

Output

```
Tick  
Tock  
Tick  
Tock
```

There are a lot of cool things that we can do with the switch statement. I have another article dedicated to this.

- [Everything you ever wanted to know about the switch statement](#)

Updating values

When your array is a collection of string or integers (value types), sometimes you may want to update the values in the array as you loop over them. Most of the loops above use a variable in the loop that holds a copy of the value. If you update that variable, the original value in the array is not updated.

The exception to that statement is the `for` loop. If you want to walk an array and update values inside it, then the `for` loop is what you're looking for.

PowerShell

```
for ( $index = 0; $index -lt $data.Count; $index++ )  
{  
    $data[$index] = "Item: [{0}]" -f $data[$index]  
}
```

This example takes a value by index, makes a few changes, and then uses that same index to assign it back.

Arrays of Objects

So far, the only thing we've placed in an array is a value type, but arrays can also contain objects.

PowerShell

```
$data = @(
    [pscustomobject]@{FirstName='Kevin';LastName='Marquette'}
    [pscustomobject]@{FirstName='John'; LastName='Doe'}
)
```

Many cmdlets return collections of objects as arrays when you assign them to a variable.

PowerShell

```
$processList = Get-Process
```

All of the basic features we already talked about still apply to arrays of objects with a few details worth pointing out.

Accessing properties

We can use an index to access an individual item in a collection just like with value types.

PowerShell

```
PS> $data[0]

FirstName LastName
----- -----
Kevin      Marquette
```

We can access and update properties directly.

PowerShell

```
PS> $data[0].FirstName

Kevin

PS> $data[0].FirstName = 'Jay'
PS> $data[0]

FirstName LastName
----- -----
Jay       Marquette
```

Array properties

Normally you would have to enumerate the whole list like this to access all the properties:

```
PowerShell

PS> $data | ForEach-Object {$_.LastName}

Marquette
Doe
```

Or by using the `Select-Object -ExpandProperty` cmdlet.

```
PowerShell

PS> $data | Select-Object -ExpandProperty LastName

Marquette
Doe
```

But PowerShell offers us the ability to request `LastName` directly. PowerShell enumerates them all for us and returns a clean list.

```
PowerShell

PS> $data.LastName

Marquette
Doe
```

The enumeration still happens but we don't see the complexity behind it.

Where-Object filtering

This is where `Where-Object` comes in so we can filter and select what we want out of the array based on the properties of the object.

```
PowerShell

PS> $data | Where-Object {$_.FirstName -eq 'Kevin'}

FirstName LastName
----- -----
Kevin      Marquette
```

We can write that same query to get the `FirstName` we are looking for.

```
PowerShell
```

```
$data | where FirstName -EQ Kevin
```

Where()

Arrays have a `Where()` method on them that allows you to specify a `scriptblock` for the filter.

```
PowerShell
```

```
$data.Where({$_.FirstName -eq 'Kevin'})
```

This feature was added in PowerShell 4.0.

Updating objects in loops

With value types, the only way to update the array is to use a for loop because we need to know the index to replace the value. We have more options with objects because they are reference types. Here is a quick example:

```
PowerShell
```

```
foreach($person in $data)
{
    $person.FirstName = 'Kevin'
}
```

This loop is walking every object in the `$data` array. Because objects are reference types, the `$person` variable references the exact same object that is in the array. So updates to its properties do update the original.

You still can't replace the whole object this way. If you try to assign a new object to the `$person` variable, you're updating the variable reference to something else that no longer points to the original object in the array. This doesn't work like you would expect:

```
PowerShell
```

```
foreach($person in $data)
{
    $person = [pscustomobject]@{
        FirstName='Kevin'
        LastName='Marquette'
```

```
}
```

Operators

The operators in PowerShell also work on arrays. Some of them work slightly differently.

-join

The `-join` operator is the most obvious one so let's look at it first. I like the `-join` operator and use it often. It joins all elements in the array with the character or string that you specify.

PowerShell

```
PS> $data = @(1,2,3,4)
PS> $data -join '-'
1-2-3-4
PS> $data -join ','
1,2,3,4
```

One of the features that I like about the `-join` operator is that it handles single items.

PowerShell

```
PS> 1 -join '-'
1
```

I use this inside logging and verbose messages.

PowerShell

```
PS> $data = @(1,2,3,4)
PS> "Data is $($data -join ',')."
Data is 1,2,3,4.
```

-join \$array

Here is a clever trick that Lee Dailey pointed out to me. If you ever want to join everything without a delimiter, instead of doing this:

PowerShell

```
PS> $data = @(1,2,3,4)
PS> $data -join $null
1234
```

You can use `-join` with the array as the parameter with no prefix. Take a look at this example to see that I'm talking about.

PowerShell

```
PS> $data = @(1,2,3,4)
PS> -join $data
1234
```

-replace and -split

The other operators like `-replace` and `-split` execute on each item in the array. I can't say that I have ever used them this way but here is an example.

PowerShell

```
PS> $data = @('ATX-SQL-01','ATX-SQL-02','ATX-SQL-03')
PS> $data -replace 'ATX','LAX'
LAX-SQL-01
LAX-SQL-02
LAX-SQL-03
```

-contains

The `-contains` operator allows you to check an array of values to see if it contains a specified value.

PowerShell

```
PS> $data = @('red','green','blue')
PS> $data -contains 'green'
True
```

-in

When you have a single value that you would like to verify matches one of several values, you can use the `-in` operator. The value would be on the left and the array on the right-hand side of the operator.

PowerShell

```
PS> $data = @('red','green','blue')
PS> 'green' -in $data
True
```

This can get expensive if the list is large. I often use a regex pattern if I'm checking more than a few values.

PowerShell

```
PS> $data = @('red','green','blue')
PS> $pattern = "^({0})$" -f ($data -join '|')
PS> $pattern
^(red|green|blue)$

PS> 'green' -match $pattern
True
```

-eq and -ne

Equality and arrays can get complicated. When the array is on the left side, every item gets compared. Instead of returning `True`, it returns the object that matches.

PowerShell

```
PS> $data = @('red','green','blue')
PS> $data -eq 'green'
green
```

When you use the `-ne` operator, we get all the values that are not equal to our value.

PowerShell

```
PS> $data = @('red','green','blue')
PS> $data -ne 'green'
red
blue
```

When you use this in an `if()` statement, a value that is returned is a `True` value. If no value is returned, then it's a `False` value. Both of these next statements evaluate to `True`.

PowerShell

```
$data = @('red','green','blue')
if ( $data -eq 'green' )
{
    'Green was found'
}
if ( $data -ne 'green' )
{
    'And green was not found'
}
```

I'll revisit this in a moment when we talk about testing for `$null`.

-match

The `-match` operator tries to match each item in the collection.

PowerShell

```
PS> $servers = @(
    'LAX-SQL-01'
    'LAX-API-01'
    'ATX-SQL-01'
    'ATX-API-01'
)
PS> $servers -match 'SQL'
LAX-SQL-01
ATX-SQL-01
```

When you use `-match` with a single value, a special variable `$Matches` gets populated with match info. This isn't the case when an array is processed this way.

We can take the same approach with `Select-String`.

PowerShell

```
$servers | Select-String SQL
```

I take a closer look at `Select-String`, `-match` and the `$Matches` variable in another post called [The many ways to use regex ↴](#).

\$null or empty

Testing for `$null` or empty arrays can be tricky. Here are the common traps with arrays.

At a glance, this statement looks like it should work.

PowerShell

```
if ( $array -eq $null)
{
    'Array is $null'
}
```

But I just went over how `-eq` checks each item in the array. So we can have an array of several items with a single `$null` value and it would evaluate to `$true`

PowerShell

```
$array = @('one',$null,'three')
if ( $array -eq $null)
{
    'I think Array is $null, but I would be wrong'
}
```

This is why it's a best practice to place the `$null` on the left side of the operator. This makes this scenario a non-issue.

PowerShell

```
if ( $null -eq $array )
{
    'Array actually is $null'
}
```

A `$null` array isn't the same thing as an empty array. If you know you have an array, check the count of objects in it. If the array is `$null`, the count is `0`.

PowerShell

```
if ( $array.Count -gt 0 )
{
    "Array isn't empty"
}
```

There is one more trap to watch out for here. You can use the `Count` even if you have a single object, unless that object is a `PSCustomObject`. This is a bug that is fixed in PowerShell 6.1. That's good news, but a lot of people are still on 5.1 and need to watch out for it.

PowerShell

```
PS> $object = [pscustomobject]@{Name='TestObject'}
PS> $object.Count
$null
```

If you're still on PowerShell 5.1, you can wrap the object in an array before checking the count to get an accurate count.

PowerShell

```
if ( @($array).Count -gt 0 )
{
    "Array isn't empty"
}
```

To fully play it safe, check for `$null`, then check the count.

PowerShell

```
if ( $null -ne $array -and @($array).Count -gt 0 )
{
    "Array isn't empty"
}
```

All -eq

I recently saw someone on Reddit ask how to verify that every value in an array matches a given value. Reddit user `u/bis` had this clever solution that checks for any incorrect values and then flips the result.

PowerShell

```
$results = Test-Something
if ( -not ( $results -ne 'Passed' ) )
{
    'All results a Passed'
```

Adding to arrays

At this point, you're starting to wonder how to add items to an array. The quick answer is that you can't. An array is a fixed size in memory. If you need to grow it or add a single item to it, then you need to create a new array and copy all the values over from

the old array. This sounds like a lot of work, however, PowerShell hides the complexity of creating the new array. PowerShell implements the addition operator (+) for arrays.

ⓘ Note

PowerShell does not implement a subtraction operation. If you want a flexible alternative to an array, you need to use a [generic List](#) object.

Array addition

We can use the addition operator with arrays to create a new array. So given these two arrays:

PowerShell

```
$first = @(  
    'Zero'  
    'One'  
)  
$second = @(  
    'Two'  
    'Three'  
)
```

We can add them together to get a new array.

PowerShell

```
PS> $first + $second  
  
Zero  
One  
Two  
Three
```

Plus equals +=

We can create a new array in place and add an item to it like this:

PowerShell

```
$data = @(  
    'Zero'  
    'One'  
    'Two'
```

```
'Three'  
)  
$data += 'four'
```

Just remember that every time you use `+=` that you're duplicating and creating a new array. This is a not an issue for small datasets but it scales extremely poorly.

Pipeline assignment

You can assign the results of any pipeline into a variable. It's an array if it contains multiple items.

PowerShell

```
$array = 1..5 | ForEach-Object {  
    "ATX-SQL-$PSItem"  
}
```

Normally when we think of using the pipeline, we think of the typical PowerShell one-liners. We can leverage the pipeline with `foreach()` statements and other loops. So instead of adding items to an array in a loop, we can drop items onto the pipeline.

PowerShell

```
$array = foreach ( $node in (1..5) )  
{  
    "ATX-SQL-$node"  
}
```

Array Types

By default, an array in PowerShell is created as a `[psobject[]]` type. This allows it to contain any type of object or value. This works because everything is inherited from the `PSObject` type.

Strongly typed arrays

You can create an array of any type using a similar syntax. When you create a strongly typed array, it can only contain values or objects the specified type.

PowerShell

```
PS> [int[]] $numbers = 1,2,3
PS> [int[]] $numbers2 = 'one','two','three'
ERROR: Cannot convert value "one" to type "System.Int32". Input string was
not in a correct format.

PS> [string[]] $strings = 'one','two','three'
```

ArrayList

Adding items to an array is one of its biggest limitations, but there are a few other collections that we can turn to that solve this problem.

The `ArrayList` is commonly one of the first things that we think of when we need an array that is faster to work with. It acts like an object array every place that we need it, but it handles adding items quickly.

Here is how we create an `ArrayList` and add items to it.

PowerShell

```
$myarray = [System.Collections.ArrayList]::new()
[void]$myArray.Add('Value')
```

We are calling into .NET to get this type. In this case, we are using the default constructor to create it. Then we call the `Add` method to add an item to it.

The reason I'm using `[void]` at the beginning of the line is to suppress the return code. Some .NET calls do this and can create unexpected output.

If the only data that you have in your array is strings, then also take a look at using `StringBuilder`. It's almost the same thing but has some methods that are just for dealing with strings. The `StringBuilder` is specially designed for performance.

It's common to see people move to `ArrayList` from arrays. But it comes from a time where C# didn't have generic support. The `ArrayList` is deprecated in support for the generic `List[]`

Generic List

A generic type is a special type in C# that defines a generalized class and the user specifies the data types it uses when created. So if you want a list of numbers or strings, you would define that you want list of `int` or `string` types.

Here is how you create a List for strings.

```
PowerShell
```

```
$mylist = [System.Collections.Generic.List[string]]::new()
```

Or a list for numbers.

```
PowerShell
```

```
$mylist = [System.Collections.Generic.List[int]]::new()
```

We can cast an existing array to a list like this without creating the object first:

```
PowerShell
```

```
$mylist = [System.Collections.Generic.List[int]]@(1,2,3)
```

We can shorten the syntax with the `using namespace` statement in PowerShell 5 and newer. The `using` statement needs to be the first line of your script. By declaring a namespace, PowerShell lets you leave it off of the data types when you reference them.

```
PowerShell
```

```
using namespace System.Collections.Generic  
$myList = [List[int]]@(1,2,3)
```

This makes the `List` much more usable.

You have a similar `Add` method available to you. Unlike the `ArrayList`, there is no return value on the `Add` method so we don't have to `void` it.

```
PowerShell
```

```
$myList.Add(10)
```

And we can still access the elements like other arrays.

```
PowerShell
```

```
PS> $myList[-1]  
10
```

List[psobject]

You can have a list of any type, but when you don't know the type of objects, you can use `[List[psobject]]` to contain them.

PowerShell

```
$list = [List[psobject]]::new()
```

Remove()

The `ArrayList` and the generic `List[]` both support removing items from the collection.

PowerShell

```
using namespace System.Collections.Generic
$list = [List[string]]@('Zero', 'One', 'Two', 'Three')
[void]$list.Remove("Two")
Zero
One
Three
```

When working with value types, it removes the first one from the list. You can call it over and over again to keep removing that value. If you have reference types, you have to provide the object that you want removed.

PowerShell

```
[List[System.Management.Automation.PSDriveInfo]]$drives = Get-PSDrive
$drives.Remove($drives[2])
```

PowerShell

```
$delete = $drives[2]
$drives.Remove($delete)
```

The remove method returns `true` if it was able to find and remove the item from the collection.

More collections

There are many other collections that can be used but these are the good generic array replacements. If you're interested in learning about more of these options, take a look at this [Gist](#) that [Mark Kraus](#) put together.

Other nuances

Now that I have covered all the major functionality, here are a few more things that I wanted to mention before I wrap this up.

Pre-sized arrays

I mentioned that you can't change the size of an array once it's created. We can create an array of a pre-determined size by calling it with the `new($size)` constructor.

```
PowerShell
```

```
$data = [Object[]]::new(4)  
$data.Count  
4
```

Multiplying arrays

An interesting little trick is that you can multiply an array by an integer.

```
PowerShell
```

```
PS> $data = @('red','green','blue')  
PS> $data * 3  
red  
green  
blue  
red  
green  
blue  
red  
green  
blue
```

Initialize with 0

A common scenario is that you want to create an array with all zeros. If you're only going to have integers, a strongly typed array of integers defaults to all zeros.

PowerShell

```
PS> [int[]]::new(4)
0
0
0
0
```

We can use the multiplying trick to do this too.

PowerShell

```
PS> $data = @(0) * 4
PS> $data
0
0
0
0
```

The nice thing about the multiplying trick is that you can use any value. So if you would rather have 255 as your default value, this would be a good way to do it.

PowerShell

```
PS> $data = @(255) * 4
PS> $data
255
255
255
255
```

Nested arrays

An array inside an array is called a nested array. I don't use these much in PowerShell but I have used them more in other languages. Consider using an array of arrays when your data fits in a grid like pattern.

Here are two ways we can create a two-dimensional array.

PowerShell

```
$data = @(@(1,2,3),@(4,5,6),@(7,8,9))

$data2 = @(
    @(1,2,3),
    @(4,5,6),
```

```
@(7,8,9)  
)
```

The comma is very important in those examples. I gave an earlier example of a normal array on multiple lines where the comma was optional. That isn't the case with a multi-dimensional array.

The way we use the index notation changes slightly now that we've a nested array. Using the `$data` above, this is how we would access the value 3.

PowerShell

```
PS> $outside = 0  
PS> $inside = 2  
PS> $data[$outside][$inside]  
3
```

Add a set of bracket for each level of array nesting. The first set of brackets is for the outer most array and then you work your way in from there.

Write-Output -NoEnumerate

PowerShell likes to unwrap or enumerate arrays. This is a core aspect of the way PowerShell uses the pipeline but there are times that you don't want that to happen.

I commonly pipe objects to `Get-Member` to learn more about them. When I pipe an array to it, it gets unwrapped and Get-Member sees the members of the array and not the actual array.

PowerShell

```
PS> $data = @('red','green','blue')  
PS> $data | Get-Member  
TypeName: System.String  
...
```

To prevent that unwrap of the array, you can use `Write-Output -NoEnumerate`.

PowerShell

```
PS> Write-Output -NoEnumerate $data | Get-Member  
TypeName: System.Object[]  
...
```

I have a second way that's more of a hack (and I try to avoid hacks like this). You can place a comma in front of the array before you pipe it. This wraps `$data` into another array where it is the only element, so after the unwrapping the outer array we get back `$data` unwrapped.

```
PowerShell
```

```
PS> ,$data | Get-Member
TypeName: System.Object[]
...
...
```

Return an array

This unwrapping of arrays also happens when you output or return values from a function. You can still get an array if you assign the output to a variable so this isn't commonly an issue.

The catch is that you have a new array. If that is ever a problem, you can use `Write-Output -NoEnumerate $array` or `return ,$array` to work around it.

Anything else?

I know this is all a lot to take in. My hope is that you learn something from this article every time you read it and that it turns out to be a good reference for you for a long time to come. If you found this to be helpful, please share it with others you think may get value out of it.

From here, I would recommend you check out a similar post that I wrote about [hashables](#).

Everything you wanted to know about hashtables

Article • 06/26/2023

I want to take a step back and talk about [hashtables](#). I use them all the time now. I was teaching someone about them after our user group meeting last night and I realized I had the same confusion about them as he had. Hashtables are really important in PowerShell so it's good to have a solid understanding of them.

ⓘ Note

The [original version](#) of this article appeared on the blog written by [@KevinMarquette](#). The PowerShell team thanks Kevin for sharing this content with us. Please check out his blog at [PowerShellExplained.com](#).

Hashtable as a collection of things

I want you to first see a **Hashtable** as a collection in the traditional definition of a hashtable. This definition gives you a fundamental understanding of how they work when they get used for more advanced stuff later. Skipping this understanding is often a source of confusion.

What is an array?

Before I jump into what a **Hashtable** is, I need to mention [arrays](#) first. For the purpose of this discussion, an array is a list or collection of values or objects.

```
PowerShell
```

```
$array = @(1,2,3,5,7,11)
```

Once you have your items into an array, you can either use `foreach` to iterate over the list or use an index to access individual elements in the array.

```
PowerShell
```

```
foreach($item in $array)
{
    Write-Output $item
```

```
}
```

```
Write-Output $array[3]
```

You can also update values using an index in the same way.

```
PowerShell
```

```
$array[2] = 13
```

I just scratched the surface on arrays but that should put them into the right context as I move onto hashtables.

What is a hashtable?

I'm going to start with a basic technical description of what hashtables are, in the general sense, before I shift into the other ways PowerShell uses them.

A hashtable is a data structure, much like an array, except you store each value (object) using a key. It's a basic key/value store. First, we create an empty hashtable.

```
PowerShell
```

```
$ageList = @{}  
 
```

Notice that braces, instead of parentheses, are used to define a hashtable. Then we add an item using a key like this:

```
PowerShell
```

```
$key = 'Kevin'  
$value = 36  
$ageList.Add( $key, $value )  
  
$ageList.Add( 'Alex', 9 )
```

The person's name is the key and their age is the value that I want to save.

Using the brackets for access

Once you add your values to the hashtable, you can pull them back out using that same key (instead of using a numeric index like you would have for an array).

```
PowerShell
```

```
$ageList['Kevin']  
$ageList['Alex']
```

When I want Kevin's age, I use his name to access it. We can use this approach to add or update values into the hashtable too. This is just like using the `Add()` method above.

```
PowerShell
```

```
$ageList = @{}  
  
$key = 'Kevin'  
$value = 36  
$ageList[$key] = $value  
  
$ageList['Alex'] = 9
```

There's another syntax you can use for accessing and updating values that I'll cover in a later section. If you're coming to PowerShell from another language, these examples should fit in with how you may have used hashtables before.

Creating hashtables with values

So far I've created an empty hashtable for these examples. You can pre-populate the keys and values when you create them.

```
PowerShell
```

```
$ageList = @{  
    Kevin = 36  
    Alex = 9  
}
```

As a lookup table

The real value of this type of a hashtable is that you can use them as a lookup table. Here is a simple example.

```
PowerShell
```

```
$environments = @{  
    Prod = 'SrvProd05'  
    QA = 'SrvQA02'  
    Dev = 'SrvDev12'
```

```
}
```

```
$server = $environments[$env]
```

In this example, you specify an environment for the `$env` variable and it will pick the correct server. You could use a `switch($env){...}` for a selection like this but a hashtable is a nice option.

This gets even better when you dynamically build the lookup table to use it later. So think about using this approach when you need to cross reference something. I think we would see this even more if PowerShell wasn't so good at filtering on the pipe with `Where-Object`. If you're ever in a situation where performance matters, this approach needs to be considered.

I won't say that it's faster, but it does fit into the rule of [If performance matters, test it ↗](#).

Multiselection

Generally, you think of a hashtable as a key/value pair, where you provide one key and get one value. PowerShell allows you to provide an array of keys to get multiple values.

```
PowerShell
```

```
$environments[@('QA', 'DEV')]
```

```
$environments[('QA', 'DEV')]
```

```
$environments['QA', 'DEV']
```

In this example, I use the same lookup hashtable from above and provide three different array styles to get the matches. This is a hidden gem in PowerShell that most people aren't aware of.

Iterating hashtables

Because a hashtable is a collection of key/value pairs, you iterate over it differently than you do for an array or a normal list of items.

The first thing to notice is that if you pipe your hashtable, the pipe treats it like one object.

```
PowerShell
```

```
PS> $ageList | Measure-Object
```

```
count : 1
```

Even though the `Count` property tells you how many values it contains.

```
PowerShell
```

```
PS> $ageList.Count  
2
```

You get around this issue by using the `Values` property if all you need is just the values.

```
PowerShell
```

```
PS> $ageList.Values | Measure-Object -Average  
Count : 2  
Average : 22.5
```

It's often more useful to enumerate the keys and use them to access the values.

```
PowerShell
```

```
PS> $ageList.Keys | ForEach-Object{  
    $message = '{0} is {1} years old!' -f $_, $ageList[$_]  
    Write-Output $message  
}  
Kevin is 36 years old  
Alex is 9 years old
```

Here is the same example with a `foreach(){...}` loop.

```
PowerShell
```

```
foreach($key in $ageList.Keys)  
{  
    $message = '{0} is {1} years old' -f $key, $ageList[$key]  
    Write-Output $message  
}
```

We are walking each key in the hashtable and then using it to access the value. This is a common pattern when working with hashtables as a collection.

GetEnumerator()

That brings us to `GetEnumerator()` for iterating over our hashtable.

```
PowerShell
```

```
$ageList.GetEnumerator() | ForEach-Object{
    $message = '{0} is {1} years old!' -f $_.Key, $_.Value
    Write-Output $message
}
```

The enumerator gives you each key/value pair one after another. It was designed specifically for this use case. Thank you to [Mark Kraus](#) for reminding me of this one.

BadEnumeration

One important detail is that you can't modify a hashtable while it's being enumerated. If we start with our basic `$environments` example:

PowerShell

```
$environments = @{
    Prod = 'SrvProd05'
    QA   = 'SrvQA02'
    Dev  = 'SrvDev12'
}
```

And trying to set every key to the same server value fails.

PowerShell

```
$environments.Keys | ForEach-Object {
    $environments[$_] = 'SrvDev03'
}
```

```
An error occurred while enumerating through a collection: Collection was modified;
enumeration operation may not execute.
+ CategoryInfo          : InvalidOperation:
tableEnumerator:HashtableEnumerator) [],
RuntimeException
+ FullyQualifiedErrorId : BadEnumeration
```

This will also fail even though it looks like it should also be fine:

PowerShell

```
foreach($key in $environments.Keys) {
    $environments[$key] = 'SrvDev03'
}
```

```
Collection was modified; enumeration operation may not execute.
+ CategoryInfo          : OperationStopped: () [],

```

```
InvalidOperationException  
+ FullyQualifiedErrorId : System.InvalidOperationException
```

The trick to this situation is to clone the keys before doing the enumeration.

PowerShell

```
$environments.Keys.Clone() | ForEach-Object {  
    $environments[$_] = 'SrvDev03'  
}
```

Hashtable as a collection of properties

So far the type of objects we placed in our hashtable were all the same type of object. I used ages in all those examples and the key was the person's name. This is a great way to look at it when your collection of objects each have a name. Another common way to use hashtables in PowerShell is to hold a collection of properties where the key is the name of the property. I'll step into that idea in this next example.

Property-based access

The use of property-based access changes the dynamics of hashtables and how you can use them in PowerShell. Here is our usual example from above treating the keys as properties.

PowerShell

```
$ageList = @{}  
$ageList.Kevin = 35  
$ageList.Alex = 9
```

Just like the examples above, this example adds those keys if they don't exist in the hashtable already. Depending on how you defined your keys and what your values are, this is either a little strange or a perfect fit. The age list example has worked great up until this point. We need a new example for this to feel right going forward.

PowerShell

```
$person = @{  
    name = 'Kevin'  
    age = 36  
}
```

And we can add and access attributes on the `$person` like this.

PowerShell

```
$person.city = 'Austin'  
$person.state = 'TX'
```

All of a sudden this hashtable starts to feel and act like an object. It's still a collection of things, so all the examples above still apply. We just approach it from a different point of view.

Checking for keys and values

In most cases, you can just test for the value with something like this:

PowerShell

```
if( $person.age ){...}
```

It's simple but has been the source of many bugs for me because I was overlooking one important detail in my logic. I started to use it to test if a key was present. When the value was `$false` or zero, that statement would return `$false` unexpectedly.

PowerShell

```
if( $person.age -ne $null ){...}
```

This works around that issue for zero values but not `$null` vs non-existent keys. Most of the time you don't need to make that distinction but there are methods for when you do.

PowerShell

```
if( $person.ContainsKey('age') ){...}
```

We also have a `ContainsValue()` for the situation where you need to test for a value without knowing the key or iterating the whole collection.

Removing and clearing keys

You can remove keys with the `Remove()` method.

```
PowerShell
```

```
$person.Remove('age')
```

Assigning them a `$null` value just leaves you with a key that has a `$null` value.

A common way to clear a hashtable is to just initialize it to an empty hashtable.

```
PowerShell
```

```
$person = @{}
```

While that does work, try to use the `Clear()` method instead.

```
PowerShell
```

```
$person.Clear()
```

This is one of those instances where using the method creates self-documenting code and it makes the intentions of the code very clean.

All the fun stuff

Ordered hashtables

By default, hashtables aren't ordered (or sorted). In the traditional context, the order doesn't matter when you always use a key to access values. You may find that you want the properties to stay in the order that you define them. Thankfully, there's a way to do that with the `ordered` keyword.

```
PowerShell
```

```
$person = [ordered]@{  
    name = 'Kevin'  
    age  = 36  
}
```

Now when you enumerate the keys and values, they stay in that order.

Inline hashtables

When you're defining a hashtable on one line, you can separate the key/value pairs with a semicolon.

```
PowerShell
```

```
$person = @{ name = 'kevin'; age = 36; }
```

This will come in handy if you're creating them on the pipe.

Custom expressions in common pipeline commands

There are a few cmdlets that support the use of hashtables to create custom or calculated properties. You commonly see this with `Select-Object` and `Format-Table`. The hashtables have a special syntax that looks like this when fully expanded.

```
PowerShell
```

```
$property = @{
    Name = 'TotalSpaceGB'
    Expression = { ($_.Used + $_.Free) / 1GB }
}
```

The `Name` is what the cmdlet would label that column. The `Expression` is a script block that is executed where `$_` is the value of the object on the pipe. Here is that script in action:

```
PowerShell
```

```
$drives = Get-PSDrive | where Used
$drives | Select-Object -Property Name, $property

Name      TotalSpaceGB
----      -----
C        238.472652435303
```

I placed that in a variable but it could easily be defined inline and you can shorten `Name` to `n` and `Expression` to `e` while you're at it.

```
PowerShell
```

```
$drives | Select-Object -Property Name, @{n='TotalSpaceGB';e={($_.Used +
$_.Free) / 1GB}}
```

I personally don't like how long that makes commands and it often promotes some bad behaviors that I won't get into. I'm more likely to create a new hashtable or `pscustomobject` with all the fields and properties that I want instead of using this approach in scripts. But there's a lot of code out there that does this so I wanted you to be aware of it. I talk about creating a `pscustomobject` later on.

Custom sort expression

It's easy to sort a collection if the objects have the data that you want to sort on. You can either add the data to the object before you sort it or create a custom expression for `Sort-Object`.

PowerShell

```
Get-ADUser | Sort-Object -Property @{ e={ Get-TotalSales $_.Name } }
```

In this example I'm taking a list of users and using some custom cmdlet to get additional information just for the sort.

Sort a list of Hashtables

If you have a list of hashtables that you want to sort, you'll find that the `Sort-Object` doesn't treat your keys as properties. We can get around that by using a custom sort expression.

PowerShell

```
$data = @(
    @{name='a'}
    @{name='c'}
    @{name='e'}
    @{name='f'}
    @{name='d'}
    @{name='b'}
)
$data | Sort-Object -Property @{e={$_ .name}}
```

Splatting hashtables at cmdlets

This is one of my favorite things about hashtables that many people don't discover early on. The idea is that instead of providing all the properties to a cmdlet on one line, you

can instead pack them into a hashtable first. Then you can give the hashtable to the function in a special way. Here is an example of creating a DHCP scope the normal way.

```
PowerShell
```

```
Add-DhcpServerV4Scope -Name 'TestNetwork' -StartRange '10.0.0.2' -EndRange  
'10.0.0.254' -SubnetMask '255.255.255.0' -Description 'Network for testlab  
A' -LeaseDuration (New-TimeSpan -Days 8) -Type "Both"
```

Without using [splatting](#), all those things need to be defined on a single line. It either scrolls off the screen or will wrap where ever it feels like. Now compare that to a command that uses splatting.

```
PowerShell
```

```
$DHCPScope = @{  
    Name      = 'TestNetwork'  
    StartRange = '10.0.0.2'  
    EndRange   = '10.0.0.254'  
    SubnetMask = '255.255.255.0'  
    Description = 'Network for testlab A'  
    LeaseDuration = (New-TimeSpan -Days 8)  
    Type       = "Both"  
}  
Add-DhcpServerV4Scope @DHCPscope
```

The use of the `@` sign instead of the `$` is what invokes the splat operation.

Just take a moment to appreciate how easy that example is to read. They are the exact same command with all the same values. The second one is easier to understand and maintain going forward.

I use splatting anytime the command gets too long. I define too long as causing my window to scroll right. If I hit three properties for a function, odds are that I'll rewrite it using a splatted hashtable.

Splatting for optional parameters

One of the most common ways I use splatting is to deal with optional parameters that come from some place else in my script. Let's say I have a function that wraps a `Get-CimInstance` call that has an optional `$Credential` argument.

```
PowerShell
```

```
$CIMParams = @{  
    ClassName = 'Win32_BIOS'
```

```

ComputerName = $ComputerName
}

if($Credential)
{
    $CIMParams.Credential = $Credential
}

Get-CimInstance @CIMParams

```

I start by creating my hashtable with common parameters. Then I add the `$Credential` if it exists. Because I'm using splatting here, I only need to have the call to `Get-CimInstance` in my code once. This design pattern is very clean and can handle lots of optional parameters easily.

To be fair, you could write your commands to allow `$null` values for parameters. You just don't always have control over the other commands you're calling.

Multiple splats

You can splat multiple hashtables to the same cmdlet. If we revisit our original splatting example:

```

PowerShell

$Common = @{
    SubnetMask = '255.255.255.0'
    LeaseDuration = (New-TimeSpan -Days 8)
    Type = "Both"
}

$DHCPScope = @{
    Name      = 'TestNetwork'
    StartRange = '10.0.0.2'
    EndRange   = '10.0.0.254'
    Description = 'Network for testlab A'
}

Add-DhcpServerv4Scope @DHCPScope @Common

```

I'll use this method when I have a common set of parameters that I'm passing to lots of commands.

Splatting for clean code

There's nothing wrong with splatting a single parameter if makes you code cleaner.

```
PowerShell
```

```
$log = @{Path = '.\logfile.log'}
Add-Content "logging this command" @log
```

Splatting executables

Splatting also works on some executables that use a `/param:value` syntax. `Robocopy.exe`, for example, has some parameters like this.

```
PowerShell
```

```
$robo = @{R=1;W=1;MT=8}
robocopy source destination @robo
```

I don't know that this is all that useful, but I found it interesting.

Adding hashTables

HashTables support the addition operator to combine two hashTables.

```
PowerShell
```

```
$person += @{Zip = '78701'}
```

This only works if the two hashTables don't share a key.

Nested hashTables

We can use hashTables as values inside a hashtable.

```
PowerShell
```

```
$person = @{
    name = 'Kevin'
    age  = 36
}
$person.location = {}
$person.location.city = 'Austin'
$person.location.state = 'TX'
```

I started with a basic hashtable containing two keys. I added a key called `location` with an empty hashtable. Then I added the last two items to that `location` hashtable. We can do this all inline too.

PowerShell

```
$person = @{
    name = 'Kevin'
    age  = 36
    location = @{
        city  = 'Austin'
        state = 'TX'
    }
}
```

This creates the same hashtable that we saw above and can access the properties the same way.

PowerShell

```
$person.location.city
Austin
```

There are many ways to approach the structure of your objects. Here is a second way to look at a nested hashtable.

PowerShell

```
$people = @{
    Kevin = @{
        age  = 36
        city = 'Austin'
    }
    Alex = @{
        age  = 9
        city = 'Austin'
    }
}
```

This mixes the concept of using hashtables as a collection of objects and a collection of properties. The values are still easy to access even when they're nested using whatever approach you prefer.

PowerShell

```
PS> $people.Kevin.age
36
```

```
PS> $people.kevin['city']
Austin
PS> $people['Alex'].age
9
PS> $people['Alex']['City']
Austin
```

I tend to use the dot property when I'm treating it like a property. Those are generally things I've defined statically in my code and I know them off the top of my head. If I need to walk the list or programmatically access the keys, I use the brackets to provide the key name.

PowerShell

```
foreach($name in $people.Keys)
{
    $person = $people[$name]
    '{0}, age {1}, is in {2}' -f $name, $person.age, $person.city
}
```

Having the ability to nest hashtables gives you a lot of flexibility and options.

Looking at nested hashtables

As soon as you start nesting hashtables, you're going to need an easy way to look at them from the console. If I take that last hashtable, I get an output that looks like this and it only goes so deep:

PowerShell

```
PS> $people
Name          Value
----          -----
Kevin         {age, city}
Alex          {age, city}
```

My go to command for looking at these things is `ConvertTo-Json` because it's very clean and I frequently use JSON on other things.

PowerShell

```
PS> $people | ConvertTo-Json
{
    "Kevin":  {
        "age": 36,
        "city": "Austin"
```

```
        },
    "Alex":  {
        "age":  9,
        "city": "Austin"
    }
}
```

Even if you don't know JSON, you should be able to see what you're looking for. There's a `Format-Custom` command for structured data like this but I still like the JSON view better.

Creating objects

Sometimes you just need to have an object and using a hashtable to hold properties just isn't getting the job done. Most commonly you want to see the keys as column names. A `pscustomobject` makes that easy.

PowerShell

```
$person = [pscustomobject]@{
    name = 'Kevin'
    age  = 36
}

$person

name  age
----  --
Kevin  36
```

Even if you don't create it as a `pscustomobject` initially, you can always cast it later when needed.

PowerShell

```
$person = @{
    name = 'Kevin'
    age  = 36
}

[pscustomobject]$person

name  age
----  --
Kevin  36
```

I already have detailed write-up for [pscustomobject](#) that you should go read after this one. It builds on a lot of the things learned here.

Reading and writing hashtables to file

Saving to CSV

Struggling with getting a hashtable to save to a CSV is one of the difficulties that I was referring to above. Convert your hashtable to a `pscustomobject` and it will save correctly to CSV. It helps if you start with a `pscustomobject` so the column order is preserved. But you can cast it to a `pscustomobject` inline if needed.

PowerShell

```
$person | ForEach-Object{ [pscustomobject]$_. } | Export-Csv -Path $path
```

Again, check out my write-up on using a [pscustomobject](#).

Saving a nested hashtable to file

If I need to save a nested hashtable to a file and then read it back in again, I use the JSON cmdlets to do it.

PowerShell

```
$people | ConvertTo-Json | Set-Content -Path $path  
$people = Get-Content -Path $path -Raw | ConvertFrom-Json
```

There are two important points about this method. First is that the JSON is written out multiline so I need to use the `-Raw` option to read it back into a single string. The Second is that the imported object is no longer a `[hashtable]`. It's now a `[pscustomobject]` and that can cause issues if you don't expect it.

Watch for deeply-nested hashtables. When you convert it to JSON you might not get the results you expect.

PowerShell

```
@{ a = @{ b = @{ c = @{ d = "e" }}} } | ConvertTo-Json  
{  
    "a": {
```

```
        "b": {
            "c": "System.Collections.Hashtable"
        }
    }
}
```

Use **Depth** parameter to ensure that you have expanded all the nested hashtables.

PowerShell

```
@{ a = @{ b = @{ c = @{ d = "e" }}} } | ConvertTo-Json -Depth 3

{
    "a": {
        "b": {
            "c": {
                "d": "e"
            }
        }
    }
}
```

If you need it to be a `[hashtable]` on import, then you need to use the `Export-CliXml` and `Import-CliXml` commands.

Converting JSON to Hashtable

If you need to convert JSON to a `[hashtable]`, there's one way that I know of to do it with the [JavaScriptSerializer](#) in .NET.

PowerShell

```
[Reflection.Assembly]::LoadWithPartialName("System.Web.Script.Serialization")
)
$JSSerializer =
[System.Web.Script.Serialization.JavaScriptSerializer]::new()
$JSSerializer.Deserialize($json, 'Hashtable')
```

Beginning in PowerShell v6, JSON support uses the [NewtonSoft JSON.NET](#) and adds hashtable support.

PowerShell

```
'{ "a": "b" }' | ConvertFrom-Json -AsHashtable
```

Name	Value

```
----      ----  
a          b
```

PowerShell 6.2 added the **Depth** parameter to `ConvertFrom-Json`. The default **Depth** is 1024.

Reading directly from a file

If you have a file that contains a hashtable using PowerShell syntax, there's a way to import it directly.

```
PowerShell
```

```
$content = Get-Content -Path $Path -Raw -ErrorAction Stop  
$scriptBlock = [scriptblock]::Create( $content )  
$scriptBlock.CheckRestrictedLanguage( $allowedCommands, $allowedVariables,  
$true )  
$hashtable = ( & $scriptBlock )
```

It imports the contents of the file into a `scriptblock`, then checks to make sure it doesn't have any other PowerShell commands in it before it executes it.

On that note, did you know that a module manifest (the `.psd1` file) is just a hashtable?

Keys can be any object

Most of the time, the keys are just strings. So we can put quotes around anything and make it a key.

```
PowerShell
```

```
$person = @{  
    'full name' = 'Kevin Marquette'  
    '#' = 3978  
}  
$person['full name']
```

You can do some odd things that you may not have realized you could do.

```
PowerShell
```

```
$person.'full name'
```

```
$key = 'full name'  
$person.$key
```

Just because you can do something, it doesn't mean that you should. That last one just looks like a bug waiting to happen and would be easily misunderstood by anyone reading your code.

Technically your key doesn't have to be a string but they're easier to think about if you only use strings. However, indexing doesn't work well with the complex keys.

PowerShell

```
$ht = @{ @(1,2,3) = "a" }  
$ht  
  
Name          Value  
----          ----  
{1, 2, 3}      a
```

Accessing a value in the hashtable by its key doesn't always work. For example:

PowerShell

```
$key = $ht.Keys[0]  
$ht.$($key)  
a  
$ht[$key]  
a
```

When the key is an array, you must wrap the `$key` variable in a subexpression so that it can be used with member access (`.`) notation. Or, you can use array index (`[]`) notation.

Use in automatic variables

\$PSBoundParameters

[\\$PSBoundParameters](#) is an automatic variable that only exists inside the context of a function. It contains all the parameters that the function was called with. This isn't exactly a hashtable but close enough that you can treat it like one.

That includes removing keys and splatting it to other functions. If you find yourself writing proxy functions, take a closer look at this one.

See [about_Automatic_Variables](#) for more details.

PSBoundParameters gotcha

One important thing to remember is that this only includes the values that are passed in as parameters. If you also have parameters with default values but aren't passed in by the caller, `$PSBoundParameters` doesn't contain those values. This is commonly overlooked.

\$PSDefaultParameterValues

This automatic variable lets you assign default values to any cmdlet without changing the cmdlet. Take a look at this example.

PowerShell

```
$PSDefaultParameterValues["Out-File:Encoding"] = "UTF8"
```

This adds an entry to the `$PSDefaultParameterValues` hashtable that sets `UTF8` as the default value for the `Out-File -Encoding` parameter. This is session-specific so you should place it in your `$PROFILE`.

I use this often to pre-assign values that I type quite often.

PowerShell

```
$PSDefaultParameterValues[ "Connect-VIServer:Server" ] =  
'VCENTER01.contoso.local'
```

This also accepts wildcards so you can set values in bulk. Here are some ways you can use that:

PowerShell

```
$PSDefaultParameterValues[ "Get-*:Verbose" ] = $true  
$PSDefaultParameterValues[ "*:Credential" ] = Get-Credential
```

For a more in-depth breakdown, see this great article on [Automatic Defaults ↗](#) by Michael Sorens ↗.

Regex \$Matches

When you use the `-match` operator, an automatic variable called `$Matches` is created with the results of the match. If you have any sub expressions in your regex, those sub matches are also listed.

PowerShell

```
$message = 'My SSN is 123-45-6789.'  
  
$message -match 'My SSN is (.)\.'  
$Matches[0]  
$Matches[1]
```

Named matches

This is one of my favorite features that most people don't know about. If you use a named regex match, then you can access that match by name on the matches.

PowerShell

```
$message = 'My Name is Kevin and my SSN is 123-45-6789.'  
  
if($message -match 'My Name is (?<Name>.+) and my SSN is (?<SSN>.+)\.')  
{  
    $Matches.Name  
    $Matches.SSN  
}
```

In the example above, the `(?<Name>.*)` is a named sub expression. This value is then placed in the `$Matches.Name` property.

Group-Object -AsHashtable

One little known feature of `Group-Object` is that it can turn some datasets into a hashtable for you.

PowerShell

```
Import-Csv $Path | Group-Object -AsHashtable -Property Email
```

This will add each row into a hashtable and use the specified property as the key to access it.

Copying Hashtables

One important thing to know is that hashtables are objects. And each variable is just a reference to an object. This means that it takes more work to make a valid copy of a hashtable.

Assigning reference types

When you have one hashtable and assign it to a second variable, both variables point to the same hashtable.

PowerShell

```
PS> $orig = @{name='orig'}
PS> $copy = $orig
PS> $copy.name = 'copy'
PS> 'Copy: [{0}]' -f $copy.name
PS> 'Orig: [{0}]' -f $orig.name

Copy: [copy]
Orig: [copy]
```

This highlights that they're the same because altering the values in one will also alter the values in the other. This also applies when passing hashtables into other functions. If those functions make changes to that hashtable, your original is also altered.

Shallow copies, single level

If we have a simple hashtable like our example above, we can use `Clone()` to make a shallow copy.

PowerShell

```
PS> $orig = @{name='orig'}
PS> $copy = $orig.Clone()
PS> $copy.name = 'copy'
PS> 'Copy: [{0}]' -f $copy.name
PS> 'Orig: [{0}]' -f $orig.name

Copy: [copy]
Orig: [orig]
```

This will allow us to make some basic changes to one that don't impact the other.

Shallow copies, nested

The reason why it's called a shallow copy is because it only copies the base level properties. If one of those properties is a reference type (like another hashtable), then those nested objects will still point to each other.

```
PowerShell

PS> $orig = @{
    person=@{
        name='orig'
    }
}
PS> $copy = $orig.Clone()
PS> $copy.person.name = 'copy'
PS> 'Copy: [{0}]' -f $copy.person.name
PS> 'Orig: [{0}]' -f $orig.person.name

Copy: [copy]
Orig: [copy]
```

So you can see that even though I cloned the hashtable, the reference to `person` wasn't cloned. We need to make a deep copy to truly have a second hashtable that isn't linked to the first.

Deep copies

There are a couple of ways to make a deep copy of a hashtable (and keep it as a hashtable). Here's a function using PowerShell to recursively create a deep copy:

```
PowerShell

function Get-DeepClone
{
    [CmdletBinding()]
    param(
        $InputObject
    )
    process
    {
        if($InputObject -is [hashtable]) {
            $clone = @{}
            foreach($key in $InputObject.Keys)
            {
                $clone[$key] = Get-DeepClone $InputObject[$key]
            }
            return $clone
        } else {
            return $InputObject
        }
    }
}
```

```
        }
    }
}
```

It doesn't handle any other reference types or arrays, but it's a good starting point.

Another way is to use .NET to deserialize it using **CliXml** like in this function:

PowerShell

```
function Get-DeepClone
{
    param(
        $InputObject
    )
    $TempCliXmlString =
[System.Management.Automation.PSSerializer]::Serialize($obj,
[int32]::.MaxValue)
    return
[System.Management.Automation.PSSerializer]::Deserialize($TempCliXmlString)
}
```

For extremely large hashtables, the deserializing function is faster as it scales out. However, there are some things to consider when using this method. Since it uses **CliXml**, it's memory intensive and if you are cloning huge hashtables, that might be a problem. Another limitation of the **CliXml** is there is a depth limitation of 48. Meaning, if you have a hashtable with 48 layers of nested hashtables, the cloning will fail and no hashtable will be output at all.

Anything else?

I covered a lot of ground quickly. My hope is that you walk away leaning something new or understanding it better every time you read this. Because I covered the full spectrum of this feature, there are aspects that just may not apply to you right now. That is perfectly OK and is kind of expected depending on how much you work with PowerShell.

Everything you wanted to know about PSCustomObject

Article • 06/20/2024

`PSCustomObject` is a great tool to add into your PowerShell tool belt. Let's start with the basics and work our way into the more advanced features. The idea behind using a `PSCustomObject` is to have a simple way to create structured data. Take a look at the first example and you'll have a better idea of what that means.

ⓘ Note

The [original version](#) of this article appeared on the blog written by [@KevinMarquette](#). The PowerShell team thanks Kevin for sharing this content with us. Please check out his blog at [PowerShellExplained.com](#).

Creating a PSCustomObject

I love using `[pscustomobject]` in PowerShell. Creating a usable object has never been easier. Because of that, I'm going to skip over all the other ways you can create an object but I need to mention that most of these examples are PowerShell v3.0 and newer.

PowerShell

```
$myObject = [pscustomobject]@{  
    Name      = 'Kevin'  
    Language  = 'PowerShell'  
    State     = 'Texas'  
}
```

This method works well for me because I use hashtables for just about everything. But there are times when I would like PowerShell to treat hashtables more like an object. The first place you notice the difference is when you want to use `Format-Table` or `Export-Csv` and you realize that a hashtable is just a collection of key/value pairs.

You can then access and use the values like you would a normal object.

PowerShell

```
$myObject.Name
```

Converting a hashtable

While I am on the topic, did you know you could do this:

PowerShell

```
$myHashtable = @{
    Name      = 'Kevin'
    Language = 'PowerShell'
    State     = 'Texas'
}
$myObject = [pscustomobject]$myHashtable
```

I do prefer to create the object from the start but there are times you have to work with a hashtable first. This example works because the constructor takes a hashtable for the object properties. One important note is that while this method works, it isn't an exact equivalent. The biggest difference is that the order of the properties isn't preserved.

If you want to preserve the order, see [Ordered hashtables](#).

Legacy approach

You may have seen people use `New-Object` to create custom objects.

PowerShell

```
$myHashtable = @{
    Name      = 'Kevin'
    Language = 'PowerShell'
    State     = 'Texas'
}

$myObject = New-Object -TypeName psobject -Property $myHashtable
```

This way is quite a bit slower but it may be your best option on early versions of PowerShell.

Saving to a file

I find the best way to save a hashtable to a file is to save it as JSON. You can import it back into a `[pscustomobject]`

```
PowerShell
```

```
$myObject | ConvertTo-Json -Depth 1 | Set-Content -Path $Path  
$myObject = Get-Content -Path $Path | ConvertFrom-Json
```

I cover more ways to save objects to a file in my article on [The many ways to read and write to files ↗](#).

Working with properties

Adding properties

You can still add new properties to your `PSCustomObject` with `Add-Member`.

```
PowerShell
```

```
$myObject | Add-Member -MemberType NoteProperty -Name 'ID' -Value  
'KevinMarquette'  
  
$myObject.ID
```

Remove properties

You can also remove properties off of an object.

```
PowerShell
```

```
$myObject.psobject.Properties.Remove('ID')
```

The `.psobject` is an intrinsic member that gives you access to base object metadata. For more information about intrinsic members, see [about_Intrinsic_Members](#).

Enumerating property names

Sometimes you need a list of all the property names on an object.

```
PowerShell
```

```
$myObject | Get-Member -MemberType NoteProperty | select -ExpandProperty  
Name
```

We can get this same list off of the `psobject` property too.

```
PowerShell
```

```
$myobject.psobject.Properties.Name
```

 **Note**

`Get-Member` returns the properties in alphabetical order. Using the member-access operator to enumerate the property names returns the properties in the order they were defined on the object.

Dynamically accessing properties

I already mentioned that you can access property values directly.

```
PowerShell
```

```
$myObject.Name
```

You can use a string for the property name and it will still work.

```
PowerShell
```

```
$myObject.'Name'
```

We can take this one more step and use a variable for the property name.

```
PowerShell
```

```
$property = 'Name'  
$myObject.$property
```

I know that looks strange, but it works.

Convert `PSCustomObject` into a hashtable

To continue on from the last section, you can dynamically walk the properties and create a hashtable from them.

```
PowerShell
```

```
$hashtable = @{}
foreach( $property in $myobject.psobject.Properties.Name )
{
    $hashtable[$property] = $myObject.$property
}
```

Testing for properties

If you need to know if a property exists, you could just check for that property to have a value.

PowerShell

```
if( $null -ne $myObject.ID )
```

But if the value could be `$null` you can check to see if it exists by checking the `psobject.Properties` for it.

PowerShell

```
if( $myobject.psobject.Properties.Match('ID').Count )
```

Adding object methods

If you need to add a script method to an object, you can do it with `Add-Member` and a `ScriptBlock`. You have to use the `this` automatic variable reference the current object. Here is a `scriptblock` to turn an object into a hashtable. (same code form the last example)

PowerShell

```
$ScriptBlock = {
    $hashtable = @{}
    foreach( $property in $this.psobject.Properties.Name )
    {
        $hashtable[$property] = $this.$property
    }
    return $hashtable
}
```

Then we add it to our object as a script property.

```
PowerShell
```

```
$memberParam = @{
    MemberType = "ScriptMethod"
    InputObject = $myobject
    Name = "ToHashtable"
    Value = $scriptBlock
}
Add-Member @memberParam
```

Then we can call our function like this:

```
PowerShell
```

```
$myObject.ToHashtable()
```

Objects vs Value types

Objects and value types don't handle variable assignments the same way. If you assign value types to each other, only the value get copied to the new variable.

```
PowerShell
```

```
$first = 1
$second = $first
$second = 2
```

In this case, `$first` is 1 and `$second` is 2.

Object variables hold a reference to the actual object. When you assign one object to a new variable, they still reference the same object.

```
PowerShell
```

```
$third = [pscustomobject]@{Key=3}
$fourth = $third
$fourth.Key = 4
```

Because `$third` and `$fourth` reference the same instance of an object, both `$third.Key` and `$fourth.Key` are 4.

psobject.Copy()

If you need a true copy of an object, you can clone it.

PowerShell

```
$third = [pscustomobject]@{Key=3}
$fourth = $third.psobject.Copy()
$fourth.Key = 4
```

Clone creates a shallow copy of the object. They have different instances now and `$third.Key` is 3 and `$fourth.Key` is 4 in this example.

I call this a shallow copy because if you have nested objects (objects with properties contain other objects), only the top-level values are copied. The child objects will reference each other.

PSTypeName for custom object types

Now that we have an object, there are a few more things we can do with it that may not be nearly as obvious. First thing we need to do is give it a `PSTypeName`. This is the most common way I see people do it:

PowerShell

```
$myObject.psobject.TypeNames.Insert(0, "My.Object")
```

I recently discovered another way to do this from Redditor [u/markekraus](#). He talks about this approach that allows you to define it inline.

PowerShell

```
$myObject = [pscustomobject]@{
    PSTypeName = 'My.Object'
    Name      = 'Kevin'
    Language   = 'PowerShell'
    State     = 'Texas'
}
```

I love how nicely this just fits into the language. Now that we have an object with a proper type name, we can do some more things.

ⓘ Note

You can also create custom PowerShell types using PowerShell classes. For more information, see [PowerShell Class Overview](#).

Using DefaultPropertySet (the long way)

PowerShell decides for us what properties to display by default. A lot of the native commands have a `.ps1xml` [formatting file](#) that does all the heavy lifting. From this [post by Boe Prox](#), there's another way for us to do this on our custom object using just PowerShell. We can give it a `MemberSet` for it to use.

PowerShell

```
$defaultDisplaySet = 'Name', 'Language'  
$defaultDisplayPropertySet = New-Object  
System.Management.Automation.PSPropertySet('DefaultDisplayPropertySet',  
[string[]]$defaultDisplaySet)  
$PSStandardMembers =  
[System.Management.Automation.PSMemberInfo[]]@($defaultDisplayPropertySet)  
$MyObject | Add-Member MemberSet PSStandardMembers $PSStandardMembers
```

Now when my object just falls to the shell, it will only show those properties by default.

Update-TypeData with DefaultPropertySet

This is nice but I recently saw a better way using `Update-TypeData` to specify the default properties.

PowerShell

```
$TypeData = @{  
    TypeName = 'My.Object'  
    DefaultDisplayPropertySet = 'Name', 'Language'  
}  
Update-TypeData @TypeData
```

That is simple enough that I could almost remember it if I didn't have this post as a quick reference. Now I can easily create objects with lots of properties and still give it a nice clean view when looking at it from the shell. If I need to access or see those other properties, they're still there.

PowerShell

```
$myObject | Format-List *
```

Update-TypeData with ScriptProperty

Something else I got out of that video was creating script properties for your objects. This would be a good time to point out that this works for existing objects too.

```
PowerShell

$TypeData = @{
    TypeName = 'My.Object'
    MemberType = 'ScriptProperty'
    MemberName = 'UpperCaseName'
    Value = {$this.Name.ToUpper()}
}
Update-TypeData @TypeData
```

You can do this before your object is created or after and it will still work. This is what makes this different than using `Add-Member` with a script property. When you use `Add-Member` the way I referenced earlier, it only exists on that specific instance of the object. This one applies to all objects with this `TypeName`.

Function parameters

You can now use these custom types for parameters in your functions and scripts. You can have one function create these custom objects and then pass them into other functions.

```
PowerShell

param( [PSTypeName('My.Object')]$Data )
```

PowerShell requires that the object is the type you specified. It throws a validation error if the type doesn't match automatically to save you the step of testing for it in your code. A great example of letting PowerShell do what it does best.

Function OutputType

You can also define an `OutputType` for your advanced functions.

```
PowerShell

function Get-MyObject
{
    [OutputType('My.Object')]
    [CmdletBinding()]
    param
```

```
(  
...)
```

The **OutputType** attribute value is only a documentation note. It isn't derived from the function code or compared to the actual function output.

The main reason you would use an output type is so that meta information about your function reflects your intentions. Things like `Get-Command` and `Get-Help` that your development environment can take advantage of. If you want more information, then take a look at the help for it: [about_Functions_OutputTypeAttribute](#).

With that said, if you're using Pester to unit test your functions then it would be a good idea to validate the output objects match your **OutputType**. This could catch variables that just fall to the pipe when they shouldn't.

Closing thoughts

The context of this was all about `[pscustomobject]`, but a lot of this information applies to objects in general.

I have seen most of these features in passing before but never saw them presented as a collection of information on `PSCustomObject`. Just this last week I stumbled upon another one and was surprised that I had not seen it before. I wanted to pull all these ideas together so you can hopefully see the bigger picture and be aware of them when you have an opportunity to use them. I hope you learned something and can find a way to work this into your scripts.

Everything you wanted to know about variable substitution in strings

Article • 06/20/2024

There are many ways to use variables in strings. I'm calling this variable substitution but I'm referring to any time you want to format a string to include values from variables. This is something that I often find myself explaining to new scripters.

ⓘ Note

The [original version](#) of this article appeared on the blog written by [@KevinMarquette](#). The PowerShell team thanks Kevin for sharing this content with us. Please check out his blog at [PowerShellExplained.com](#).

Concatenation

The first class of methods can be referred to as concatenation. It's basically taking several strings and joining them together. There's a long history of using concatenation to build formatted strings.

PowerShell

```
$name = 'Kevin Marquette'  
$message = 'Hello, ' + $name
```

Concatenation works out OK when there are only a few values to add. But this can get complicated quickly.

PowerShell

```
$first = 'Kevin'  
$last = 'Marquette'
```

PowerShell

```
$message = 'Hello, ' + $first + ' ' + $last + '.'
```

This simple example is already getting harder to read.

Variable substitution

PowerShell has another option that is easier. You can specify your variables directly in the strings.

```
PowerShell
```

```
$message = "Hello, $first $last."
```

The type of quotes you use around the string makes a difference. A double quoted string allows the substitution but a single quoted string doesn't. There are times you want one or the other so you have an option.

Command substitution

Things get a little tricky when you start trying to get the values of properties into a string. This is where many new people get tripped up. First let me show you what they think should work (and at face value almost looks like it should).

```
PowerShell
```

```
$directory = Get-Item 'C:\windows'  
$message = "Time: $directory.CreationTime"
```

You would be expecting to get the `CreationTime` off of the `$directory`, but instead you get this `Time: C:\windows.CreationTime` as your value. The reason is that this type of substitution only sees the base variable. It considers the period as part of the string so it stops resolving the value any deeper.

It just so happens that this object gives a string as a default value when placed into a string. Some objects give you the type name instead like `System.Collections.Hashtable`. Just something to watch for.

PowerShell allows you to do command execution inside the string with a special syntax. This allows us to get the properties of these objects and run any other command to get a value.

```
PowerShell
```

```
$message = "Time: $($directory.CreationTime)"
```

This works great for some situations but it can get just as crazy as concatenation if you have just a few variables.

Command execution

You can run commands inside a string. Even though I have this option, I don't like it. It gets cluttered quickly and hard to debug. I either run the command and save to a variable or use a format string.

```
PowerShell
```

```
$message = "Date: $(Get-Date)"
```

Format string

.NET has a way to format strings that I find fairly easy to work with. First let me show you the static method for it before I show you the PowerShell shortcut to do the same thing.

```
PowerShell
```

```
# .NET string format string
[string]::Format('Hello, {0} {1}.',$first,$last)

# PowerShell format string
'Hello, {0} {1}.' -f $first, $last
```

What is happening here is that the string is parsed for the tokens `{0}` and `{1}`, then it uses that number to pick from the values provided. If you want to repeat one value some place in the string, you can reuse that values number.

The more complicated the string gets, the more value you get out of this approach.

Format values as arrays

If your format line gets too long, you can place your values into an array first.

```
PowerShell
```

```
$values = @(
    "Kevin"
    "Marquette"
)
'Hello, {0} {1}.' -f $values
```

This is not splatting because I'm passing the whole array in, but the idea is similar.

Advanced formatting

I intentionally called these out as coming from .NET because there are lots of formatting options already well [documented](#) on it. There are built-in ways to format various data types.

PowerShell

```
"{0:yyyyMMdd}" -f (Get-Date)  
"Population {0:N0}" -f 8175133
```

Output

```
20211110  
Population 8,175,133
```

I'm not going to go into them but I just wanted to let you know that this is a very powerful formatting engine if you need it.

Joining strings

Sometimes you actually do want to concatenate a list of values together. There's a `-join` operator that can do that for you. It even lets you specify a character to join between the strings.

PowerShell

```
$servers = @(  
    'server1'  
    'server2'  
    'server3'  
)  
  
$servers -join ','
```

If you want to `-join` some strings without a separator, you need to specify an empty string `''`. But if that is all you need, there's a faster option.

PowerShell

```
[string]::Concat('server1','server2','server3')
[string]::Concat($servers)
```

It's also worth pointing out that you can also `-split` strings too.

Join-Path

This is often overlooked but a great cmdlet for building a file path.

PowerShell

```
$folder = 'Temp'
Join-Path -Path 'C:\windows' -ChildPath $folder
```

The great thing about this is it works out the backslashes correctly when it puts the values together. This is especially important if you are taking values from users or config files.

This also goes well with `Split-Path` and `Test-Path`. I also cover these in my post about [reading and saving to files ↗](#).

Strings are arrays

I do need to mention adding strings here before I go on. Remember that a string is just an array of characters. When you add multiple strings together, a new array is created each time.

Look at this example:

PowerShell

```
$message = "Numbers: "
foreach($number in 1..10000)
{
    $message += " $number"
}
```

It looks very basic but what you don't see is that each time a string is added to `$message` that a whole new string is created. Memory gets allocated, data gets copied and the old one is discarded. Not a big deal when it's only done a few times, but a loop like this would really expose the issue.

StringBuilder

StringBuilder is also very popular for building large strings from lots of smaller strings. The reason why is because it just collects all the strings you add to it and only concatenates all of them at the end when you retrieve the value.

PowerShell

```
$stringBuilder = New-Object -TypeName "System.Text.StringBuilder"

[void]$stringBuilder.Append("Numbers: ")
foreach($number in 1..10000)
{
    [void]$stringBuilder.Append(" $number")
}
$message = $stringBuilder.ToString()
```

Again, this is something that I'm reaching out to .NET for. I don't use it often anymore but it's good to know it's there.

Delineation with braces

This is used for suffix concatenation within the string. Sometimes your variable doesn't have a clean word boundary.

PowerShell

```
$test = "Bet"
$tester = "Better"
Write-Host "$test $tester ${test}ter"
```

Thank you Redditor [u/real_parbold](#) for that one.

Here is an alternate to this approach:

PowerShell

```
Write-Host "$test $tester $($test)ter"
Write-Host "{0} {1} {0}ter" -f $test, $tester
```

I personally use format string for this, but this is good to know incase you see it in the wild.

Find and replace tokens

While most of these features limit your need to roll your own solution, there are times where you may have large template files where you want to replace strings inside.

Let us assume you pulled in a template from a file that has a lot of text.

```
PowerShell
```

```
$letter = Get-Content -Path TemplateLetter.txt -RAW  
$letter = $letter -replace '#FULL_NAME#', 'Kevin Marquette'
```

You may have lots of tokens to replace. The trick is to use a very distinct token that is easy to find and replace. I tend to use a special character at both ends to help distinguish it.

I recently found a new way to approach this. I decided to leave this section in here because this is a pattern that is commonly used.

Replace multiple tokens

When I have a list of tokens that I need to replace, I take a more generic approach. I would place them in a hashtable and iterate over them to do the replace.

```
PowerShell
```

```
$tokenList = @{  
    Full_Name = 'Kevin Marquette'  
    Location = 'Orange County'  
    State = 'CA'  
}  
  
$letter = Get-Content -Path TemplateLetter.txt -RAW  
foreach( $token in $tokenList.GetEnumerator() )  
{  
    $pattern = '#{0}#' -f $token.key  
    $letter = $letter -replace $pattern, $token.Value  
}
```

Those tokens could be loaded from JSON or CSV if needed.

ExecutionContext ExpandString

There's a clever way to define a substitution string with single quotes and expand the variables later. Look at this example:

```
PowerShell
```

```
$message = 'Hello, $Name!'
$name = 'Kevin Marquette'
$string = $ExecutionContext.InvokeCommand.ExpandString($message)
```

The call to `InvokeCommand.ExpandString` on the current execution context uses the variables in the current scope for substitution. The key thing here is that the `$message` can be defined very early before the variables even exist.

If we expand on that just a little bit, we can perform this substitution over and over with different values.

PowerShell

```
$message = 'Hello, $Name!'
$nameList = 'Mark Kraus','Kevin Marquette','Lee Dailey'
foreach($name in $nameList){
    $ExecutionContext.InvokeCommand.ExpandString($message)
}
```

To keep going on this idea; you could be importing a large email template from a text file to do this. I have to thank [Mark Kraus ↗](#) for this suggestion.

Whatever works the best for you

I'm a fan of the format string approach. I definitely do this with the more complicated strings or if there are multiple variables. On anything that is very short, I may use any one of these.

Anything else?

I covered a lot of ground on this one. My hope is that you walk away learning something new.

Links

If you'd like to learn more about the methods and features that make string interpolation possible, see the following list for the reference documentation.

- Concatenation uses the [addition operator](#)
- Variable and command substitution follow the [quoting rules](#)
- Formatting uses the [format operator](#)

- Joining strings uses the [join operator](#) and references [Join-Path](#), but you could also read about [Join-String](#)
- Arrays are documented in [About arrays](#)
- `StringBuilder` is a .NET class, with its [own documentation](#)
- Braces in strings is also covered in the [quoting rules](#)
- Token replacement uses the [replace operator](#)
- The `$ExecutionContext.InvokeCommand.ExpandString()` method has [.NET API reference documentation](#)

Everything you wanted to know about the `if` statement

Article • 12/18/2023

Like many other languages, PowerShell has statements for conditionally executing code in your scripts. One of those statements is the `If` statement. Today we will take a deep dive into one of the most fundamental commands in PowerShell.

ⓘ Note

The [original version](#) of this article appeared on the blog written by [@KevinMarquette](#). The PowerShell team thanks Kevin for sharing this content with us. Please check out his blog at [PowerShellExplained.com](#).

Conditional execution

Your scripts often need to make decisions and perform different logic based on those decisions. This is what I mean by conditional execution. You have one statement or value to evaluate, then execute a different section of code based on that evaluation. This is exactly what the `if` statement does.

The `if` statement

Here is a basic example of the `if` statement:

```
PowerShell

$condition = $true
if ( $condition )
{
    Write-Output "The condition was true"
}
```

The first thing the `if` statement does is evaluate the expression in parentheses. If it evaluates to `$true`, then it executes the `scriptblock` in the braces. If the value was `$false`, then it would skip over that scriptblock.

In the previous example, the `if` statement was just evaluating the `$condition` variable. It was `$true` and would have executed the `Write-Output` command inside the

scriptblock.

In some languages, you can place a single line of code after the `if` statement and it gets executed. That isn't the case in PowerShell. You must provide a full `scriptblock` with braces for it to work correctly.

Comparison operators

The most common use of the `if` statement for is comparing two items with each other. PowerShell has special operators for different comparison scenarios. When you use a comparison operator, the value on the left-hand side is compared to the value on the right-hand side.

-eq for equality

The `-eq` does an equality check between two values to make sure they're equal to each other.

PowerShell

```
$value = Get-MysteryValue
if ( 5 -eq $value )
{
    # do something
}
```

In this example, I'm taking a known value of `5` and comparing it to my `$value` to see if they match.

One possible use case is to check the status of a value before you take an action on it. You could get a service and check that the status was running before you called `Restart-Service` on it.

It's common in other languages like C# to use `==` for equality (ex: `5 == $value`) but that doesn't work with PowerShell. Another common mistake that people make is to use the equals sign (ex: `5 = $value`) that is reserved for assigning values to variables. By placing your known value on the left, it makes that mistake more awkward to make.

This operator (and others) has a few variations.

- `-eq` case-insensitive equality
- `-ieq` case-insensitive equality
- `-ceq` case-sensitive equality

-ne not equal

Many operators have a related operator that is checking for the opposite result. `-ne` verifies that the values don't equal each other.

PowerShell

```
if ( 5 -ne $value )  
{  
    # do something  
}
```

Use this to make sure that the action only executes if the value isn't `5`. A good use-cases where would be to check if a service was in the running state before you try to start it.

Variations:

- `-ne` case-insensitive not equal
- `-ine` case-insensitive not equal
- `-cne` case-sensitive not equal

These are inverse variations of `-eq`. I'll group these types together when I list variations for other operators.

-gt -ge -lt -le for greater than or less than

These operators are used when checking to see if a value is larger or smaller than another value. The `-gt -ge -lt -le` stand for GreaterThan, GreaterThanOrEqual, LessThan, and LessThanOrEqual.

PowerShell

```
if ( $value -gt 5 )  
{  
    # do something  
}
```

Variations:

- `-gt` greater than
- `-igt` greater than, case-insensitive
- `-cgt` greater than, case-sensitive
- `-ge` greater than or equal

- `-ige` greater than or equal, case-insensitive
- `-cge` greater than or equal, case-sensitive
- `-lt` less than
- `-ilt` less than, case-insensitive
- `-clt` less than, case-sensitive
- `-le` less than or equal
- `-ile` less than or equal, case-insensitive
- `-cle` less than or equal, case-sensitive

I don't know why you would use case-sensitive and insensitive options for these operators.

-like wildcard matches

PowerShell has its own wildcard-based pattern matching syntax and you can use it with the `-like` operator. These wildcard patterns are fairly basic.

- `?` matches any single character
- `*` matches any number of characters

PowerShell

```
$value = 'S-ATX-SQL01'
if ( $value -like 'S-*SQL??' )
{
    # do something
}
```

It's important to point out that the pattern matches the whole string. If you need to match something in the middle of the string, you need to place the `*` on both ends of the string.

PowerShell

```
$value = 'S-ATX-SQL02'
if ( $value -like '*SQL*' )
{
    # do something
}
```

Variations:

- `-like` case-insensitive wildcard

- `-ilike` case-insensitive wildcard
- `-clike` case-sensitive wildcard
- `-notlike` case-insensitive wildcard not matched
- `-inotlike` case-insensitive wildcard not matched
- `-cnotlike` case-sensitive wildcard not matched

-match regular expression

The `-match` operator allows you to check a string for a regular-expression-based match. Use this when the wildcard patterns aren't flexible enough for you.

PowerShell

```
$value = 'S-ATX-SQL01'
if ( $value -match 'S-\w\w\w-SQL\d\d' )
{
    # do something
}
```

A regex pattern matches anywhere in the string by default. So you can specify a substring that you want matched like this:

PowerShell

```
$value = 'S-ATX-SQL01'
if ( $value -match 'SQL' )
{
    # do something
}
```

Regex is a complex language of its own and worth looking into. I talk more about `-match` and [the many ways to use regex ↗](#) in another article.

Variations:

- `-match` case-insensitive regex
- `-imatch` case-insensitive regex
- `-cmatch` case-sensitive regex
- `-notmatch` case-insensitive regex not matched
- `-inotmatch` case-insensitive regex not matched
- `-cnotmatch` case-sensitive regex not matched

-is of type

You can check a value's type with the `-is` operator.

PowerShell

```
if ( $value -is [string] )
{
    # do something
}
```

You may use this if you're working with classes or accepting various objects over the pipeline. You could have either a service or a service name as your input. Then check to see if you have a service and fetch the service if you only have the name.

PowerShell

```
if ( $Service -isnot [System.ServiceProcess.ServiceController] )
{
    $Service = Get-Service -Name $Service
}
```

Variations:

- `-is` of type
- `-isnot` not of type

Collection operators

When you use the previous operators with a single value, the result is `$true` or `$false`. This is handled slightly differently when working with a collection. Each item in the collection gets evaluated and the operator returns every value that evaluates to `$true`.

PowerShell

```
PS> 1,2,3,4 -eq 3
3
```

This still works correctly in an `if` statement. So a value is returned by your operator, then the whole statement is `$true`.

PowerShell

```
$array = 1..6
if ( $array -gt 3 )
{
```

```
# do something  
}
```

There's one small trap hiding in the details here that I need to point out. When using the `-ne` operator this way, it's easy to mistakenly look at the logic backwards. Using `-ne` with a collection returns `$true` if any item in the collection doesn't match your value.

PowerShell

```
PS> 1,2,3 -ne 4  
1  
2  
3
```

This may look like a clever trick, but we have operators `-contains` and `-in` that handle this more efficiently. And `-notcontains` does what you expect.

-contains

The `-contains` operator checks the collection for your value. As soon as it finds a match, it returns `$true`.

PowerShell

```
$array = 1..6  
if ( $array -contains 3 )  
{  
    # do something  
}
```

This is the preferred way to see if a collection contains your value. Using `Where-Object` (or `-eq`) walks the entire list every time and is significantly slower.

Variations:

- `-contains` case-insensitive match
- `-icontains` case-insensitive match
- `-cccontains` case-sensitive match
- `-notcontains` case-insensitive not matched
- `-inotcontains` case-insensitive not matched
- `-cnotcontains` case-sensitive not matched

-in

The `-in` operator is just like the `-contains` operator except the collection is on the right-hand side.

PowerShell

```
$array = 1..6
if ( 3 -in $array )
{
    # do something
}
```

Variations:

- `-in` case-insensitive match
- `-iin` case-insensitive match
- `-cin` case-sensitive match
- `-notin` case-insensitive not matched
- `-inotin` case-insensitive not matched
- `-cnotin` case-sensitive not matched

Logical operators

Logical operators are used to invert or combine other expressions.

-not

The `-not` operator flips an expression from `$false` to `$true` or from `$true` to `$false`. Here is an example where we want to perform an action when `Test-Path` is `$false`.

PowerShell

```
if ( -not ( Test-Path -Path $path ) )
```

Most of the operators we talked about do have a variation where you do not need to use the `-not` operator. But there are still times it is useful.

! operator

You can use `!` as an alias for `-not`.

PowerShell

```
if ( -not $value ){}  
if ( !$value ){}
```

You may see `!` used more by people that come from another languages like C#. I prefer to type it out because I find it hard to see when quickly looking at my scripts.

-and

You can combine expressions with the `-and` operator. When you do that, both sides need to be `$true` for the whole expression to be `$true`.

PowerShell

```
if ( ($age -gt 13) -and ($age -lt 55) )
```

In that example, `$age` must be 13 or older for the left side and less than 55 for the right side. I added extra parentheses to make it clearer in that example but they're optional as long as the expression is simple. Here is the same example without them.

PowerShell

```
if ( $age -gt 13 -and $age -lt 55 )
```

Evaluation happens from left to right. If the first item evaluates to `$false`, it exits early and doesn't perform the right comparison. This is handy when you need to make sure a value exists before you use it. For example, `Test-Path` throws an error if you give it a `$null` path.

PowerShell

```
if ( $null -ne $path -and (Test-Path -Path $path) )
```

-Or

The `-or` allows for you to specify two expressions and returns `$true` if either one of them is `$true`.

PowerShell

```
if ( $age -le 13 -or $age -ge 55 )
```

Just like with the `-and` operator, the evaluation happens from left to right. Except that if the first part is `$true`, then the whole statement is `$true` and it doesn't process the rest of the expression.

Also make note of how the syntax works for these operators. You need two separate expressions. I have seen users try to do something like this `$value -eq 5 -or 6` without realizing their mistake.

-xor exclusive or

This one is a little unusual. `-xor` allows only one expression to evaluate to `$true`. So if both items are `$false` or both items are `$true`, then the whole expression is `$false`.

Another way to look at this is the expression is only `$true` when the results of the expression are different.

It's rare that anyone would ever use this logical operator and I can't think up a good example as to why I would ever use it.

Bitwise operators

Bitwise operators perform calculations on the bits within the values and produce a new value as the result. Teaching [bitwise operators](#) is beyond the scope of this article, but here is the list of them.

- `-band` binary AND
- `-bor` binary OR
- `-bxor` binary exclusive OR
- `-bnot` binary NOT
- `-shl` shift left
- `-shr` shift right

PowerShell expressions

We can use normal PowerShell inside the condition statement.

```
PowerShell
```

```
if ( Test-Path -Path $Path )
```

`Test-Path` returns `$true` or `$false` when it executes. This also applies to commands that return other values.

PowerShell

```
if ( Get-Process Notepad* )
```

It evaluates to `$true` if there's a returned process and `$false` if there isn't. It's perfectly valid to use pipeline expressions or other PowerShell statements like this:

PowerShell

```
if ( Get-Process | where Name -EQ Notepad )
```

These expressions can be combined with each other with the `-and` and `-or` operators, but you may have to use parenthesis to break them into subexpressions.

PowerShell

```
if ( (Get-Process) -and (Get-Service) )
```

Checking for `$null`

Having a no result or a `$null` value evaluates to `$false` in the `if` statement. When checking specifically for `$null`, it's a best practice to place the `$null` on the left-hand side.

PowerShell

```
if ( $null -eq $value )
```

There are quite a few nuances when dealing with `$null` values in PowerShell. If you're interested in diving deeper, I have an article about [everything you wanted to know about `\$null`](#).

Variable assignment within the condition

I almost forgot to add this one until [Prasoon Karunan V](#) reminded me of it.

PowerShell

```
if ($process=Get-Process notepad -ErrorAction Ignore) {$process} else
{$false}
```

Normally when you assign a value to a variable, the value isn't passed onto the pipeline or console. When you do a variable assignment in a sub expression, it does get passed on to the pipeline.

PowerShell

```
PS> $first = 1
PS> ($second = 2)
2
```

See how the `$first` assignment has no output and the `$second` assignment does?

When an assignment is done in an `if` statement, it executes just like the `$second` assignment above. Here is a clean example on how you could use it:

PowerShell

```
if ( $process = Get-Process Notepad* )
{
    $process | Stop-Process
}
```

If `$process` gets assigned a value, then the statement is `$true` and `$process` gets stopped.

Make sure you don't confuse this with `-eq` because this isn't an equality check. This is a more obscure feature that most people don't realize works this way.

Variable assignment from the scriptblock

You can also use the `if` statement scriptblock to assign a value to a variable.

PowerShell

```
$discount = if ( $age -ge 55 )
{
    Get-SeniorDiscount
}
elseif ( $age -le 13 )
{
    Get-ChildDiscount
```

```
    }
else
{
    0.00
}
```

Each script block is writing the results of the commands, or the value, as output. We can assign the result of the `if` statement to the `$discount` variable. That example could have just as easily assigned those values to the `$discount` variable directly in each scriptblock. I can't say that I use this with the `if` statement often, but I do have an example where I used this recently.

Alternate execution path

The `if` statement allows you to specify an action for not only when the statement is `$true`, but also for when it's `$false`. This is where the `else` statement comes into play.

else

The `else` statement is always the last part of the `if` statement when used.

PowerShell

```
if ( Test-Path -Path $Path -PathType Leaf )
{
    Move-Item -Path $Path -Destination $archivePath
}
else
{
    Write-Warning "$path doesn't exist or isn't a file."
}
```

In this example, we check the `$path` to make sure it's a file. If we find the file, we move it. If not, we write a warning. This type of branching logic is very common.

Nested if

The `if` and `else` statements take a script block, so we can place any PowerShell command inside them, including another `if` statement. This allows you to make use of much more complicated logic.

PowerShell

```
if ( Test-Path -Path $Path -PathType Leaf )
{
    Move-Item -Path $Path -Destination $archivePath
}
else
{
    if ( Test-Path -Path $Path )
    {
        Write-Warning "A file was required but a directory was found instead."
    }
    else
    {
        Write-Warning "$path could not be found."
    }
}
```

In this example, we test the happy path first and then take action on it. If that fails, we do another check and to provide more detailed information to the user.

elseif

We aren't limited to just a single conditional check. We can chain `if` and `else` statements together instead of nesting them by using the `elseif` statement.

```
PowerShell

if ( Test-Path -Path $Path -PathType Leaf )
{
    Move-Item -Path $Path -Destination $archivePath
}
elseif ( Test-Path -Path $Path )
{
    Write-Warning "A file was required but a directory was found instead."
}
else
{
    Write-Warning "$path could not be found."
}
```

The execution happens from the top to the bottom. The top `if` statement is evaluated first. If that is `$false`, then it moves down to the next `elseif` or `else` in the list. That last `else` is the default action to take if none of the others return `$true`.

switch

At this point, I need to mention the `switch` statement. It provides an alternate syntax for doing multiple comparisons with a value. With the `switch`, you specify an expression and that result gets compared with several different values. If one of those values match, the matching code block is executed. Take a look at this example:

```
PowerShell

$itemType = 'Role'
switch ( $ itemType )
{
    'Component'
    {
        'is a component'
    }
    'Role'
    {
        'is a role'
    }
    'Location'
    {
        'is a location'
    }
}
```

There three possible values that can match the `$itemType`. In this case, it matches with `Role`. I used a simple example just to give you some exposure to the `switch` operator. I talk more about [everything you ever wanted to know about the switch statement](#) in another article.

Array inline

I have a function called [Invoke-SnowSql](#) that launches an executable with several command-line arguments. Here is a clip from that function where I build the array of arguments.

```
PowerShell

$snowSqlParam = @(
    '--accountname', $Endpoint
    '--username', $Credential.UserName
    '--option', 'exit_on_error=true'
    '--option', 'output_format=csv'
    '--option', 'friendly=false'
    '--option', 'timing=false'
    if ($Debug)
    {
        '--option', 'log_level=DEBUG'
    }
```

```

if ($Path)
{
    '--filename', $Path
}
else
{
    '--query', $singleLineQuery
}
)

```

The `$Debug` and `$Path` variables are parameters on the function that are provided by the end user. I evaluate them inline inside the initialization of my array. If `$Debug` is true, then those values fall into the `$snowSqlParam` in the correct place. Same holds true for the `$Path` variable.

Simplify complex operations

It's inevitable that you run into a situation that has way too many comparisons to check and your `if` statement scrolls way off the right side of the screen.

PowerShell

```

$user = Get-ADUser -Identity $UserName
if ( $null -ne $user -and $user.Department -eq 'Finance' -and $user.Title -
match 'Senior' -and $user.HomeDrive -notlike '\\server\*' )
{
    # Do Something
}

```

They can be hard to read and that make you more prone to make mistakes. There are a few things we can do about that.

Line continuation

There some operators in PowerShell that let you wrap your command to the next line. The logical operators `-and` and `-or` are good operators to use if you want to break your expression into multiple lines.

PowerShell

```

if ($null -ne $user -and
    $user.Department -eq 'Finance' -and
    $user.Title -match 'Senior' -and
    $user.HomeDrive -notlike '\\server\*'
)

```

```
{  
    # Do Something  
}
```

There's still a lot going on there, but placing each piece on its own line makes a big difference. I generally use this when I get more than two comparisons or if I have to scroll to the right to read any of the logic.

Pre-calculating results

We can take that statement out of the `if` statement and only check the result.

```
PowerShell  
  
$needsSecureHomeDrive = $null -ne $user -and  
    $user.Department -eq 'Finance' -and  
    $user.Title -match 'Senior' -and  
    $user.HomeDrive -notlike '\\server*'  
  
if ( $needsSecureHomeDrive )  
{  
    # Do Something  
}
```

This just feels much cleaner than the previous example. You also are given an opportunity to use a variable name that explains what it's that you're really checking. This is also an example of self-documenting code that saves unnecessary comments.

Multiple if statements

We can break this up into multiple statements and check them one at a time. In this case, we use a flag or a tracking variable to combine the results.

```
PowerShell  
  
$skipUser = $false  
  
if( $null -eq $user )  
{  
    $skipUser = $true  
}  
  
if( $user.Department -ne 'Finance' )  
{  
    Write-Verbose "isn't in Finance department"  
    $skipUser = $true
```

```

}

if( $user.Title -match 'Senior' )
{
    Write-Verbose "Doesn't have Senior title"
    $skipUser = $true
}

if( $user.HomeDrive -like '\\server*' )
{
    Write-Verbose "Home drive already configured"
    $skipUser = $true
}

if ( -not $skipUser )
{
    # do something
}

```

I did have to invert the logic to make the flag logic work correctly. Each evaluation is an individual `if` statement. The advantage of this is that when you're debugging, you can tell exactly what the logic is doing. I was able to add much better verbosity at the same time.

The obvious downside is that it's so much more code to write. The code is more complex to look at as it takes a single line of logic and explodes it into 25 or more lines.

Using functions

We can also move all that validation logic into a function. Look at how clean this looks at a glance.

PowerShell

```

if ( Test-SecureDriveConfiguration -ADUser $user )
{
    # do something
}

```

You still have to create the function to do the validation, but it makes this code much easier to work with. It makes this code easier to test. In your tests, you can mock the call to `Test-ADDriveConfiguration` and you only need two tests for this function. One where it returns `$true` and one where it returns `$false`. Testing the other function is simpler because it's so small.

The body of that function could still be that one-liner we started with or the exploded logic that we used in the last section. This works well for both scenarios and allows you to easily change that implementation later.

Error handling

One important use of the `if` statement is to check for error conditions before you run into errors. A good example is to check if a folder already exists before you try to create it.

PowerShell

```
if ( -not (Test-Path -Path $folder) )
{
    New-Item -Type Directory -Path $folder
}
```

I like to say that if you expect an exception to happen, then it's not really an exception. So check your values and validate your conditions where you can.

If you want to dive a little more into actual exception handling, I have an article on [everything you ever wanted to know about exceptions](#).

Final words

The `if` statement is such a simple statement but is a fundamental piece of PowerShell. You will find yourself using this multiple times in almost every script you write. I hope you have a better understanding than you had before.

Everything you ever wanted to know about the switch statement

Article • 11/17/2022

Like many other languages, PowerShell has commands for controlling the flow of execution within your scripts. One of those statements is the `switch` statement and in PowerShell, it offers features that aren't found in other languages. Today, we take a deep dive into working with the PowerShell `switch`.

ⓘ Note

The [original version](#) of this article appeared on the blog written by [@KevinMarquette](#). The PowerShell team thanks Kevin for sharing this content with us. Please check out his blog at [PowerShellExplained.com](#).

The `if` statement

One of the first statements that you learn is the `if` statement. It lets you execute a script block if a statement is `$true`.

PowerShell

```
if ( Test-Path $Path )
{
    Remove-Item $Path
}
```

You can have much more complicated logic using `elseif` and `else` statements. Here is an example where I have a numeric value for day of the week and I want to get the name as a string.

PowerShell

```
$day = 3

if ( $day -eq 0 ) { $result = 'Sunday'      }
elseif ( $day -eq 1 ) { $result = 'Monday'     }
elseif ( $day -eq 2 ) { $result = 'Tuesday'    }
elseif ( $day -eq 3 ) { $result = 'Wednesday'  }
elseif ( $day -eq 4 ) { $result = 'Thursday'   }
elseif ( $day -eq 5 ) { $result = 'Friday'     }
elseif ( $day -eq 6 ) { $result = 'Saturday'  }
```

```
$result
```

Output

```
Wednesday
```

It turns out that this is a common pattern and there are many ways to deal with this. One of them is with a `switch`.

Switch statement

The `switch` statement allows you to provide a variable and a list of possible values. If the value matches the variable, then its scriptblock is executed.

PowerShell

```
$day = 3

switch ( $day )
{
    0 { $result = 'Sunday'      }
    1 { $result = 'Monday'      }
    2 { $result = 'Tuesday'     }
    3 { $result = 'Wednesday'   }
    4 { $result = 'Thursday'    }
    5 { $result = 'Friday'      }
    6 { $result = 'Saturday'    }
}

$result
```

Output

```
'Wednesday'
```

For this example, the value of `$day` matches one of the numeric values, then the correct name is assigned to `$result`. We're only doing a variable assignment in this example, but any PowerShell can be executed in those script blocks.

Assign to a variable

We can write that last example in another way.

PowerShell

```
$result = switch ( $day )
{
    0 { 'Sunday' }
    1 { 'Monday' }
    2 { 'Tuesday' }
    3 { 'Wednesday' }
    4 { 'Thursday' }
    5 { 'Friday' }
    6 { 'Saturday' }
}
```

We're placing the value on the PowerShell pipeline and assigning it to the `$result`. You can do this same thing with the `if` and `foreach` statements.

Default

We can use the `default` keyword to identify what should happen if there is no match.

PowerShell

```
$result = switch ( $day )
{
    0 { 'Sunday' }
    # ...
    6 { 'Saturday' }
    default { 'Unknown' }
}
```

Here we return the value `Unknown` in the default case.

Strings

I was matching numbers in those last examples, but you can also match strings.

PowerShell

```
$item = 'Role'

switch ( $item )
{
    Component
    {
        'is a component'
    }
}
```

```
Role
{
    'is a role'
}
Location
{
    'is a location'
}
}
```

Output

```
is a role
```

I decided not to wrap the `Component`, `Role` and `Location` matches in quotes here to highlight that they're optional. The `switch` treats those as a string in most cases.

Arrays

One of the cool features of the PowerShell `switch` is the way it handles arrays. If you give a `switch` an array, it processes each element in that collection.

PowerShell

```
$roles = @('WEB', 'Database')

switch ( $roles ) {
    'Database'   { 'Configure SQL' }
    'WEB'         { 'Configure IIS' }
    'FileServer' { 'Configure Share' }
}
```

Output

```
Configure IIS
Configure SQL
```

If you have repeated items in your array, then they're matched multiple times by the appropriate section.

PSItem

You can use the `$PSItem` or `$_` to reference the current item that was processed. When we do a simple match, `$PSItem` is the value that we're matching. I'll be performing some

advanced matches in the next section where this variable is used.

Parameters

A unique feature of the PowerShell `switch` is that it has a number of switch parameters that change how it performs.

-CaseSensitive

The matches aren't case-sensitive by default. If you need to be case-sensitive, you can use `-CaseSensitive`. This can be used in combination with the other switch parameters.

-Wildcard

We can enable wildcard support with the `-Wildcard` switch. This uses the same wildcard logic as the `-like` operator to do each match.

PowerShell

```
$Message = 'Warning, out of disk space'

switch -Wildcard ( $message )
{
    'Error*'
    {
        Write-Error -Message $Message
    }
    'Warning*'
    {
        Write-Warning -Message $Message
    }
    default
    {
        Write-Information $message
    }
}
```

Output

```
WARNING: Warning, out of disk space
```

Here we're processing a message and then outputting it on different streams based on the contents.

-Regex

The switch statement supports regex matches just like it does wildcards.

PowerShell

```
switch -Regex ( $message )
{
    '^Error'
    {
        Write-Error -Message $Message
    }
    '^Warning'
    {
        Write-Warning -Message $Message
    }
    default
    {
        Write-Information $message
    }
}
```

I have more examples of using regex in another article I wrote: [The many ways to use regex ↴](#).

-File

A little known feature of the switch statement is that it can process a file with the `-File` parameter. You use `-File` with a path to a file instead of giving it a variable expression.

PowerShell

```
switch -Wildcard -File $path
{
    'Error*'
    {
        Write-Error -Message $PSItem
    }
    'Warning*'
    {
        Write-Warning -Message $PSItem
    }
    default
    {
        Write-Output $PSItem
    }
}
```

It works just like processing an array. In this example, I combine it with wildcard matching and make use of the `$PSItem`. This would process a log file and convert it to warning and error messages depending on the regex matches.

Advanced details

Now that you're aware of all these documented features, we can use them in the context of more advanced processing.

Expressions

The `switch` can be on an expression instead of a variable.

PowerShell

```
switch ( ( Get-Service | where Status -EQ 'running' ).Name ) {...}
```

Whatever the expression evaluates to is the value used for the match.

Multiple matches

You may have already picked up on this, but a `switch` can match to multiple conditions. This is especially true when using `-Wildcard` or `-Regex` matches. You can add the same condition multiple times and all are triggered.

PowerShell

```
switch ( 'Word' )
{
    'word' { 'lower case word match' }
    'Word' { 'mixed case word match' }
    'WORD' { 'upper case word match' }
}
```

Output

```
lower case word match
mixed case word match
upper case word match
```

All three of these statements are fired. This shows that every condition is checked (in order). This holds true for processing arrays where each item checks each condition.

Continue

Normally, this is where I would introduce the `break` statement, but it's better that we learn how to use `continue` first. Just like with a `foreach` loop, `continue` continues onto the next item in the collection or exits the `switch` if there are no more items. We can rewrite that last example with `continue` statements so that only one statement executes.

PowerShell

```
switch ( 'Word' )
{
    'word'
    {
        'lower case word match'
        continue
    }
    'Word'
    {
        'mixed case word match'
        continue
    }
    'WORD'
    {
        'upper case word match'
        continue
    }
}
```

Output

```
lower case word match
```

Instead of matching all three items, the first one is matched and the switch continues to the next value. Because there are no values left to process, the switch exits. This next example is showing how a wildcard could match multiple items.

PowerShell

```
switch -Wildcard -File $path
{
    '*Error*'
    {
        Write-Error -Message $PSItem
        continue
    }
    '*Warning*'
    {
        Write-Warning -Message $PSItem
    }
}
```

```
        continue
    }
default
{
    Write-Output $PSItem
}
}
```

Because a line in the input file could contain both the word `Error` and `Warning`, we only want the first one to execute and then continue processing the file.

Break

A `break` statement exits the switch. This is the same behavior that `continue` presents for single values. The difference is shown when processing an array. `break` stops all processing in the switch and `continue` moves onto the next item.

PowerShell

```
$Messages = @(
    'Downloading update'
    'Ran into errors downloading file'
    'Error: out of disk space'
    'Sending email'
    '...'
)

switch -Wildcard ($Messages)
{
    'Error*'
    {
        Write-Error -Message $PSItem
        break
    }
    '*Error*'
    {
        Write-Warning -Message $PSItem
        continue
    }
    '*Warning*'
    {
        Write-Warning -Message $PSItem
        continue
    }
    default
    {
        Write-Output $PSItem
    }
}
```

Output

```
Downloading update
WARNING: Ran into errors downloading file
Write-Error -Message $PSItem : Error: out of disk space
+ CategoryInfo          : NotSpecified: (:) [Write-Error],
WriteErrorException
+ FullyQualifiedErrorCode : Microsoft.PowerShell.Commands.WriteErrorException
```

In this case, if we hit any lines that start with `Error` then we get an error and the switch stops. This is what that `break` statement is doing for us. If we find `Error` inside the string and not just at the beginning, we write it as a warning. We do the same thing for `Warning`. It's possible that a line could have both the word `Error` and `Warning`, but we only need one to process. This is what the `continue` statement is doing for us.

Break labels

The `switch` statement supports `break/continue` labels just like `foreach`.

PowerShell

```
:filelist foreach($path in $logs)
{
    :logFile switch -Wildcard -File $path
    {
        'Error*'
        {
            Write-Error -Message $PSItem
            break filelist
        }
        'Warning*'
        {
            Write-Error -Message $PSItem
            break logFile
        }
        default
        {
            Write-Output $PSItem
        }
    }
}
```

I personally don't like the use of break labels but I wanted to point them out because they're confusing if you've never seen them before. When you have multiple `switch` or `foreach` statements that are nested, you may want to break out of more than the inner most item. You can place a label on a `switch` that can be the target of your `break`.

Enum

PowerShell 5.0 gave us enums and we can use them in a switch.

```
PowerShell

enum Context {
    Component
    Role
    Location
}

$item = [Context]::Role

switch ( $item )
{
    Component
    {
        'is a component'
    }
    Role
    {
        'is a role'
    }
    Location
    {
        'is a location'
    }
}
```

```
Output
```

```
is a role
```

If you want to keep everything as strongly typed enums, then you can place them in parentheses.

```
PowerShell

switch ($item )
{
    ([Context]::Component)
    {
        'is a component'
    }
    ([Context]::Role)
    {
        'is a role'
    }
    ([Context]::Location)
```

```
{  
    'is a location'  
}  
}
```

The parentheses are needed here so that the switch doesn't treat the value `[Context]::Location` as a literal string.

ScriptBlock

We can use a scriptblock to perform the evaluation for a match if needed.

PowerShell

```
$age = 37  
  
switch ( $age )  
{  
    {$PSItem -le 18}  
    {  
        'child'  
    }  
    {$PSItem -gt 18}  
    {  
        'adult'  
    }  
}
```

Output

```
'adult'
```

This adds complexity and can make your `switch` hard to read. In most cases where you would use something like this it would be better to use `if` and `elseif` statements. I would consider using this if I already had a large switch in place and I needed two items to hit the same evaluation block.

One thing that I think helps with legibility is to place the scriptblock in parentheses.

PowerShell

```
switch ( $age )  
{  
    ($PSItem -le 18)  
    {  
        'child'  
    }  
}
```

```

    ($PSItem -gt 18)
{
    'adult'
}
}

```

It still executes the same way and gives a better visual break when quickly looking at it.

Regex \$Matches

We need to revisit regex to touch on something that isn't immediately obvious. The use of regex populates the `$Matches` variable. I do go into the use of `$Matches` more when I talk about [The many ways to use regex](#). Here is a quick sample to show it in action with named matches.

PowerShell

```

$message = 'my ssn is 123-23-3456 and credit card: 1234-5678-1234-5678'

switch -Regex ($message)
{
    '(?<SSN>\d\d\d-\d\d-\d\d\d\d\d)' {
        Write-Warning "message contains a SSN: $($Matches.SSN)"
    }
    '(?<CC>\d\d\d\d-\d\d\d\d-\d\d\d\d-\d\d\d\d\d\d)' {
        Write-Warning "message contains a credit card number:
 $($Matches.CC)"
    }
    '(?<Phone>\d\d\d-\d\d\d\d-\d\d\d\d\d)' {
        Write-Warning "message contains a phone number: $($Matches.Phone)"
    }
}

```

Output

```

WARNING: message may contain a SSN: 123-23-3456
WARNING: message may contain a credit card number: 1234-5678-1234-5678

```

\$null

You can match a `$null` value that doesn't have to be the default.

PowerShell

```
$values = '', 5, $null
switch ( $values )
{
    $null          { "Value '$_' is `$null" }
    '' -eq $_     { "Value '$_' is an empty string" }
    default       { "Value [$_] isn't an empty string or `$null" }
}
```

Output

```
Value '' is an empty string
Value [5] isn't an empty string or $null
Value '' is $null
```

When testing for an empty string in a `switch` statement, it's important to use the comparison statement as shown in this example instead of the raw value `''`. In a `switch` statement, the raw value `''` also matches `$null`. For example:

PowerShell

```
$values = '', 5, $null
switch ( $values )
{
    $null          { "Value '$_' is `$null" }
    ''            { "Value '$_' is an empty string" }
    default       { "Value [$_] isn't an empty string or `$null" }
}
```

Output

```
Value '' is an empty string
Value [5] isn't an empty string or $null
Value '' is $null
Value '' is an empty string
```

Also, be careful with empty returns from cmdlets. Cmdlets or pipelines that have no output are treated as an empty array that doesn't match anything, including the `default` case.

PowerShell

```
$file = Get-ChildItem NonExistantFile*
switch ( $file )
{
    $null      { '$file is $null' }
    default   { "`$file is type $($file.GetType().Name)" }
```

```
}
```

No matches

Constant expression

Lee Dailey pointed out that we can use a constant `$true` expression to evaluate `[bool]` items. Imagine if we have several boolean checks that need to happen.

PowerShell

```
$isVisible = $false
$isEnabled = $true
$isSecure = $true

switch ( $true )
{
    $isEnabled
    {
        'Do-Action'
    }
    $isVisible
    {
        'Show-Animation'
    }
    $isSecure
    {
        'Enable-AdminMenu'
    }
}
```

Output

```
Do-Action
Enabled-AdminMenu
```

This is a clean way to evaluate and take action on the status of several boolean fields. The cool thing about this is that you can have one match flip the status of a value that hasn't been evaluated yet.

PowerShell

```
$isVisible = $false
$isEnabled = $true
$isAdmin = $false

switch ( $true )
{
    $isEnabled
    {
```

```
{  
    'Do-Action'  
    $isVisible = $true  
}  
$isVisible  
{  
    'Show-Animation'  
}  
$isAdmin  
{  
    'Enable-AdminMenu'  
}  
}
```

Output

```
Do-Action  
Show-Animation
```

Setting `$isEnabled` to `$true` in this example makes sure that `$isVisible` is also set to `$true`. Then when `$isVisible` gets evaluated, its scriptblock is invoked. This is a bit counter-intuitive but is a clever use of the mechanics.

\$switch automatic variable

When the `switch` is processing its values, it creates an enumerator and calls it `$switch`. This is an automatic variable created by PowerShell and you can manipulate it directly.

PowerShell

```
$a = 1, 2, 3, 4  
  
switch($a) {  
    1 { [void]$switch.MoveNext(); $switch.Current }  
    3 { [void]$switch.MoveNext(); $switch.Current }  
}
```

This gives you the results of:

Output

```
2  
4
```

By moving the enumerator forward, the next item doesn't get processed by the `switch` but you can access that value directly. I would call it madness.

Other patterns

Hashtables

One of my most popular posts is the one I did on [hashtables](#). One of the use cases for a `hashtable` is to be a lookup table. That's an alternate approach to a common pattern that a `switch` statement is often addressing.

PowerShell

```
$day = 3

$lookup = @{
    0 = 'Sunday'
    1 = 'Monday'
    2 = 'Tuesday'
    3 = 'Wednesday'
    4 = 'Thursday'
    5 = 'Friday'
    6 = 'Saturday'
}

$lookup[$day]
```

Output

```
Wednesday
```

If I'm only using a `switch` as a lookup, I often use a `hashtable` instead.

Enum

PowerShell 5.0 introduced the `enum` and it's also an option in this case.

PowerShell

```
$day = 3

enum DayOfTheWeek {
    Sunday
    Monday
    Tuesday
    Wednesday
    Thursday
    Friday
    Saturday
```

```
}
```

```
[DayOfTheWeek]$day
```

Output

Wednesday

We could go all day looking at different ways to solve this problem. I just wanted to make sure you knew you had options.

Final words

The switch statement is simple on the surface but it offers some advanced features that most people don't realize are available. Stringing those features together makes this a powerful feature. I hope you learned something that you had not realized before.

Everything you wanted to know about exceptions

Article • 06/20/2024

Error handling is just part of life when it comes to writing code. We can often check and validate conditions for expected behavior. When the unexpected happens, we turn to exception handling. You can easily handle exceptions generated by other people's code or you can generate your own exceptions for others to handle.

ⓘ Note

The [original version](#) of this article appeared on the blog written by [@KevinMarquette](#). The PowerShell team thanks Kevin for sharing this content with us. Please check out his blog at [PowerShellExplained.com](#).

Basic terminology

We need to cover some basic terms before we jump into this one.

Exception

An Exception is like an event that is created when normal error handling can't deal with the issue. Trying to divide a number by zero or running out of memory are examples of something that creates an exception. Sometimes the author of the code you're using creates exceptions for certain issues when they happen.

Throw and Catch

When an exception happens, we say that an exception is thrown. To handle a thrown exception, you need to catch it. If an exception is thrown and it isn't caught by something, the script stops executing.

The call stack

The call stack is the list of functions that have called each other. When a function is called, it gets added to the stack or the top of the list. When the function exits or returns, it is removed from the stack.

When an exception is thrown, that call stack is checked in order for an exception handler to catch it.

Terminating and non-terminating errors

An exception is generally a terminating error. A thrown exception is either caught or it terminates the current execution. By default, a non-terminating error is generated by `Write-Error` and it adds an error to the output stream without throwing an exception.

I point this out because `Write-Error` and other non-terminating errors do not trigger the `catch`.

Swallowing an exception

This is when you catch an error just to suppress it. Do this with caution because it can make troubleshooting issues very difficult.

Basic command syntax

Here is a quick overview of the basic exception handling syntax used in PowerShell.

Throw

To create our own exception event, we throw an exception with the `throw` keyword.

```
PowerShell

function Start-Something
{
    throw "Bad thing happened"
}
```

This creates a runtime exception that is a terminating error. It's handled by a `catch` in a calling function or exits the script with a message like this.

```
PowerShell

PS> Start-Something

Bad thing happened
At line:1 char:1
+ throw "Bad thing happened"
+ ~~~~~~
```

```
+ CategoryInfo          : OperationStopped: (Bad thing happened:String)
[], RuntimeException
+ FullyQualifiedErrorId : Bad thing happened
```

Write-Error -ErrorAction Stop

I mentioned that `Write-Error` doesn't throw a terminating error by default. If you specify `-ErrorAction Stop`, `Write-Error` generates a terminating error that can be handled with a `catch`.

PowerShell

```
Write-Error -Message "Houston, we have a problem." -ErrorAction Stop
```

Thank you to Lee Dailey for reminding about using `-ErrorAction Stop` this way.

Cmdlet -ErrorAction Stop

If you specify `-ErrorAction Stop` on any advanced function or cmdlet, it turns all `Write-Error` statements into terminating errors that stop execution or that can be handled by a `catch`.

PowerShell

```
Start-Something -ErrorAction Stop
```

For more information about the `ErrorAction` parameter, see [about_CommonParameters](#).

For more information about the `$ErrorActionPreference` variable, see [about_Preference_Variables](#).

Try/Catch

The way exception handling works in PowerShell (and many other languages) is that you first `try` a section of code and if it throws an error, you can `catch` it. Here is a quick sample.

PowerShell

```
try
{
    Start-Something
}
```

```
catch
{
    Write-Output "Something threw an exception"
    Write-Output $_
}

try
{
    Start-Something -ErrorAction Stop
}
catch
{
    Write-Output "Something threw an exception or used Write-Error"
    Write-Output $_
}
```

The `catch` script only runs if there's a terminating error. If the `try` executes correctly, then it skips over the `catch`. You can access the exception information in the `catch` block using the `$_` variable.

Try/Finally

Sometimes you don't need to handle an error but still need some code to execute if an exception happens or not. A `finally` script does exactly that.

Take a look at this example:

PowerShell

```
$command = [System.Data.SqlClient.SqlCommand]::new(queryString, connection)
$command.Connection.Open()
$command.ExecuteNonQuery()
$command.Connection.Close()
```

Anytime you open or connect to a resource, you should close it. If the `ExecuteNonQuery()` throws an exception, the connection isn't closed. Here is the same code inside a `try/finally` block.

PowerShell

```
$command = [System.Data.SqlClient.SqlCommand]::new(queryString, connection)
try
{
    $command.Connection.Open()
    $command.ExecuteNonQuery()
}
finally
{
```

```
$command.Connection.Close()  
}
```

In this example, the connection is closed if there's an error. It also is closed if there's no error. The `finally` script runs every time.

Because you're not catching the exception, it still gets propagated up the call stack.

Try/Catch/Finally

It's perfectly valid to use `catch` and `finally` together. Most of the time you'll use one or the other, but you may find scenarios where you use both.

\$PSItem

Now that we got the basics out of the way, we can dig a little deeper.

Inside the `catch` block, there's an automatic variable (`$PSItem` or `$_`) of type `ErrorRecord` that contains the details about the exception. Here is a quick overview of some of the key properties.

For these examples, I used an invalid path in `ReadAllText` to generate this exception.

PowerShell

```
[System.IO.File]::ReadAllText( '\\\test\no\filefound.log')
```

PSItem.ToString()

This gives you the cleanest message to use in logging and general output. `ToString()` is automatically called if `$PSItem` is placed inside a string.

PowerShell

```
catch  
{  
    Write-Output "Ran into an issue: $($PSItem.ToString())"  
}  
  
catch  
{  
    Write-Output "Ran into an issue: $PSItem"  
}
```

\$PSItem.InvocationInfo

This property contains additional information collected by PowerShell about the function or script where the exception was thrown. Here is the `InvocationInfo` from the sample exception that I created.

```
PowerShell

PS> $PSItem.InvocationInfo | Format-List *

MyCommand          : Get-Resource
BoundParameters    : {}
UnboundArguments   : {}
ScriptLineNumber   : 5
OffsetInLine       : 5
ScriptName         : C:\blog\throwerror.ps1
Line               :      Get-Resource
PositionMessage    : At C:\blog\throwerror.ps1:5 char:5
                     +      Get-Resource
                     + ~~~~~
PSScriptRoot       : C:\blog
PSCommandPath      : C:\blog\throwerror.ps1
InvocationName     : Get-Resource
```

The important details here show the `ScriptName`, the `Line` of code and the `ScriptLineNumber` where the invocation started.

\$PSItem.ScriptStackTrace

This property shows the order of function calls that got you to the code where the exception was generated.

```
PowerShell

PS> $PSItem.ScriptStackTrace
at Get-Resource, C:\blog\throwerror.ps1: line 13
at Start-Something, C:\blog\throwerror.ps1: line 5
at <ScriptBlock>, C:\blog\throwerror.ps1: line 18
```

I'm only making calls to functions in the same script but this would track the calls if multiple scripts were involved.

\$PSItem.Exception

This is the actual exception that was thrown.

\$PSItem.Exception.Message

This is the general message that describes the exception and is a good starting point when troubleshooting. Most exceptions have a default message but can also be set to something custom when the exception is thrown.

PowerShell

```
PS> $PSItem.Exception.Message
```

```
Exception calling "ReadAllText" with "1" argument(s): "The network path was  
not found."
```

This is also the message returned when calling `$PSItem.ToString()` if there was not one set on the `ErrorRecord`.

\$PSItem.Exception.InnerException

Exceptions can contain inner exceptions. This is often the case when the code you're calling catches an exception and throws a different exception. The original exception is placed inside the new exception.

PowerShell

```
PS> $PSItem.Exception.InnerExceptionMessage  
The network path was not found.
```

I will revisit this later when I talk about re-throwing exceptions.

\$PSItem.Exception.StackTrace

This is the `StackTrace` for the exception. I showed a `ScriptStackTrace` above, but this one is for the calls to managed code.

Output

```
at System.IO.FileStream.Init(String path, FileMode mode, FileAccess access,  
Int32 rights, Boolean  
useRights, FileShare share, Int32 bufferSize, FileOptions options,  
SECURITY_ATTRIBUTES secAttrs,  
String msgPath, Boolean bFromProxy, Boolean useLongPath, Boolean checkHost)  
at System.IO.FileStream..ctor(String path, FileMode mode, FileAccess access,  
FileShare share, Int32  
bufferSize, FileOptions options, String msgPath, Boolean bFromProxy,  
Boolean useLongPath, Boolean
```

```
checkHost)
at System.IO.StreamReader..ctor(String path, Encoding encoding, Boolean
detectEncodingFromByteOrderMarks,
    Int32 bufferSize, Boolean checkHost)
at System.IO.File.InternalReadAllText(String path, Encoding encoding,
Boolean checkHost)
at CallSite.Target(Closure , CallSite , Type , String )
```

You only get this stack trace when the event is thrown from managed code. I'm calling a .NET Framework function directly so that is all we can see in this example. Generally when you're looking at a stack trace, you're looking for where your code stops and the system calls begin.

Working with exceptions

There is more to exceptions than the basic syntax and exception properties.

Catching typed exceptions

You can be selective with the exceptions that you catch. Exceptions have a type and you can specify the type of exception you want to catch.

PowerShell

```
try
{
    Start-Something -Path $path
}
catch [System.IO.FileNotFoundException]
{
    Write-Output "Could not find $path"
}
catch [System.IO.IOException]
{
    Write-Output "IO error with the file: $path"
}
```

The exception type is checked for each `catch` block until one is found that matches your exception. It's important to realize that exceptions can inherit from other exceptions. In the example above, `FileNotFoundException` inherits from `IOException`. So if the `IOException` was first, then it would get called instead. Only one catch block is invoked even if there are multiple matches.

If we had a `System.IO.PathTooLongException`, the `IOException` would match but if we had an `InsufficientMemoryException` then nothing would catch it and it would

propagate up the stack.

Catch multiple types at once

It's possible to catch multiple exception types with the same `catch` statement.

PowerShell

```
try
{
    Start-Something -Path $path -ErrorAction Stop
}
catch [System.IO.DirectoryNotFoundException],
[System.IO.FileNotFoundException]
{
    Write-Output "The path or file was not found: [$path]"
}
catch [System.IO.IOException]
{
    Write-Output "IO error with the file: [$path]"
}
```

Thank you Redditor `u/Sheppard_Ra` for suggesting this addition.

Throwing typed exceptions

You can throw typed exceptions in PowerShell. Instead of calling `throw` with a string:

PowerShell

```
throw "Could not find: $path"
```

Use an exception accelerator like this:

PowerShell

```
throw [System.IO.FileNotFoundException] "Could not find: $path"
```

But you have to specify a message when you do it that way.

You can also create a new instance of an exception to be thrown. The message is optional when you do this because the system has default messages for all built-in exceptions.

PowerShell

```
throw [System.IO.FileNotFoundException]::new()
throw [System.IO.FileNotFoundException]::new("Could not find path: $path")
```

If you're not using PowerShell 5.0 or higher, you must use the older `New-Object` approach.

PowerShell

```
throw (New-Object -TypeName System.IO.FileNotFoundException )
throw (New-Object -TypeName System.IO.FileNotFoundException -ArgumentList
"Could not find path: $path")
```

By using a typed exception, you (or others) can catch the exception by the type as mentioned in the previous section.

Write-Error -Exception

We can add these typed exceptions to `Write-Error` and we can still `catch` the errors by exception type. Use `Write-Error` like in these examples:

PowerShell

```
# with normal message
Write-Error -Message "Could not find path: $path" -Exception
([System.IO.FileNotFoundException]::new()) -ErrorAction Stop

# With message inside new exception
Write-Error -Exception ([System.IO.FileNotFoundException]::new("Could not
find path: $path")) -ErrorAction Stop

# Pre PS 5.0
Write-Error -Exception ([System.IO.FileNotFoundException]"Could not find
path: $path") -ErrorAction Stop

Write-Error -Message "Could not find path: $path" -Exception (New-Object -
TypeName System.IO.FileNotFoundException) -ErrorAction Stop
```

Then we can catch it like this:

PowerShell

```
catch [System.IO.FileNotFoundException]
{
    Write-Log $PSItem.ToString()
}
```

The big list of .NET exceptions

I compiled a master list with the help of the Reddit [r/PowerShell](#) community that contains hundreds of .NET exceptions to complement this post.

- [The big list of .NET exceptions ↗](#)

I start by searching that list for exceptions that feel like they would be a good fit for my situation. You should try to use exceptions in the base `System` namespace.

Exceptions are objects

If you start using a lot of typed exceptions, remember that they are objects. Different exceptions have different constructors and properties. If we look at the [FileNotFoundException](#) documentation for `System.IO.FileNotFoundException`, we see that we can pass in a message and a file path.

```
PowerShell
```

```
[System.IO.FileNotFoundException]::new("Could not find file", $path)
```

And it has a `FileName` property that exposes that file path.

```
PowerShell
```

```
catch [System.IO.FileNotFoundException]
{
    Write-Output $PSItem.Exception.FileName
}
```

You should consult the [.NET documentation](#) for other constructors and object properties.

Re-throwing an exception

If all you're going to do in your `catch` block is `throw` the same exception, then don't `catch` it. You should only `catch` an exception that you plan to handle or perform some action when it happens.

There are times where you want to perform an action on an exception but re-throw the exception so something downstream can deal with it. We could write a message or log the problem close to where we discover it but handle the issue further up the stack.

PowerShell

```
catch
{
    Write-Log $PSItem.ToString()
    throw $PSItem
}
```

Interestingly enough, we can call `throw` from within the `catch` and it re-throws the current exception.

PowerShell

```
catch
{
    Write-Log $PSItem.ToString()
    throw
}
```

We want to re-throw the exception to preserve the original execution information like source script and line number. If we throw a new exception at this point, it hides where the exception started.

Re-throwing a new exception

If you catch an exception but you want to throw a different one, then you should nest the original exception inside the new one. This allows someone down the stack to access it as the `$PSItem.Exception.InnerException`.

PowerShell

```
catch
{
    throw [System.MissingFieldException]::new('Could not access
field',$PSItem.Exception)
}
```

\$PSCmdlet.ThrowTerminatingError()

The one thing that I don't like about using `throw` for raw exceptions is that the error message points at the `throw` statement and indicates that line is where the problem is.

Output

```
Unable to find the specified file.  
At line:31 char:9  
+         throw [System.IO.FileNotFoundException]::new()  
+  
+             + CategoryInfo          : OperationStopped: () [],  
FileNotFoundException  
+ FullyQualifiedErrorId : Unable to find the specified file.
```

Having the error message tell me that my script is broken because I called `throw` on line 31 is a bad message for users of your script to see. It doesn't tell them anything useful.

Dexter Dhami pointed out that I can use `ThrowTerminatingError()` to correct that.

PowerShell

```
$PSCmdlet.ThrowTerminatingError(  
    [System.Management.Automation.ErrorRecord]::new(  
        ([System.IO.FileNotFoundException]"Could not find $Path"),  
        'My.ID',  
        [System.Management.Automation.ErrorCategory]::OpenError,  
        $MyObject  
    )  
)
```

If we assume that `ThrowTerminatingError()` was called inside a function called `Get-Resource`, then this is the error that we would see.

Output

```
Get-Resource : Could not find C:\Program Files (x86)\Reference  
Assemblies\Microsoft\Framework\.NETPortable\v4.6\System.IO.xml  
At line:6 char:5  
+     Get-Resource -Path $Path  
+  
+             + CategoryInfo          : OpenError: () [Get-Resource],  
FileNotFoundException  
+ FullyQualifiedErrorId : My.ID,Get-Resource
```

Do you see how it points to the `Get-Resource` function as the source of the problem? That tells the user something useful.

Because `$PSItem` is an `ErrorRecord`, we can also use `ThrowTerminatingError` this way to re-throw.

PowerShell

```
catch
{
    $PSCmdlet.ThrowTerminatingError($PSItem)
}
```

This changes the source of the error to the Cmdlet and hide the internals of your function from the users of your Cmdlet.

Try can create terminating errors

Kirk Munro points out that some exceptions are only terminating errors when executed inside a `try/catch` block. Here is the example he gave me that generates a divide by zero runtime exception.

```
PowerShell

function Start-Something { 1/(1-1) }
```

Then invoke it like this to see it generate the error and still output the message.

```
PowerShell

&{ Start-Something; Write-Output "We did it. Send Email" }
```

But by placing that same code inside a `try/catch`, we see something else happen.

```
PowerShell

try
{
    &{ Start-Something; Write-Output "We did it. Send Email" }
}
catch
{
    Write-Output "Notify Admin to fix error and send email"
}
```

We see the error become a terminating error and not output the first message. What I don't like about this one is that you can have this code in a function and it acts differently if someone is using a `try/catch`.

I have not ran into issues with this myself but it is corner case to be aware of.

\$PSCmdlet.ThrowTerminatingError() inside try/catch

One nuance of `$PSCmdlet.ThrowTerminatingError()` is that it creates a terminating error within your Cmdlet but it turns into a non-terminating error after it leaves your Cmdlet. This leaves the burden on the caller of your function to decide how to handle the error. They can turn it back into a terminating error by using `-ErrorAction Stop` or calling it from within a `try{...}catch{...}`.

Public function templates

One last take a way I had with my conversation with Kirk Munro was that he places a `try{...}catch{...}` around every `begin`, `process` and `end` block in all of his advanced functions. In those generic catch blocks, he has a single line using `$PSCmdlet.ThrowTerminatingError($PSItem)` to deal with all exceptions leaving his functions.

```
PowerShell

function Start-Something
{
    [CmdletBinding()]
    param()

    process
    {
        try
        {
            ...
        }
        catch
        {
            $PSCmdlet.ThrowTerminatingError($PSItem)
        }
    }
}
```

Because everything is in a `try` statement within his functions, everything acts consistently. This also gives clean errors to the end user that hides the internal code from the generated error.

Trap

I focused on the `try/catch` aspect of exceptions. But there's one legacy feature I need to mention before we wrap this up.

A `trap` is placed in a script or function to catch all exceptions that happen in that scope. When an exception happens, the code in the `trap` is executed and then the normal code continues. If multiple exceptions happen, then the trap is called over and over.

PowerShell

```
trap
{
    Write-Log $PSItem.ToString()
}

throw [System.Exception]::new('first')
throw [System.Exception]::new('second')
throw [System.Exception]::new('third')
```

I personally never adopted this approach but I can see the value in admin or controller scripts that log any and all exceptions, then still continue to execute.

Closing remarks

Adding proper exception handling to your scripts not only make them more stable, but also makes it easier for you to troubleshoot those exceptions.

I spent a lot of time talking `throw` because it is a core concept when talking about exception handling. PowerShell also gave us `Write-Error` that handles all the situations where you would use `throw`. So don't think that you need to be using `throw` after reading this.

Now that I have taken the time to write about exception handling in this detail, I'm going to switch over to using `Write-Error -Stop` to generate errors in my code. I'm also going to take Kirk's advice and make `ThrowTerminatingError` my goto exception handler for every function.

Everything you wanted to know about \$null

Article • 06/11/2024

The PowerShell `$null` often appears to be simple but it has a lot of nuances. Let's take a close look at `$null` so you know what happens when you unexpectedly run into a `$null` value.

ⓘ Note

The [original version](#) of this article appeared on the blog written by [@KevinMarquette](#). The PowerShell team thanks Kevin for sharing this content with us. Please check out his blog at [PowerShellExplained.com](#).

What is NULL?

You can think of NULL as an unknown or empty value. A variable is NULL until you assign a value or an object to it. This can be important because there are some commands that require a value and generate errors if the value is NULL.

PowerShell \$null

`$null` is an automatic variable in PowerShell used to represent NULL. You can assign it to variables, use it in comparisons and use it as a place holder for NULL in a collection.

PowerShell treats `$null` as an object with a value of NULL. This is different than what you may expect if you come from another language.

Examples of \$null

Anytime you try to use a variable that you have not initialized, the value is `$null`. This is one of the most common ways that `$null` values sneak into your code.

PowerShell

```
PS> $null -eq $undefinedVariable  
True
```

If you happen to mistype a variable name then PowerShell sees it as a different variable and the value is `$null`.

The other way you find `$null` values is when they come from other commands that don't give you any results.

PowerShell

```
PS> function Get-Nothing {}  
PS> $value = Get-Nothing  
PS> $null -eq $value  
True
```

Impact of `$null`

`$null` values impact your code differently depending on where they show up.

In strings

If you use `$null` in a string, then it's a blank value (or empty string).

PowerShell

```
PS> $value = $null  
PS> Write-Output "'The value is $value'"  
'The value is '
```

This is one of the reasons that I like to place brackets around variables when using them in log messages. It's even more important to identify the edges of your variable values when the value is at the end of the string.

PowerShell

```
PS> $value = $null  
PS> Write-Output "The value is [$value]"  
The value is []
```

This makes empty strings and `$null` values easy to spot.

In numeric equation

When a `$null` value is used in a numeric equation then your results are invalid if they don't give an error. Sometimes the `$null` evaluates to `0` and other times it makes the whole result `$null`. Here is an example with multiplication that gives 0 or `$null` depending on the order of the values.

PowerShell

```
PS> $null * 5
PS> $null -eq ( $null * 5 )
True

PS> 5 * $null
0
PS> $null -eq ( 5 * $null )
False
```

In place of a collection

A collection allows you use an index to access values. If you try to index into a collection that is actually `null`, you get this error: `Cannot index into a null array`.

PowerShell

```
PS> $value = $null
PS> $value[10]
Cannot index into a null array.
At line:1 char:1
+ $value[10]
+ ~~~~~
+ CategoryInfo          : InvalidOperation: (:) [], RuntimeException
+ FullyQualifiedErrorId : NullArray
```

If you have a collection but try to access an element that is not in the collection, you get a `$null` result.

PowerShell

```
$array = @('one','two','three')
$null -eq $array[100]
True
```

In place of an object

If you try to access a property or sub property of an object that doesn't have the specified property, you get a `$null` value like you would for an undefined variable. It doesn't matter if the variable is `$null` or an actual object in this case.

```
PowerShell
```

```
PS> $null -eq $undefined.Some.Fake.Property
True

PS> $date = Get-Date
PS> $null -eq $date.Some.Fake.Property
True
```

Method on a null-valued expression

Calling a method on a `$null` object throws a `RuntimeException`.

```
PowerShell
```

```
PS> $value = $null
PS> $value.ToString()
You cannot call a method on a null-valued expression.
At line:1 char:1
+ $value.ToString()
+ ~~~~~
+ CategoryInfo          : InvalidOperationException: () [], RuntimeException
+ FullyQualifiedErrorId : InvokeMethodOnNull
```

Whenever I see the phrase `You cannot call a method on a null-valued expression` then the first thing I look for are places where I am calling a method on a variable without first checking it for `$null`.

Checking for `$null`

You may have noticed that I always place the `$null` on the left when checking for `$null` in my examples. This is intentional and accepted as a PowerShell best practice. There are some scenarios where placing it on the right doesn't give you the expected result.

Look at this next example and try to predict the results:

```
PowerShell
```

```
if ( $value -eq $null )
{
    'The array is $null'
```

```
}
```

```
if ( $value -ne $null )
```

```
{
```

```
    'The array is not $null'
```

```
}
```

If I do not define `$value`, the first one evaluates to `$true` and our message is `The array is $null`. The trap here is that it's possible to create a `$value` that allows both of them to be `$false`

PowerShell

```
$value = @( $null )
```

In this case, the `$value` is an array that contains a `$null`. The `-eq` checks every value in the array and returns the `$null` that is matched. This evaluates to `$false`. The `-ne` returns everything that doesn't match `$null` and in this case there are no results (This also evaluates to `$false`). Neither one is `$true` even though it looks like one of them should be.

Not only can we create a value that makes both of them evaluate to `$false`, it's possible to create a value where they both evaluate to `$true`. Mathias Jessen (@IISResetMe) has a [good post](#) that dives into that scenario.

PSScriptAnalyzer and VSCode

The [PSScriptAnalyzer](#) module has a rule that checks for this issue called `PSPossibleIncorrectComparisonWithNull`.

PowerShell

```
PS> Invoke-ScriptAnalyzer ./myscript.ps1
```

RuleName	Message
-----	-----
PSPossibleIncorrectComparisonWithNull	<code>\$null</code> should be on the left side of equality comparisons.

Because VS Code uses the PSScriptAnalyzer rules too, it also highlights or identifies this as a problem in your script.

Simple if check

A common way that people check for a non-\$null value is to use a simple `if()` statement without the comparison.

PowerShell

```
if ( $value )
{
    Do-Something
}
```

If the value is `$null`, this evaluates to `$false`. This is easy to read, but be careful that it's looking for exactly what you're expecting it to look for. I read that line of code as:

If `$value` has a value.

But that's not the whole story. That line is actually saying:

If `$value` is not `$null` or `0` or `$false` or an empty string or an empty array.

Here is a more complete sample of that statement.

PowerShell

```
if ( $null -ne $value -and
    $value -ne 0 -and
    $value -ne '' -and
    ($value -isnot [array] -or $value.Length -ne 0) -and
    $value -ne $false )
{
    Do-Something
}
```

It's perfectly OK to use a basic `if` check as long as you remember those other values count as `$false` and not just that a variable has a value.

I ran into this issue when refactoring some code a few days ago. It had a basic property check like this.

PowerShell

```
if ( $object.Property )
{
    $object.Property = $value
}
```

I wanted to assign a value to the object property only if it existed. In most cases, the original object had a value that would evaluate to `$true` in the `if` statement. But I ran into an issue where the value was occasionally not getting set. I debugged the code and found that the object had the property but it was a blank string value. This prevented it from ever getting updated with the previous logic. So I added a proper `$null` check and everything worked.

PowerShell

```
if ( $null -ne $object.Property )  
{  
    $object.Property = $value  
}
```

It's little bugs like these that are hard to spot and make me aggressively check values for `$null`.

\$null.Count

If you try to access a property on a `$null` value, that the property is also `$null`. The `Count` property is the exception to this rule.

PowerShell

```
PS> $value = $null  
PS> $value.Count  
0
```

When you have a `$null` value, then the `Count` is `0`. This special property is added by PowerShell.

[PSCustomObject] Count

Almost all objects in PowerShell have that `Count` property. One important exception is the `[pscustomobject]` in Windows PowerShell 5.1 (This is fixed in PowerShell 6.0). It doesn't have a `Count` property so you get a `$null` value if you try to use it. I call this out here so that you don't try to use `Count` instead of a `$null` check.

Running this example on Windows PowerShell 5.1 and PowerShell 6.0 gives you different results.

PowerShell

```
$value = [pscustomobject]@{Name='MyObject'}
if ( $value.Count -eq 1 )
{
    "We have a value"
}
```

Enumerable null

There is one special type of `$null` that acts differently than the others. I am going to call it the enumerable null but it's really a [System.Management.Automation.Internal.AutomationNull](#). This enumerable null is the one you get as the result of a function or script block that returns nothing (a void result).

PowerShell

```
PS> function Get-Nothing {}
PS> $nothing = Get-Nothing
PS> $null -eq $nothing
True
```

If you compare it with `$null`, you get a `$null` value. When used in an evaluation where a value is required, the value is always `$null`. But if you place it inside an array, it's treated the same as an empty array.

PowerShell

```
PS> $containEmpty = @( () )
PS> $containNothing = @($nothing)
PS> $containNull = @($null)

PS> $containEmpty.Count
0
PS> $containNothing.Count
0
PS> $containNull.Count
1
```

You can have an array that contains one `$null` value and its `Count` is `1`. But if you place an empty array inside an array then it's not counted as an item. The count is `0`.

If you treat the enumerable null like a collection, then it's empty.

If you pass in an enumerable null to a function parameter that isn't strongly typed, PowerShell coerces the enumerable null into a `$null` value by default. This means inside

the function, the value is treated as `$null` instead of the `System.Management.Automation.Internal.AutomationNull` type.

Pipeline

The primary place you see the difference is when using the pipeline. You can pipe a `$null` value but not an enumerable null value.

PowerShell

```
PS> $null | ForEach-Object{ Write-Output 'NULL Value' }
'NULL Value'
PS> $nothing | ForEach-Object{ Write-Output 'No Value' }
```

Depending on your code, you should account for the `$null` in your logic.

Either check for `$null` first

- Filter out null on the pipeline (`... | where {$null -ne $_} | ...`)
- Handle it in the pipeline function

foreach

One of my favorite features of `foreach` is that it doesn't enumerate over a `$null` collection.

PowerShell

```
foreach ( $node in $null )
{
    #skipped
}
```

This saves me from having to `$null` check the collection before I enumerate it. If you have a collection of `$null` values, the `$node` can still be `$null`.

The `foreach` started working this way with PowerShell 3.0. If you happen to be on an older version, then this is not the case. This is one of the important changes to be aware of when back-porting code for 2.0 compatibility.

Value types

Technically, only reference types can be `$null`. But PowerShell is very generous and allows for variables to be any type. If you decide to strongly type a value type, it cannot be `$null`. PowerShell converts `$null` to a default value for many types.

PowerShell

```
PS> [int]$number = $null
PS> $number
0

PS> [bool]$boolean = $null
PS> $boolean
False

PS> [string]$string = $null
PS> $string -eq ''
True
```

There are some types that do not have a valid conversion from `$null`. These types generate a `Cannot convert null to type` error.

PowerShell

```
PS> [datetime]$date = $null
Cannot convert null to type "System.DateTime".
At line:1 char:1
+ [datetime]$date = $null
+ ~~~~~
+ CategoryInfo          : MetadataError: (:) [],
ArgumentTransformationMetadataException
+ FullyQualifiedErrorId : RuntimeException
```

Function parameters

Using a strongly typed values in function parameters is very common. We generally learn to define the types of our parameters even if we tend not to define the types of other variables in our scripts. You may already have some strongly typed variables in your functions and not even realize it.

PowerShell

```
function Do-Something
{
    param(
        [string] $Value
```

```
)  
}
```

As soon as you set the type of the parameter as a `string`, the value can never be `$null`. It's common to check if a value is `$null` to see if the user provided a value or not.

PowerShell

```
if ( $null -ne $Value ){...}
```

`$Value` is an empty string `''` when no value is provided. Use the automatic variable `$PSBoundParameters.Value` instead.

PowerShell

```
if ( $null -ne $PSBoundParameters.Value ){...}
```

`$PSBoundParameters` only contains the parameters that were specified when the function was called. You can also use the `ContainsKey` method to check for the property.

PowerShell

```
if ( $PSBoundParameters.ContainsKey('Value') ){...}
```

IsNotNullOrEmpty

If the value is a string, you can use a static string function to check if the value is `$null` or an empty string at the same time.

PowerShell

```
if ( -not [string]::IsNullOrEmpty( $value ) ){...}
```

I find myself using this often when I know the value type should be a string.

When I `$null` check

I am a defensive scripter. Anytime I call a function and assign it to a variable, I check it for `$null`.

PowerShell

```
$userList = Get-ADUser kevmar
if ($null -ne $userList){...}
```

I much prefer using `if` or `foreach` over using `try/catch`. Don't get me wrong, I still use `try/catch` a lot. But if I can test for an error condition or an empty set of results, I can allow my exception handling be for true exceptions.

I also tend to check for `$null` before I index into a value or call methods on an object. These two actions fail for a `$null` object so I find it important to validate them first. I already covered those scenarios earlier in this post.

No results scenario

It's important to know that different functions and commands handle the no results scenario differently. Many PowerShell commands return the enumerable null and an error in the error stream. But others throw exceptions or give you a status object. It's still up to you to know how the commands you use deal with the no results and error scenarios.

Initializing to `$null`

One habit that I have picked up is initializing all my variables before I use them. You are required to do this in other languages. At the top of my function or as I enter a `foreach` loop, I define all the values that I'm using.

Here is a scenario that I want you to take a close look at. It's an example of a bug I had to chase down before.

PowerShell

```
function Do-Something
{
    foreach ( $node in 1..6 )
    {
        try
        {
            $result = Get-Something -Id $node
        }
        catch
        {
            Write-Verbose "[ $result ] not valid"
        }

        if ( $null -ne $result )
```

```
    {
        Update-Something $result
    }
}
```

The expectation here is that `Get-Something` returns either a result or an enumerable null. If there's an error, we log it. Then we check to make sure we got a valid result before processing it.

The bug hiding in this code is when `Get-Something` throws an exception and doesn't assign a value to `$result`. It fails before the assignment so we don't even assign `$null` to the `$result` variable. `$result` still contains the previous valid `$result` from other iterations. `Update-Something` to execute multiple times on the same object in this example.

I set `$result` to `$null` right inside the `foreach` loop before I use it to mitigate this issue.

PowerShell

```
foreach ( $node in 1..6 )
{
    $result = $null
    try
    {
        ...
    }
```

Scope issues

This also helps mitigate scoping issues. In that example, we assign values to `$result` over and over in a loop. But because PowerShell allows variable values from outside the function to bleed into the scope of the current function, initializing them inside your function mitigates bugs that can be introduced that way.

An uninitialized variable in your function is not `$null` if it's set to a value in a parent scope. The parent scope could be another function that calls your function and uses the same variable names.

If I take that same `Do-something` example and remove the loop, I would end up with something that looks like this example:

PowerShell

```

function Invoke-Something
{
    $result = 'ParentScope'
    Do-Something
}

function Do-Something
{
    try
    {
        $result = Get-Something -Id $node
    }
    catch
    {
        Write-Verbose "[{$result}] not valid"
    }

    if ( $null -ne $result )
    {
        Update-Something $result
    }
}

```

If the call to `Get-Something` throws an exception, then my `$null` check finds the `$result` from `Invoke-Something`. Initializing the value inside your function mitigates this issue.

Naming variables is hard and it's common for an author to use the same variable names in multiple functions. I know I use `$node`, `$result`, `$data` all the time. So it would be very easy for values from different scopes to show up in places where they should not be.

Redirect output to `$null`

I have been talking about `$null` values for this entire article but the topic is not complete if I didn't mention redirecting output to `$null`. There are times when you have commands that output information or objects that you want to suppress. Redirecting output to `$null` does that.

Out-Null

The `Out-Null` command is the built-in way to redirect pipeline data to `$null`.

PowerShell

```
New-Item -Type Directory -Path $path | Out-Null
```

Assign to \$null

You can assign the results of a command to `$null` for the same effect as using `Out-Null`.

```
PowerShell
```

```
$null = New-Item -Type Directory -Path $path
```

Because `$null` is a constant value, you can never overwrite it. I don't like the way it looks in my code but it often performs faster than `Out-Null`.

Redirect to \$null

You can also use the redirection operator to send output to `$null`.

```
PowerShell
```

```
New-Item -Type Directory -Path $path > $null
```

If you're dealing with command-line executables that output on the different streams. You can redirect all output streams to `$null` like this:

```
PowerShell
```

```
git status *> $null
```

Summary

I covered a lot of ground on this one and I know this article is more fragmented than most of my deep dives. That is because `$null` values can pop up in many different places in PowerShell and all the nuances are specific to where you find it. I hope you walk away from this with a better understanding of `$null` and an awareness of the more obscure scenarios you may run into.

Everything you wanted to know about ShouldProcess

Article • 09/24/2024

PowerShell functions have several features that greatly improve the way users interact with them. One important feature that is often overlooked is `-WhatIf` and `-Confirm` support and it's easy to add to your functions. In this article, we dive deep into how to implement this feature.

ⓘ Note

The [original version](#) of this article appeared on the blog written by [@KevinMarquette](#). The PowerShell team thanks Kevin for sharing this content with us. Please check out his blog at [PowerShellExplained.com](#).

This is a simple feature you can enable in your functions to provide a safety net for the users that need it. There's nothing scarier than running a command that you know can be dangerous for the first time. The option to run it with `-WhatIf` can make a big difference.

CommonParameters

Before we look at implementing these [common parameters](#), I want to take a quick look at how they're used.

Using -WhatIf

When a command supports the `-WhatIf` parameter, it allows you to see what the command would have done instead of making changes. It's a good way to test out the impact of a command, especially before you do something destructive.

PowerShell

```
PS C:\temp> Get-ChildItem
Directory: C:\temp

Mode                LastWriteTime         Length Name
----                -----          ----
-a----   4/19/2021 8:59 AM            0 importantfile.txt
-a----   4/19/2021 8:58 AM            0 myfile1.txt
-a----   4/19/2021 8:59 AM            0 myfile2.txt
```

```
PS C:\temp> Remove-Item -Path .\myfile1.txt -WhatIf
What if: Performing the operation "Remove File" on target
"C:\Temp\myfile1.txt".
```

If the command correctly implements `ShouldProcess`, it should show you all the changes that it would have made. Here is an example using a wildcard to delete multiple files.

PowerShell

```
PS C:\temp> Remove-Item -Path * -WhatIf
What if: Performing the operation "Remove File" on target
"C:\Temp\myfile1.txt".
What if: Performing the operation "Remove File" on target
"C:\Temp\myfile2.txt".
What if: Performing the operation "Remove File" on target
"C:\Temp\importantfile.txt".
```

Using -Confirm

Commands that support `-WhatIf` also support `-Confirm`. This gives you a chance to confirm an action before performing it.

PowerShell

```
PS C:\temp> Remove-Item .\myfile1.txt -Confirm

Confirm
Are you sure you want to perform this action?
Performing the operation "Remove File" on target "C:\Temp\myfile1.txt".
[Y] Yes [A] Yes to All [N] No [L] No to All [S] Suspend [?] Help
(default is "Y"):
```

In this case, you have multiple options that allow you to continue, skip a change, or stop the script. The help prompt describes each of those options like this.

Output

```
Y - Continue with only the next step of the operation.
A - Continue with all the steps of the operation.
N - Skip this operation and proceed with the next operation.
L - Skip this operation and all subsequent operations.
S - Pause the current pipeline and return to the command prompt. Type "exit"
to resume the pipeline.
[Y] Yes [A] Yes to All [N] No [L] No to All [S] Suspend [?] Help
(default is "Y"):
```

Localization

This prompt is localized in PowerShell so the language changes based on the language of your operating system. This is one more thing that PowerShell manages for you.

Switch parameters

Let's take quick moment to look at ways to pass a value to a switch parameter. The main reason I call this out is that you often want to pass parameter values to functions you call.

The first approach is a specific parameter syntax that can be used for all parameters but you mostly see it used for switch parameters. You specify a colon to attach a value to the parameter.

```
PowerShell  
  
Remove-Item -Path:* -WhatIf:$true
```

You can do the same with a variable.

```
PowerShell  
  
$DoWhatIf = $true  
Remove-Item -Path * -WhatIf:$DoWhatIf
```

The second approach is to use a hashtable to splat the value.

```
PowerShell  
  
$RemoveSplat = @{  
    Path = '*'  
    WhatIf = $true  
}  
Remove-Item @RemoveSplat
```

If you're new to hashtables or splatting, I have another article on that covers [everything you wanted to know about hashtables](#).

SupportsShouldProcess

The first step to enable `-WhatIf` and `-Confirm` support is to specify `SupportsShouldProcess` in the `CmdletBinding` of your function.

PowerShell

```
function Test-ShouldProcess {  
    [CmdletBinding(SupportsShouldProcess)]  
    param()  
    Remove-Item .\myfile1.txt  
}
```

By specifying `SupportsShouldProcess` in this way, we can now call our function with `-WhatIf` (or `-Confirm`).

PowerShell

```
PS> Test-ShouldProcess -WhatIf  
What if: Performing the operation "Remove File" on target  
"C:\Temp\myfile1.txt".
```

Notice that I did not create a parameter called `-WhatIf`. Specifying `SupportsShouldProcess` automatically creates it for us. When we specify the `-WhatIf` parameter on `Test-ShouldProcess`, some things we call also perform `-WhatIf` processing.

ⓘ Note

When you use `SupportsShouldProcess`, PowerShell doesn't add the `$WhatIf` variable to the function. You don't need to check the value of `$WhatIf` because the `ShouldProcess()` method takes care of that for you.

Trust but verify

There's some danger here trusting that everything you call inherits `-WhatIf` values. For the rest of the examples, I'm going to assume that it doesn't work and be very explicit when making calls to other commands. I recommend that you do the same.

PowerShell

```
function Test-ShouldProcess {  
    [CmdletBinding(SupportsShouldProcess)]  
    param()  
    Remove-Item .\myfile1.txt -WhatIf:$WhatIfPreference  
}
```

I will revisit the nuances much later once you have a better understanding of all the pieces in play.

\$PSCmdlet.ShouldProcess

The method that allows you to implement `SupportsShouldProcess` is `$PSCmdlet.ShouldProcess`. You call `$PSCmdlet.ShouldProcess(...)` to see if you should process some logic and PowerShell takes care of the rest. Let's start with an example:

```
PowerShell

function Test-ShouldProcess {
    [CmdletBinding(SupportsShouldProcess)]
    param()

    $file = Get-ChildItem './myfile1.txt'
    if($PSCmdlet.ShouldProcess($file.Name)){
        $file.Delete()
    }
}
```

The call to `$PSCmdlet.ShouldProcess($file.Name)` checks for the `-WhatIf` (and `-Confirm` parameter) then handles it accordingly. The `-WhatIf` causes `ShouldProcess` to output a description of the change and return `$false`:

```
PowerShell

PS> Test-ShouldProcess -WhatIf
What if: Performing the operation "Test-ShouldProcess" on target
"myfile1.txt".
```

A call using `-Confirm` pauses the script and prompts the user with the option to continue. It returns `$true` if the user selected `Y`.

```
PowerShell

PS> Test-ShouldProcess -Confirm
Confirm
Are you sure you want to perform this action?
Performing the operation "Test-ShouldProcess" on target "myfile1.txt".
[Y] Yes  [A] Yes to All  [N] No  [L] No to All  [S] Suspend  [?] Help
(default is "Y"):
```

An awesome feature of `$PSCmdlet.ShouldProcess` is that it doubles as verbose output. I depend on this often when implementing `ShouldProcess`.

PowerShell

```
PS> Test-ShouldProcess -Verbose  
VERBOSE: Performing the operation "Test-ShouldProcess" on target  
"myfile1.txt".
```

Overloads

There are a few different overloads for `$PSCmdlet.ShouldProcess` with different parameters for customizing the messaging. We already saw the first one in the example above. Let's take a closer look at it.

PowerShell

```
function Test-ShouldProcess {  
    [CmdletBinding(SupportsShouldProcess)]  
    param()  
  
    if($PSCmdlet.ShouldProcess('TARGET')){  
        # ...  
    }  
}
```

This produces output that includes both the function name and the target (value of the parameter).

PowerShell

```
What if: Performing the operation "Test-ShouldProcess" on target "TARGET".
```

Specifying a second parameter as the operation uses the operation value instead of the function name in the message.

PowerShell

```
## $PSCmdlet.ShouldProcess('TARGET','OPERATION')  
What if: Performing the operation "OPERATION" on target "TARGET".
```

The next option is to specify three parameters to fully customize the message. When three parameters are used, the first one is the entire message. The second two parameters are still used in the `-Confirm` message output.

PowerShell

```
## $PSCmdlet.ShouldProcess('MESSAGE','TARGET','OPERATION')
What if: MESSAGE
```

Quick parameter reference

Just in case you came here only to figure out what parameters you should use, here is a quick reference showing how the parameters change the message in the different `-WhatIf` scenarios.

PowerShell

```
## $PSCmdlet.ShouldProcess('TARGET')
What if: Performing the operation "FUNCTION_NAME" on target "TARGET".

## $PSCmdlet.ShouldProcess('TARGET','OPERATION')
What if: Performing the operation "OPERATION" on target "TARGET".

## $PSCmdlet.ShouldProcess('MESSAGE','TARGET','OPERATION')
What if: MESSAGE
```

I tend to use the one with two parameters.

ShouldProcessReason

We have a fourth overload that's more advanced than the others. It allows you to get the reason `ShouldProcess` was executed. I'm only adding this here for completeness because we can just check if `$WhatIfPreference` is `$true` instead.

PowerShell

```
$reason = ''
if($PSCmdlet.ShouldProcess('MESSAGE','TARGET','OPERATION',[ref]$reason)){
    Write-Output "Some Action"
}
$reason
```

We have to pass the `$reason` variable into the fourth parameter as a reference variable with `[ref]`. `ShouldProcess` populates `$reason` with the value `None` or `WhatIf`. I didn't say this was useful and I have had no reason to ever use it.

Where to place it

You use `ShouldProcess` to make your scripts safer. So you use it when your scripts are making changes. I like to place the `$PSCmdlet.ShouldProcess` call as close to the change as possible.

PowerShell

```
## general logic and variable work
if ($PSCmdlet.ShouldProcess('TARGET', 'OPERATION')){
    # Change goes here
}
```

If I'm processing a collection of items, I call it for each item. So the call gets placed inside the `foreach` loop.

PowerShell

```
foreach ($node in $collection){
    # general logic and variable work
    if ($PSCmdlet.ShouldProcess($node, 'OPERATION')){
        # Change goes here
    }
}
```

The reason why I place `ShouldProcess` tightly around the change, is that I want as much code to execute as possible when `-WhatIf` is specified. I want the setup and validation to run if possible so the user gets to see those errors.

I also like to use this in my Pester tests that validate my projects. If I have a piece of logic that is hard to mock in pester, I can often wrap it in `ShouldProcess` and call it with `-WhatIf` in my tests. It's better to test some of your code than none of it.

\$WhatIfPreference

The first preference variable we have is `$WhatIfPreference`. This is `$false` by default. If you set it to `$true` then your function executes as if you specified `-WhatIf`. If you set this in your session, all commands perform `-WhatIf` execution.

When you call a function with `-WhatIf`, the value of `$WhatIfPreference` gets set to `$true` inside the scope of your function.

ConfirmImpact

Most of my examples are for `-WhatIf` but everything so far also works with `-Confirm` to prompt the user. You can set the `ConfirmImpact` of the function to high and it prompts the user as if it was called with `-Confirm`.

PowerShell

```
function Test-ShouldProcess {
    [CmdletBinding(
        SupportsShouldProcess,
        ConfirmImpact = 'High'
    )]
    param()

    if ($PSCmdlet.ShouldProcess('TARGET')){
        Write-Output "Some Action"
    }
}
```

This call to `Test-ShouldProcess` is performing the `-Confirm` action because of the `High` impact.

PowerShell

```
PS> Test-ShouldProcess

Confirm
Are you sure you want to perform this action?
Performing the operation "Test-ShouldProcess" on target "TARGET".
[Y] Yes [A] Yes to All [N] No [L] No to All [S] Suspend [?] Help
(default is "Y"): y
Some Action
```

The obvious issue is that now it's harder to use in other scripts without prompting the user. In this case, we can pass a `$false` to `-Confirm` to suppress the prompt.

PowerShell

```
PS> Test-ShouldProcess -Confirm:$false
Some Action
```

I'll cover how to add `-Force` support in a later section.

\$ConfirmPreference

`$ConfirmPreference` is an automatic variable that controls when `ConfirmImpact` asks you to confirm execution. Here are the possible values for both `$ConfirmPreference` and

`ConfirmImpact`.

- `High`
- `Medium`
- `Low`
- `None`

With these values, you can specify different levels of impact for each function. If you have `$ConfirmPreference` set to a value higher than `ConfirmImpact`, then you aren't prompted to confirm execution.

By default, `$ConfirmPreference` is set to `High` and `ConfirmImpact` is `Medium`. If you want your function to automatically prompt the user, set your `ConfirmImpact` to `High`. Otherwise set it to `Medium` if its destructive and use `Low` if the command is always safe run in production. If you set it to `none`, it doesn't prompt even if `-Confirm` was specified (but it still gives you `-WhatIf` support).

When calling a function with `-Confirm`, the value of `$ConfirmPreference` gets set to `Low` inside the scope of your function.

Suppressing nested confirm prompts

The `$ConfirmPreference` can get picked up by functions that you call. This can create scenarios where you add a confirm prompt and the function you call also prompts the user.

What I tend to do is specify `-Confirm:$false` on the commands that I call when I have already handled the prompting.

PowerShell

```
function Test-ShouldProcess {
    [CmdletBinding(SupportsShouldProcess)]
    param()

    $file = Get-ChildItem './myfile1.txt'
    if($PSCmdlet.ShouldProcess($file.Name)){
        Remove-Item -Path $file.FullName -Confirm:$false
    }
}
```

This brings us back to an earlier warning: There are nuances as to when `-WhatIf` is not passed to a function and when `-Confirm` passes to a function. I promise I'll get back to this later.

\$PSCmdlet.ShouldContinue

If you need more control than `ShouldProcess` provides, you can trigger the prompt directly with `ShouldContinue`. `ShouldContinue` ignores `$ConfirmPreference`, `ConfirmImpact`, `-Confirm`, `$WhatIfPreference`, and `-WhatIf` because it prompts every time it's executed.

At a quick glance, it's easy to confuse `ShouldProcess` and `ShouldContinue`. I tend to remember to use `ShouldProcess` because the parameter is called `SupportsShouldProcess` in the `CmdletBinding`. You should use `ShouldProcess` in almost every scenario. That is why I covered that method first.

Let's take a look at `ShouldContinue` in action.

```
PowerShell

function Test-ShouldContinue {
    [CmdletBinding()]
    param()

    if($PSCmdlet.ShouldContinue('TARGET', 'OPERATION')){
        Write-Output "Some Action"
    }
}
```

This provides us a simpler prompt with fewer options.

```
PowerShell

Test-ShouldContinue

Second
TARGET
[Y] Yes  [N] No  [S] Suspend  [?] Help (default is "Y"):
```

The biggest issue with `ShouldContinue` is that it requires the user to run it interactively because it always prompts the user. You should always be building tools that can be used by other scripts. The way you do this is by implementing `-Force`. I'll revisit this idea later.

Yes to all

This is automatically handled with `ShouldProcess` but we have to do a little more work for `ShouldContinue`. There's a second method overload where we have to pass in a few

values by reference to control the logic.

PowerShell

```
function Test-ShouldContinue {
    [CmdletBinding()]
    param()

    $collection = 1..5
    $yesToAll = $false
    $noToAll = $false

    foreach($target in $collection) {

        $continue = $PSCmdlet.ShouldContinue(
            "TARGET_$target",
            'OPERATION',
            [ref]$yesToAll,
            [ref]$noToAll
        )

        if ($continue){
            Write-Output "Some Action [$target]"
        }
    }
}
```

I added a `foreach` loop and a collection to show it in action. I pulled the `ShouldContinue` call out of the `if` statement to make it easier to read. Calling a method with four parameters starts to get a little ugly, but I tried to make it look as clean as I could.

Implementing -Force

`ShouldProcess` and `ShouldContinue` need to implement `-Force` in different ways. The trick to these implementations is that `ShouldProcess` should always get executed, but `ShouldContinue` should not get executed if `-Force` is specified.

ShouldProcess -Force

If you set your `ConfirmImpact` to `high`, the first thing your users are going to try is to suppress it with `-Force`. That's the first thing I do anyway.

PowerShell

```
Test-ShouldProcess -Force
Error: Test-ShouldProcess: A parameter cannot be found that matches
```

```
parameter name 'force'.
```

If you recall from the `ConfirmImpact` section, they actually need to call it like this:

PowerShell

```
Test-ShouldProcess -Confirm:$false
```

Not everyone realizes they need to do that and `-Force` doesn't suppress `ShouldContinue`. So we should implement `-Force` for the sanity of our users. Take a look at this full example here:

PowerShell

```
function Test-ShouldProcess {
    [CmdletBinding(
        SupportsShouldProcess,
        ConfirmImpact = 'High'
    )]
    param(
        [switch]$Force
    )

    if ($Force -and -not $PSBoundParameters.ContainsKey('Confirm')) {
        $ConfirmPreference = 'None'
    }

    if ($PSCmdlet.ShouldProcess('TARGET')) {
        Write-Output "Some Action"
    }
}
```

We add our own `-Force` switch as a parameter. The `-Confirm` parameter is automatically added when using `SupportsShouldProcess` in the `CmdletBinding`. However, when you use `SupportsShouldProcess`, PowerShell doesn't add the `$Confirm` variable to the function. If you are running in Strict Mode and try to use the `$Confirm` variable before it has been defined, you get an error. To avoid the error you can use `$PSBoundParameters` to test if the parameter was passed by the user.

PowerShell

```
if ($Force -and -not $PSBoundParameters.ContainsKey('Confirm')) {
    $ConfirmPreference = 'None'
}
```

If the user specifies `-Force` we set `$ConfirmPreference` to `None` in the local scope. If the user also specifies `-Confirm` then `ShouldProcess()` honors the values of the `-Confirm` parameter.

PowerShell

```
if ($PSCmdlet.ShouldProcess('TARGET')){
    Write-Output "Some Action"
}
```

If someone specifies both `-Force` and `-WhatIf`, then `-WhatIf` needs to take priority. This approach preserves `-WhatIf` processing because `ShouldProcess` always gets executed.

Don't add a test for the `$Force` value inside the `if` statement with the `ShouldProcess`. That is an anti-pattern for this specific scenario even though that's what I show you in the next section for `ShouldContinue`.

ShouldContinue -Force

This is the correct way to implement `-Force` with `ShouldContinue`.

PowerShell

```
function Test-ShouldContinue {
    [CmdletBinding()]
    param(
        [switch]$Force
    )

    if($Force -or $PSCmdlet.ShouldContinue('TARGET', 'OPERATION')){
        Write-Output "Some Action"
    }
}
```

By placing the `$Force` to the left of the `-or` operator, it gets evaluated first. Writing it this way short circuits the execution of the `if` statement. If `$Force` is `$true`, then the `ShouldContinue` is not executed.

PowerShell

```
PS> Test-ShouldContinue -Force
Some Action
```

We don't have to worry about `-Confirm` or `-WhatIf` in this scenario because they're not supported by `ShouldContinue`. This is why it needs to be handled differently than `ShouldProcess`.

Scope issues

Using `-WhatIf` and `-Confirm` are supposed to apply to everything inside your functions and everything they call. They do this by setting `$WhatIfPreference` to `$true` or setting `$ConfirmPreference` to `Low` in the local scope of the function. When you call another function, calls to `ShouldProcess` use those values.

This actually works correctly most of the time. Anytime you call built-in cmdlet or a function in your same scope, it works. It also works when you call a script or a function in a script module from the console.

The one specific place where it doesn't work is when a script or a script module calls a function in another script module. This may not sound like a big problem, but most of the modules you create or pull from the PSGallery are script modules.

The core issue is that script modules do not inherit the values for `$WhatIfPreference` or `$ConfirmPreference` (and several others) when called from functions in other script modules.

The best way to summarize this as a general rule is that this works correctly for binary modules and never trust it to work for script modules. If you aren't sure, either test it or just assume it doesn't work correctly.

I personally feel this is very dangerous because it creates scenarios where you add `-WhatIf` support to multiple modules that work correctly in isolation, but fail to work correctly when they call each other.

We do have a GitHub RFC working to get this issue fixed. See [Propagate execution preferences beyond script module scope ↗](#) for more details.

In closing

I have to look up how to use `ShouldProcess` every time I need to use it. It took me a long time to distinguish `ShouldProcess` from `ShouldContinue`. I almost always need to look up what parameters to use. So don't worry if you still get confused from time to time. This article will be here when you need it. I'm sure I will reference it often myself.

If you liked this post, please share your thoughts with me on Twitter using the link below. I always like hearing from people that get value from my content.

Visualize parameter binding

Article • 05/20/2024

Parameter binding is the process that PowerShell uses to determine which parameter set is being used and to associate (bind) values to the parameters of a command. These values can come from the command line and the pipeline.

The parameter binding process starts by binding named and positional command-line arguments. After binding command-line arguments, PowerShell tries to bind any pipeline input. There are two ways that values are bound from the pipeline. Parameters that accept pipeline input have one or both of the following attributes:

- [ValueFromPipeline](#) - The value from the pipeline is bound to the parameter based on its type. The type of the argument must match the type of the parameter.
- [ValueFromPipelineByPropertyName](#) - The value from the pipeline is bound to the parameter based on its name. The object in the pipeline must have a property that matches the name of the parameter or one of its aliases. The type of the property must match or be convertible to the type of the parameter.

For more information about parameter binding, see [about_Parameter_Binding](#).

Use [Trace-Command](#) to visualize parameter binding

Troubleshooting parameter binding issues can be challenging. You can use the [Trace-Command](#) cmdlet to visualize the parameter binding process.

Consider the following scenario. You have a directory with two text files, `file1.txt` and `[file2].txt`.

```
PowerShell

PS> Get-ChildItem

Directory: D:\temp\test\binding

Mode          LastWriteTime      Length Name
----          -----          ---- 
-a---  5/17/2024 12:59 PM        0 [file2].txt
-a---  5/17/2024 12:59 PM        0 file1.txt
```

You want to delete the files by passing the filenames, through the pipeline, to the `Remove-Item` cmdlet.

PowerShell

```
PS> 'file1.txt', '[file2].txt' | Remove-Item
PS> Get-ChildItem

Directory: D:\temp\test\binding

Mode                LastWriteTime         Length Name
----                -----          ----- 
-a---      5/17/2024 12:59 PM            0 [file2].txt
```

Notice that `Remove-Item` only deleted `file1.txt` and not `[file2].txt`. The filename includes square brackets, which is treated as a wildcard expression. Using `Trace-Command`, you can see that the filename is being bound to the `Path` parameter of `Remove-Item`.

PowerShell

```
Trace-Command -PSHost -Name ParameterBinding -Expression {
    '[file2].txt' | Remove-Item
}
```

The output from `Trace-Command` can be verbose. Each line of output is prefixed with a timestamp and trace provider information. For the output of this example, the prefix information has been removed to make it easier to read.

Output

```
BIND NAMED cmd line args [Remove-Item]
BIND POSITIONAL cmd line args [Remove-Item]
BIND cmd line args to DYNAMIC parameters.
    DYNAMIC parameter object:
[Microsoft.PowerShell.Commands.FileSystemProviderRemoveItemDynamicParameters

MANDATORY PARAMETER CHECK on cmdlet [Remove-Item]
CALLING ProcessRecord
CALLING EndProcessing

```

Using `Get-Help`, you can see that the `Path` parameter of `Remove-Item` accepts string objects from the pipeline `ByValue` or `ByPropertyName`. `LiteralPath` accepts string objects from the pipeline `ByPropertyName`.

PowerShell

```

PS> Get-Help Remove-Item -Parameter Path, LiteralPath

-Path <System.String[]>
    Specifies a path of the items being removed. Wildcard characters are
    permitted.

    Required?          true
    Position?         0
    Default value     None
    Accept pipeline input? True (ByPropertyName, ByValue)
    Accept wildcard characters? true

-LiteralPath <System.String[]>
    Specifies a path to one or more locations. The value of LiteralPath is
    used exactly as it's
        typed. No characters are interpreted as wildcards. If the path includes
        escape characters,
            enclose it in single quotation marks. Single quotation marks tell
        PowerShell not to interpret
            any characters as escape sequences.

    Required?          true
    Position?         named
    Default value     None
    Accept pipeline input? True (ByPropertyName)
    Accept wildcard characters? false

```

The output of `Trace-Command` shows that parameter binding starts by binding command-line parameters followed by the pipeline input. You can see that `Remove-Item` receives a string object from the pipeline. That string object is bound to the **Path** parameter.

```
BIND PIPELINE object to parameters: [Remove-Item]
PIPELINE object TYPE = [System.String]
RESTORING pipeline parameter's original values
Parameter [Path] PIPELINE INPUT ValueFromPipeline NO COERCION
BIND arg [[file2].txt] to parameter [Path]
...
BIND arg [System.String[]] to param [Path] SUCCESSFUL
```

Since the **Path** parameter accepts wildcard characters, the square brackets represent a wildcard expression. However, that expression doesn't match any files in the directory. You need to use the **LiteralPath** parameter to specify the exact path to the file.

`Get-Command` shows that the **LiteralPath** parameter accepts input from the pipeline `ByPropertyName` or `ByValue`. And, that it has two aliases, `PSPath` and `LP`.

PowerShell

```
PS> (Get-Command Remove-Item).Parameters.LiteralPath.Attributes |
>> Select-Object ValueFrom*, Alias* | Format-List

ValueFromPipeline          : False
ValueFromPipelineByPropertyName : True
ValueFromRemainingArguments   : False

AliasNames : {PSPath, LP}
```

In this next example, `Get-Item` is used to retrieve a **FileInfo** object. That object has a property named **PSPath**.

PowerShell

```
PS> Get-Item *.txt | Select-Object PSPath

PSPath
-----
Microsoft.PowerShell.Core\FileSystem::D:\temp\test\binding\[file2].txt
```

The **FileInfo** object is then passed to `Remove-Item`.

PowerShell

```
Trace-Command -PSHost -Name ParameterBinding -Expression {
    Get-Item *.txt | Remove-Item
}
```

For the output of this example, the prefix information has been removed and separated to show parameter binding for both commands.

In this output, you can see that `Get-Item` binds the positional parameter value `*.txt` to the **Path** parameter.

Output

```
BIND NAMED cmd line args [Get-Item]
BIND POSITIONAL cmd line args [Get-Item]
    BIND arg [*.txt] to parameter [Path]
        Binding collection parameter Path: argument type [String], parameter
        type [System.String[]],
            collection type Array, element type [System.String], no
        coerceElementType
            Creating array with element type [System.String] and 1 elements
            Argument type String is not IList, treating this as scalar
            Adding scalar element of type String to array position 0
            BIND arg [System.String[]} to param [Path] SUCCESSFUL
BIND cmd line args to DYNAMIC parameters.
    DYNAMIC parameter object:
[Microsoft.PowerShell.Commands.FileSystemProviderGetItemDynamicParameters]
MANDATORY PARAMETER CHECK on cmdlet [Get-Item]
```

In the trace output for parameter binding, you can see that `Remove-Item` receives a **FileInfo** object from the pipeline. Since a **FileInfo** object isn't a **String** object, it can't be bound to the **Path** parameter.

The **PSPath** property of the **FileInfo** object matches an alias for the **LiteralPath** parameter. **PSPath** is also a **String** object, so it can be bound to the **LiteralPath** parameter without type coercion.

Output

```
BIND NAMED cmd line args [Remove-Item]
BIND POSITIONAL cmd line args [Remove-Item]
BIND cmd line args to DYNAMIC parameters.
    DYNAMIC parameter object:
[Microsoft.PowerShell.Commands.FileSystemProviderRemoveItemDynamicParameters
]
MANDATORY PARAMETER CHECK on cmdlet [Remove-Item]
CALLING BeginProcessing
CALLING BeginProcessing
CALLING ProcessRecord
```

```
BIND PIPELINE object to parameters: [Remove-Item]
PIPELINE object TYPE = [System.IO.FileInfo]
RESTORING pipeline parameter's original values
Parameter [Path] PIPELINE INPUT ValueFromPipeline NO COERCION
BIND arg [D:\temp\test\binding\[file2].txt] to parameter [Path]
    Binding collection parameter Path: argument type [FileInfo],
parameter type [System.String[]],
        collection type Array, element type [System.String], no
coerceElementType
        Creating array with element type [System.String] and 1 elements
        Argument type FileInfo is not IList, treating this as scalar

Writing Progress across multiple threads with `ForEach-Object -Parallel`

Article • 11/17/2022

Starting in PowerShell 7.0, the ability to work in multiple threads simultaneously is possible using the `Parallel` parameter in the `ForEach-Object` cmdlet. Monitoring the progress of these threads can be a challenge though. Normally, you can monitor the progress of a process using `Write-Progress`. However, since PowerShell uses a separate runspace for each thread when using `Parallel`, reporting the progress back to the host isn't as straight forward as normal use of `Write-Progress`.

Using a synced hashtable to track progress

When writing the progress from multiple threads, tracking becomes difficult because when running parallel processes in PowerShell, each process has its own runspace. To get around this, you can use a [synchronized hashtable](#). A synced hashtable is a thread safe data structure that can be modified by multiple threads simultaneously without throwing an error.

Set up

One of the downsides to this approach is it takes a, somewhat, complex set up to ensure everything runs without error.

```
PowerShell

$dataset = @(
    @{
        Id      = 1
        Wait   = 3..10 | Get-Random | ForEach-Object {$_*100}
    }
    @{
        Id      = 2
        Wait   = 3..10 | Get-Random | ForEach-Object {$_*100}
    }
    @{
        Id      = 3
        Wait   = 3..10 | Get-Random | ForEach-Object {$_*100}
    }
    @{
        Id      = 4
        Wait   = 3..10 | Get-Random | ForEach-Object {$_*100}
    }
)
```

```

@{
    Id    = 5
    Wait = 3..10 | Get-Random | ForEach-Object {$_.*100}
}
)

# Create a hashtable for process.
# Keys should be ID's of the processes
$origin = @{}
$dataset | ForEach-Object {$origin.($_.Id) = @{}}

# Create synced hashtable
$sync = [System.Collections.Hashtable]::Synchronized($origin)

```

This section creates three different data structures, for three different purposes.

The `$dataset` variable stores an array of hashtables that is used to coordinate the next steps without the risk of being modified. If an object collection is modified while iterating through the collection, PowerShell throws an error. You must keep the object collection in the loop separate from the objects being modified. The `Id` key in each hashtable is the identifier for a mock process. The `Wait` key simulates the workload of each mock process being tracked.

The `$origin` variable stores a nested hashtable with each key being one of the mock process id's. Then, it is used to hydrate the synchronized hashtable stored in the `$sync` variable. The `$sync` variable is responsible for reporting the progress back to the parent runspace, which displays the progress.

Running the processes

This section runs the multi-threaded processes and creates some of the output used to display progress.

PowerShell

```

$job = $dataset | ForEach-Object -ThrottleLimit 3 -AsJob -Parallel {
    $syncCopy = $Using:sync
    $process = $syncCopy.$($PSItem.Id)

    $process.Id = $PSItem.Id
    $process.Activity = "Id $($PSItem.Id) starting"
    $process.Status = "Processing"

    # Fake workload start up that takes x amount of time to complete
    Start-Sleep -Milliseconds ($PSItem.Wait*5)

    # Process. update activity
    $process.Activity = "Id $($PSItem.Id) processing"

```

```

foreach ($percent in 1..100)
{
    # Update process on status
    $process.Status = "Handling $percent/100"
    $process.PercentComplete = (($percent / 100) * 100)

    # Fake workload that takes x amount of time to complete
    Start-Sleep -Milliseconds $PSItem.Wait
}

# Mark process as completed
$process.Completed = $true
}

```

The mock processes are sent to `ForEach-Object` and started as jobs. The `ThrottleLimit` is set to `3` to highlight running multiple processes in a queue. The jobs are stored in the `$job` variable and allows us to know when all the processes have finished later on.

When using the `Using:` statement to reference a parent scope variable in PowerShell, you can't use expressions to make it dynamic. For example, if you tried to create the `$process` variable like this, `$process = $Using:sync.$($PSItem.Id)`, you would get an error stating you can't use expressions there. So, we create the `$syncCopy` variable to be able to reference and modify the `$sync` variable without the risk of it failing.

Next, we build out a hashtable to represent the progress of the process currently in the loop using the `$process` variable by referencing the synchronized hashtable keys. The `Activity` and the `Status` keys are used as parameter values for `Write-Progress` to display the status of a given mock process in the next section.

The `foreach` loop is just a way to simulate the process working and is randomized based on the `$dataSet` `Wait` attribute to set `Start-Sleep` using milliseconds. How you calculate the progress of your process may vary.

Displaying the progress of multiple processes

Now that the mock processes are running as jobs, we can start to write the processes progress to the PowerShell window.

```

PowerShell

while($job.State -eq 'Running')
{
    $sync.Keys | ForEach-Object {
        # If key is not defined, ignore
        if(![string]::IsNullOrEmpty($sync.$_.Keys))
        {

```

```

        # Create parameter hashtable to splat
        $param = $sync.$_

        # Execute Write-Progress
        Write-Progress @param
    }
}

# Wait to refresh to not overload gui
Start-Sleep -Seconds 0.1
}

```

The `$job` variable contains the parent **job** and has a child **job** for each of the mock processes. While any of the child jobs are still running, the parent job **State** will remain "Running". This allows us to use the `while` loop to continually update the progress of every process until all processes are finished.

Within the while loop, we loop through each of the keys in the `$sync` variable. Since this is a synchronized hashtable, it is constantly updated but can still be accessed without throwing any errors.

There is a check to ensure that the process being reported is actually running using the `IsNullOrEmpty()` method. If the process hasn't been started, the loop won't report on it and move on to the next until it gets to a process that has been started. If the process is started, the hashtable from the current key is used to splat the parameters to `Write-Progress`.

Full example

PowerShell

```

# Example workload
$dataset = @(
    @{
        Id      = 1
        Wait   = 3..10 | Get-Random | ForEach-Object {$_ *100}
    }
    @{
        Id      = 2
        Wait   = 3..10 | Get-Random | ForEach-Object {$_ *100}
    }
    @{
        Id      = 3
        Wait   = 3..10 | Get-Random | ForEach-Object {$_ *100}
    }
    @{
        Id      = 4
        Wait   = 3..10 | Get-Random | ForEach-Object {$_ *100}
    }
)

```

```

}
@{
    Id    = 5
    Wait = 3..10 | Get-Random | ForEach-Object {$_*100}
}
)

# Create a hashtable for process.
# Keys should be ID's of the processes
$origin = @{}
$dataset | ForEach-Object {$origin.($_.Id) = @{}}

# Create synced hashtable
$sync = [System.Collections.Hashtable]::Synchronized($origin)

$job = $dataset | ForEach-Object -ThrottleLimit 3 -AsJob -Parallel {
    $syncCopy = $Using:sync
    $process = $syncCopy.$($PSItem.Id)

    $process.Id = $PSItem.Id
    $process.Activity = "Id $($PSItem.Id) starting"
    $process.Status = "Processing"

    # Fake workload start up that takes x amount of time to complete
    Start-Sleep -Milliseconds ($PSItem.Wait*5)

    # Process. update activity
    $process.Activity = "Id $($PSItem.Id) processing"
    foreach ($percent in 1..100)
    {
        # Update process on status
        $process.Status = "Handling $percent/100"
        $process.PercentComplete = (($percent / 100) * 100)

        # Fake workload that takes x amount of time to complete
        Start-Sleep -Milliseconds $PSItem.Wait
    }

    # Mark process as completed
    $process.Completed = $true
}

while($job.State -eq 'Running')
{
    $sync.Keys | ForEach-Object {
        # If key is not defined, ignore
        if(![string]::IsNullOrEmpty($sync.$_.Keys))
        {
            # Create parameter hashtable to splat
            $param = $sync.$_

            # Execute Write-Progress
            Write-Progress @param
        }
    }
}

```

```
# Wait to refresh to not overload gui
Start-Sleep -Seconds 0.1
}
```

Add Credential support to PowerShell functions

Article • 11/17/2022

ⓘ Note

The [original version](#) of this article appeared on the blog written by [@joshduffney](#). This article has been edited for inclusion on this site. The PowerShell team thanks Josh for sharing this content with us. Please check out his blog at [duffney.io](#).

This article shows you how to add credential parameters to PowerShell functions and why you'd want to. A credential parameter is to allow you to run the function or cmdlet as a different user. The most common use is to run the function or cmdlet as an elevated user account.

For example, the cmdlet `New-ADUser` has a **Credential** parameter, which you could provide domain admin credentials to create an account in a domain. Assuming your normal account running the PowerShell session doesn't have that access already.

Creating credential object

The **PSCredential** object represents a set of security credentials such as a user name and password. The object can be passed as a parameter to a function that runs as the user account in that credential object. There are a few ways that you can create a credential object. The first way to create a credential object is to use the PowerShell cmdlet `Get-Credential`. When you run without parameters, it prompts you for a username and password. Or you can call the cmdlet with some optional parameters.

To specify the domain name and username ahead of time you can use either the **Credential** or **UserName** parameters. When you use the **UserName** parameter, you're also required to provide a **Message** value. The code below demonstrates using the cmdlet. You can also store the credential object in a variable so that you can use the credential multiple times. In the example below, the credential object is stored in the variable `$cred`.

PowerShell

```
$Cred = Get-Credential  
$Cred = Get-Credential -Credential domain\user  
$Cred = Get-Credential -UserName domain\user -Message 'Enter Password'
```

Sometimes, you can't use the interactive method of creating credential objects shown in the previous example. Most automation tools require a non-interactive method. To create a credential without user interaction, create a secure string containing the password. Then pass the secure string and user name to the `System.Management.Automation.PSCredential()` method.

Use the following command to create a secure string containing the password:

PowerShell

```
ConvertTo-SecureString "MyPlainTextPassword" -AsPlainText -Force
```

Both the `AsPlainText` and `Force` parameters are required. Without those parameters, you receive a message warning that you shouldn't pass plain text into a secure string. PowerShell returns this warning because the plain text password gets recorded in various logs. Once you have a secure string created, you need to pass it to the `PSCredential()` method to create the credential object. In the following example, the variable `$password` contains the secure string `$cred` contains the credential object.

PowerShell

```
$password = ConvertTo-SecureString "MyPlainTextPassword" -AsPlainText -Force  
$Cred = New-Object System.Management.Automation.PSCredential ("username",  
$password)
```

Now that you know how to create credential objects, you can add credential parameters to your PowerShell functions.

Adding a Credential Parameter

Just like any other parameter, you start off by adding it in the `param` block of your function. It's recommended that you name the parameter `$Credential` because that's what existing PowerShell cmdlets use. The type of the parameter should be `[System.Management.Automation.PSCredential]`.

The following example shows the parameter block for a function called `Get-Something`. It has two parameters: `$Name` and `$Credential`.

PowerShell

```
function Get-Something {
    param(
        $Name,
        [System.Management.Automation.PSCredential]$Credential
    )
}
```

The code in this example is enough to have a working credential parameter, however there are a few things you can add to make it more robust.

- Add the `[ValidateNotNull()]` validation attribute to check that the value being passed to `Credential`. If the parameter value is null, this attribute prevents the function from executing with invalid credentials.
- Add `[System.Management.Automation.Credential()]`. This allows you to pass in a username as a string and have an interactive prompt for the password.
- Set a default value for the `$Credential` parameter to `[System.Management.Automation.PSCredential]::Empty`. Your function you might be passing this `$Credential` object to existing PowerShell cmdlets. Providing a null value to the cmdlet called inside your function causes an error. Providing an empty credential object avoids this error.

Tip

Some cmdlets that accept a credential parameter do not support `[System.Management.Automation.PSCredential]::Empty` as they should. See the [Dealing with Legacy Cmdlets](#) section for a workaround.

Using credential parameters

The following example demonstrates how to use credential parameters. This example shows a function called `Set-RemoteRegistryValue`, which is out of [The Pester Book](#). This function defines the credential parameter using the techniques described in the previous section. The function calls `Invoke-Command` using the `$Credential` variable created by the function. This allows you to change the user who's running `Invoke-Command`. Because the default value of `$Credential` is an empty credential, the function can run without providing credentials.

PowerShell

```

function Set-RemoteRegistryValue {
    param(
        $ComputerName,
        $Path,
        $Name,
        $Value,
        [ValidateNotNull()]
        [System.Management.Automation.PSCredential]
        [System.Management.Automation.Credential()]
        $Credential = [System.Management.Automation.PSCredential]::Empty
    )
    $null = Invoke-Command -ComputerName $ComputerName -ScriptBlock {
        Set-ItemProperty -Path $Using:Path -Name $Using:Name -Value
        $Using:Value
    } -Credential $Credential
}

```

The following sections show different methods of providing credentials to `Set-RemoteRegistryValue`.

Prompting for credentials

Using `Get-Credential` in parentheses `()` at run time causes the `Get-Credential` to run first. You are prompted for a username and password. You could use the `Credential` or `UserName` parameters of `Get-Credential` to pre-populate the username and domain. The following example uses a technique called splatting to pass parameters to the `Set-RemoteRegistryValue` function. For more information about splatting, check out the [about_Splatting](#) article.

PowerShell

```

$remoteKeyParams = @{
    ComputerName = $Env:COMPUTERNAME
    Path = 'HKLM:\SOFTWARE\Microsoft\WebManagement\Server'
    Name = 'EnableRemoteManagement'
    Value = '1'
}

Set-RemoteRegistryValue @remoteKeyParams -Credential (Get-Credential)

```

A screenshot of the Windows PowerShell ISE interface. The top menu bar includes File, Edit, View, Tools, Debug, Add-ons, and Help. Below the menu is a toolbar with various icons. Two tabs are open: Untitled1.ps1* and Untitled2.ps1*. The Untitled2.ps1* tab contains the following PowerShell script:

```
1 $remoteKeyParams = @{
2     ComputerName = $Env:COMPUTERNAME
3     Path = 'HKLM:\SOFTWARE\Microsoft\WebManagement\Server'
4     Name = 'EnableRemoteManagement'
5     Value = '1'
6 }
7 Set-RemoteRegistryValue @remoteKeyParams -Credential (Get-Credential)
```

The bottom status bar shows "Completed" and "Ln 8 Col 70 | 100%".

Using `(Get-Credential)` seems cumbersome. Normally, when you use the `Credential` parameter with only a username, the cmdlet automatically prompts for the password. The `[System.Management.Automation.Credential()]` attribute enables this behavior.

A screenshot of a PowerShell window titled "PowerShell". The command prompt shows "PS C:\>". The script is as follows:

```
$remoteKeyParams = @{
    ComputerName = $Env:COMPUTERNAME
    Path = 'HKLM:\SOFTWARE\Microsoft\WebManagement\Server'
    Name = 'EnableRemoteManagement'
    Value = '1'
}

Set-RemoteRegistryValue @remoteKeyParams -Credential duffney
```

A screenshot of the Windows PowerShell ISE interface. The top menu bar includes File, Edit, View, Tools, Debug, Add-ons, and Help. Below the menu is a toolbar with various icons. Four tabs are open: Untitled1.ps1*, Untitled2.ps1*, Untitled3.ps1*, and Untitled4.ps1*. The Untitled4.ps1* tab contains the following PowerShell script:

```
1 $remoteKeyParams = @{
2     ComputerName = $Env:COMPUTERNAME
3     Path = 'HKLM:\SOFTWARE\Microsoft\WebManagement\Server'
4     Name = 'EnableRemoteManagement'
5     Value = '1'
6 }
7 Set-RemoteRegistryValue @remoteKeyParams -Credential duffney
```

The bottom status bar shows "Completed" and "Ln 8 Col 61 | 100%".

ⓘ Note

To set the registry value shown, these examples assume you have the **Web Server** features of Windows installed. Run `Install-WindowsFeature Web-Server` and `Install-WindowsFeature web-mgmt-tools` if required.

Provide credentials in a variable

You can also populate a credential variable ahead of time and pass it to the **Credential** parameter of `Set-RemoteRegistryValue` function. Use this method with Continuous Integration / Continuous Deployment (CI/CD) tools such as Jenkins, TeamCity, and Octopus Deploy. For an example using Jenkins, check out Hodge's blog post [Automating with Jenkins and PowerShell on Windows - Part 2 ↗](#).

This example uses the .NET method to create the credential object and a secure string to pass in the password.

PowerShell

```
$password = ConvertTo-SecureString "P@ssw0rd" -AsPlainText -Force
$Cred = New-Object System.Management.Automation.PSCredential ("duffney",
$password)

$remoteKeyParams = @{
    ComputerName = $Env:COMPUTERNAME
    Path = 'HKLM:\SOFTWARE\Microsoft\WebManagement\Server'
    Name = 'EnableRemoteManagement'
    Value = '1'
}

Set-RemoteRegistryValue @remoteKeyParams -Credential $Cred
```

For this example, the secure string is created using a clear text password. All of the previously mentioned CI/CD have a secure method of providing that password at run time. When using those tools, replace the plain text password with the variable defined within the CI/CD tool you use.

Run without credentials

Since `$Credential` defaults to an empty credential object, you can run the command without credentials, as shown in this example:

PowerShell

```

$remoteKeyParams = @{
    ComputerName = $Env:COMPUTERNAME
    Path = 'HKLM:\SOFTWARE\Microsoft\WebManagement\Server'
    Name = 'EnableRemoteManagement'
    Value = '1'
}

Set-RemoteRegistryValue @remoteKeyParams

```

Dealing with legacy cmdlets

Not all cmdlets support credential objects or allow empty credentials. Instead, the cmdlet wants username and password parameters as strings. There are a few ways to work around this limitation.

Using if-else to handle empty credentials

In this scenario, the cmdlet you want to run doesn't accept an empty credential object. This example adds the **Credential** parameter to `Invoke-Command` only if it's not empty. Otherwise, it runs the `Invoke-Command` without the **Credential** parameter.

PowerShell

```

function Set-RemoteRegistryValue {
    param(
        $ComputerName,
        $Path,
        $Name,
        $Value,
        [ValidateNotNull()]
        [System.Management.Automation.PSCredential]
        [System.Management.Automation.Credential()]
        $Credential = [System.Management.Automation.PSCredential]::Empty
    )

    if($Credential -ne [System.Management.Automation.PSCredential]::Empty) {
        Invoke-Command -ComputerName:$ComputerName -Credential:$Credential
    }
        Set-ItemProperty -Path $Using:Path -Name $Using:Name -Value
$Using:Value
    }
} else {
    Invoke-Command -ComputerName:$ComputerName {
        Set-ItemProperty -Path $Using:Path -Name $Using:Name -Value
$Using:Value
    }
}

```

```
    }  
}
```

Using splatting to handle empty credentials

This example uses parameter splatting to call the legacy cmdlet. The `$Credential` object is conditionally added to the hash table for splatting and avoids the need to repeat the `Invoke-Command` script block. To learn more about splatting inside functions, see the [Splatting Parameters Inside Advanced Functions](#) blog post.

PowerShell

```
function Set-RemoteRegistryValue {  
    param(  
        $ComputerName,  
        $Path,  
        $Name,  
        $Value,  
        [ValidateNotNull()]  
        [System.Management.Automation.PSCredential]  
        [System.Management.Automation.Credential()]  
        $Credential = [System.Management.Automation.PSCredential]::Empty  
    )  
  
    $Splat = @{  
        ComputerName = $ComputerName  
    }  
  
    if ($Credential -ne  
        [System.Management.Automation.PSCredential]::Empty) {  
        $Splat['Credential'] = $Credential  
    }  
  
    $null = Invoke-Command -ScriptBlock {  
        Set-ItemProperty -Path $Using:Path -Name $Using:Name -Value  
        $Using:Value  
    } @splat  
}
```

Working with string passwords

The `Invoke-Sqlcmd` cmdlet is an example of a cmdlet that accepts a string as a password. `Invoke-Sqlcmd` allows you to run simple SQL insert, update, and delete statements. `Invoke-Sqlcmd` requires a clear-text username and password rather than a more secure credential object. This example shows how to extract the username and password from a credential object.

The `Get-AllSQLDatabases` function in this example calls the `Invoke-Sqlcmd` cmdlet to query a SQL server for all its databases. The function defines a **Credential** parameter with the same attribute used in the previous examples. Since the username and password exist within the `$Credential` variable, you can extract those values for use with `Invoke-Sqlcmd`.

The user name is available from the **UserName** property of the `$Credential` variable. To obtain the password, you have to use the `GetNetworkCredential()` method of the `$Credential` object. The values are extracted into variables that are added to a hash table used for splatting parameters to `Invoke-Sqlcmd`.

PowerShell

```
function Get-AllSQLDatabases {
    param(
        $SQLServer,
        [ValidateNotNull()]
        [System.Management.Automation.PSCredential]
        [System.Management.Automation.Credential()]
        $Credential = [System.Management.Automation.PSCredential]::Empty
    )

    $UserName = $Credential.UserName
    $Password = $Credential.GetNetworkCredential().Password

    $splat = @{
        UserName = $UserName
        Password = $Password
        ServerInstance = 'SQLServer'
        Query = "Select * from Sys.Databases"
    }

    Invoke-Sqlcmd @splat
}

$credSplat = @{
    TypeName = 'System.Management.Automation.PSCredential'
    ArgumentList = 'duffney',('P@ssw0rd' | ConvertTo-SecureString -AsPlainText -Force)
}
$Credential = New-Object @credSplat

Get-AllSQLDatabases -SQLServer SQL01 -Credential $Credential
```

Continued learning credential management

Creating and storing credential objects securely can be difficult. The following resources can help you maintain PowerShell credentials.

Avoid assigning variables in expressions

Article • 11/17/2022

PowerShell allows you to use assignments within expressions by enclosing the assignment in parentheses `()`. PowerShell passes the assigned value through. For example:

```
PowerShell

# In an `if` conditional
if ($foo = Get-Item $PROFILE) { "$foo exists" }

# Property access
($profileFile = Get-Item $PROFILE).LastWriteTime

# You can even *assign* to such expressions.
($profileFile = Get-Item $PROFILE).LastWriteTime = Get-Date
```

ⓘ Note

While this syntax is allowed, its use is discouraged. There are cases where this does not work and the intent of the code author can be confusing to other code reviewers.

Limitations

The assignment case doesn't always work. When it doesn't work, the assignment is discarded. If you create an instance of a *mutable* value type and attempt to both save the instance in a variable and modify one of its properties in the same expression, the property assignment is discarded.

```
PowerShell

# create mutable value type
PS> Add-Type 'public struct Foo { public int x; }'

# Create an instance, store it in a variable, and try to modify its
# property.
# This assignment is effectively IGNORED.
PS> ($var = [Foo]::new()).x = 1
PS> $var.x
0
```

The difference is that you can't return a reference to the value. Essentially, `($var = [Foo]::new())` is equivalent to `($var = [Foo]::new(); $var)`. You're no longer performing a member access on the variable you're performing a member access on the variable's output, which is a copy.

The workaround is to create the instance and save it in a variable first, and then assign to the property via the variable:

PowerShell

```
# create mutable value type
PS> Add-Type 'public struct Foo { public int x; }'

# Create an instance and store it in a variable first
# and then modify its property via the variable.
PS> $var = [Foo]::new()
PS> $var.x = 1
PS> $var.x
1
```

Avoid using Invoke-Expression

Article • 11/17/2022

The `Invoke-Expression` cmdlet should only be used as a *last resort*. In most scenarios, safer and more robust alternatives are available. Forums like Stack Overflow are filled with examples of `Invoke-Expression` misuse. Also note that **PSScriptAnalyzer** has a rule for this. For more information, see [AvoidUsingInvokeExpression](#).

Carefully consider the security implications. When a string from an untrusted source such as user input is passed directly to `Invoke-Expression`, arbitrary commands can be executed. Always consider a different, more robust and secure solution first.

Common scenarios

Consider the following usage scenarios:

- It's simpler to redirect PowerShell to execute something naturally. For example:

```
PowerShell  
Get-Content ./file.ps1 | Invoke-Expression
```

These cases are trivially avoidable. The script or code already exists in file or AST form, so you should write a script with parameters and invoke it directly instead of using `Invoke-Expression` on a string.

- Running a script from a trusted source. For example, running the install script from the PowerShell repository:

```
PowerShell  
Invoke-WebRequest https://aka.ms/install-powershell.ps1 | Invoke-Expression
```

You should only use this interactively. And, while this does make life simpler, this practice should be discouraged.

- Testing for parsing errors. The PowerShell team tests for parse errors in the source code using `Invoke-Expression` because that's the only way to turn a parse-time error into a runtime one.

Conclusion

Most other scripting languages have a way to evaluate a string as code, and as an interpreted language, PowerShell must have a way to dynamically run itself. But there's no good reason to use `Invoke-Expression` in a production environment.

Limitations of PowerShell transcripts

Article • 04/30/2025

Mixing `Write-Host` output with the output objects, strings, and PowerShell transcription is complicated. There is a subtle interaction between the script and how transcription works with PowerShell pipelines that can have unexpected results.

When you emit objects from your script the formatting of those objects is handled by `Out-Default`. But the formatting can occur after the script has completed and transcription has stopped. This means that the output doesn't get transcribed. Strings are handled differently. Sometimes string output is passed through formatting, but not always. `Write-Host` makes an immediate write to the host process. `Write-Output` is sent through the formatting system. Combining the output of complex objects with writes to the host makes it difficult to predict what gets logged in the transcript.

Scenario 1 - Output of a structured object after all other operations

Consider the following script and its output:

```
PowerShell

PS> Get-Content scenario1.ps1
Start-Transcript scenario1.log -UseMinimalHeader
Write-Host '1'
Write-Output '2'
Get-Location
Write-Host '4'
Write-Output '5'
Stop-Transcript

PS> ./scenario1.ps1
Transcript started, output file is scenario1.log
1
2

4
Path
-----
/Users/user1/src/projects/transcript
5
Transcript stopped, output file is
/Users/user1/src/projects/transcript/scenario1.log
```

The output to the console shows the output you expect, but not in the order you expect it.

`Write-Host 4` is visible before `Get-Location` because `Write-Host` is optimized to write directly to the host. There's code in transcription that copies the output to the transcript file and the console. Then we have the regular output of `Get-Location` and `Write-Output 5` sent as output of the script.

```
PowerShell

PS> Get-Content scenario1.log
*****
PowerShell transcript start
Start time: 20191106114858
*****
Transcript started, output file is s2
1
2

4
*****
PowerShell transcript end
End time: 20191106114858
*****
```

Since transcription is turned off before the script exits, it's not rendered in the transcript. The objects were sent to the next consumer in the pipeline. In this case, it's `Out-Default`, which PowerShell inserted automatically. To complicate things further, the output of strings is also optimized in the formatting system. The first `Write-Output 2` gets emitted and captured by the transcript. But the insertion of the `Get-Location` object causes its output to be pushed into the stack of things that need actual formatting, which sets a bit of state for any remaining objects that also may need formatting. This is why the second `Write-Output 5` doesn't get added to the transcript.

Scenario 2 - Move the object emission to the beginning

Consider the following script and its output:

```
PowerShell

PS> Get-Content scenario2.ps1
Start-Transcript scenario2.log -UseMinimalHeader
Get-Location
Write-Host '1'
Write-Output '2'
Get-Location
```

```
Write-Host '4'
Write-Output '5'
Stop-Transcript

PS> ./scenario2.ps1
Transcript started, output file is scenario2.log

1
4
Path
-----
/Users/user1/src/projects/transcript
2
5
Transcript stopped, output file is
/Users/user1/src/projects/transcript/scenario2.log
```

We can see that the `Write-Host` commands happen before anything, and then the objects start to come out. The `Write-Output` of a string forces the object to be rendered to the screen, but notice that the transcript contains only the output of `Write-Host`. That's because those string objects are piped to `Out-Default` for formatting after the script turned off transcription.

```
PowerShell

PS> Get-Content scenario2.log
*****
PowerShell transcript start
Start time: 20220606094609
*****
Transcript started, output file is s3

1
4
*****
PowerShell transcript end
End time: 20220606094609
*****
```

Scenario 3 - Object emitted at the end of the script

For this scenario, the output of the complex object is at the end of the script.

```
PowerShell

PS> Get-Content scenario3.ps1
Start-Transcript scenario3.log -UseMinimalHeader
Write-Host '1'
Write-Output '2'
Write-Host '4'
```

```
Write-Output '5'
Get-Location
Stop-Transcript

PS> ./scenario3.ps1
Transcript started, output file is scenario3.log
1
2
4
5

Path
-----
/Users/user1/src/projects/transcript
Transcript stopped, output file is
/Users/user1/src/projects/transcript/scenario3.log
```

The string output from both `Write-Host` and `Write-Output` makes it into the transcript. However, the output from `Get-Location` occurs after transcription has stopped.

```
*****
PowerShell transcript start
Start time: 20220606100342
*****
Transcript started, output file is scenario3.log
1
2
4
5

*****
PowerShell transcript end
End time: 20220606100342
*****
```

A way to ensure full transcription

This example is a slight variation on the original scenario, but now everything is logged to the transcript. The original code is wrapped in a script block and the formatter explicitly invoked via `Out-Default`.

```
PowerShell

PS> Get-Content scenario4.ps1
Start-Transcript scenario4.log -UseMinimalHeader
. {
    Write-Host '1'
```

```
Write-Output '2'
Get-Location
Write-Host '4'
Write-Output '5'
} | Out-Default
Stop-Transcript

PS> ./scenario4.ps1
Transcript started, output file is scenario4.log
1
2

4
Path
-----
/Users/user1/src/projects/transcript
5

Transcript stopped, output file is
/Users/user1/src/projects/transcript/scenario4.log
```

Notice that the last `Write-Host` call is still out of order, that's because of the optimization in `Write-Host` that doesn't go into the output stream.

```
PowerShell

PS> Get-Content scenario4.log
*****
PowerShell transcript start
Start time: 20220606101038
*****
Transcript started, output file is s5
1
2

4
Path
-----
/Users/user1/src/projects/transcript
5

*****
PowerShell transcript end
End time: 20220606101038
*****
```

Viewing object structure

Article • 12/09/2022

Because objects play such a central role in PowerShell, there are several native commands designed to work with arbitrary object types. The most important one is the `Get-Member` command.

The simplest technique for analyzing the objects that a command returns is to pipe the output of that command to the `Get-Member` cmdlet. The `Get-Member` cmdlet shows you the formal name of the object type and a complete listing of its members. The number of elements that are returned can sometimes be overwhelming. For example, a process object can have over 100 members.

The following command allows you to see all the members of a `Process` object and page through the output.

```
PowerShell  
  
Get-Process | Get-Member | Out-Host -Paging
```

```
Output  
  
TypeName: System.Diagnostics.Process  
  
Name                        MemberType       Definition  
----                        -----  
Handles                    AliasProperty  Handles = HandleCount  
Name                       AliasProperty  Name = ProcessName  
NPM                       AliasProperty  NPM = NonpagedSystemMemorySize  
PM                          AliasProperty  PM = PagedMemorySize  
VM                          AliasProperty  VM = VirtualMemorySize  
WS                          AliasProperty  WS = WorkingSet  
add_Disposed              Method           System.Void  
add_Disposed(Event...)  
...
```

We can make this long list of information more usable by filtering for elements we want to see. The `Get-Member` command lets you list only members that are properties. There are several forms of properties. The cmdlet displays properties of a type using the `MemberType` parameter with the value `Properties`. The resulting list is still very long, but a more manageable:

```
PowerShell
```

```
Get-Process | Get-Member -MemberType Properties
```

Output

```
TypeName: System.Diagnostics.Process
```

Name	MemberType	Definition
Handles	AliasProperty	Handles = HandleCount
Name	AliasProperty	Name = ProcessName
...		
ExitCode	Property	System.Int32 ExitCode {get;}
...		
Handle	Property	System.IntPtr Handle {get;}
...		
CPU	ScriptProperty	System.Object CPU
{get=\$this.Total...}		
...		
Path	ScriptProperty	System.Object Path
{get=\$this.Main...}		
...		

ⓘ Note

The allowed values of MemberType are AliasProperty, CodeProperty, Property, NoteProperty, ScriptProperty, Properties, PropertySet, Method, CodeMethod, ScriptMethod, Methods, ParameterizedProperty, MemberSet, and All.

There are more than 60 properties for a process. By default, PowerShell determines how to display an object type using information stored in XML files that have names ending in `.format.ps1xml`. The formatting definition for process objects is stored in

`DotNetTypes.format.ps1xml`.

If you need to look at properties other than those that PowerShell displays by default, you can format the output using the `Format-*` cmdlets.

Selecting parts of objects

Article • 12/09/2022

You can use the `Select-Object` cmdlet to create new, custom PowerShell objects that contain properties selected from the objects you use to create them. Type the following command to create a new object that includes only the **Name** and **FreeSpace** properties of the **Win32_LogicalDisk** WMI class:

PowerShell

```
Get-CimInstance -Class Win32_LogicalDisk |  
    Select-Object -Property Name, FreeSpace
```

Output

Name	FreeSpace
---	-----
C:	50664845312

With `Select-Object` you can create calculated properties to display **FreeSpace** in gigabytes rather than bytes.

PowerShell

```
Get-CimInstance -Class Win32_LogicalDisk |  
    Select-Object -Property Name, @{  
        Label='FreeSpace'  
        Expression= {($_.FreeSpace/1GB).ToString('F2')}  
    }
```

Output

Name	FreeSpace
---	-----
C:	47.18

Removing objects from the pipeline

Article • 12/09/2022

In PowerShell, you often generate and pass along more objects to a pipeline than you want. You can specify the properties of particular objects to display using the `Format-*` cmdlets, but this doesn't help with the problem of removing entire objects from the display. You may want to filter objects before the end of a pipeline, so you can perform actions on only a subset of the initially generated objects.

PowerShell includes a `Where-Object` cmdlet that allows you to test each object in the pipeline and only pass it along the pipeline if it meets a particular test condition. Objects that don't pass the test are removed from the pipeline. You supply the test condition as the value of the `FilterScript` parameter.

Performing simple tests with `Where-Object`

The value of `FilterScript` is a *script block* - one or more PowerShell commands surrounded by braces (`{}`) - that evaluates to true or false. These script blocks can be simple, but creating them requires knowing about another PowerShell concept, comparison operators. A comparison operator compares the items that appear on each side of it. Comparison operators begin with a hyphen character (`-`) and are followed by a name. Basic comparison operators work on almost any kind of object. The more advanced comparison operators might only work on text or arrays.

ⓘ Note

By default, PowerShell comparison operators are case-insensitive.

Due to parsing considerations, symbols such as `<`, `>`, and `=` aren't used as comparison operators. Instead, comparison operators are comprised of letters. The basic comparison operators are listed in the following table.

[] Expand table

Comparison Operator	Meaning	Example (returns true)
<code>-eq</code>	is equal to	<code>1 -eq 1</code>
<code>-ne</code>	isn't equal to	<code>1 -ne 2</code>
<code>-lt</code>	Is less than	<code>1 -lt 2</code>

Comparison Operator	Meaning	Example (returns true)
-le	Is less than or equal to	1 -le 2
-gt	Is greater than	2 -gt 1
-ge	Is greater than or equal to	2 -ge 1
-like	Is like (wildcard comparison for text)	"file.doc" -like "f*.do?"
-notlike	isn't like (wildcard comparison for text)	"file.doc" -notlike "p*.doc"
-contains	Contains	1,2,3 -contains 1
-notcontains	doesn't contain	1,2,3 -notcontains 4

`Where-Object` script blocks use the special variable `$_` to refer to the current object in the pipeline. Here is an example of how it works. If you have a list of numbers, and only want to return the ones that are less than 3, you can use `Where-Object` to filter the numbers by typing:

```
1,2,3,4 | Where-Object {$_ -lt 3}
1
2
```

Filtering based on object properties

Since `$_` refers to the current pipeline object, we can access its properties for our tests.

As an example, we can look at the `Win32_SystemDriver` class in WMI. There might be hundreds of system drivers on a particular system, but you might only be interested in a particular set of the system drivers, such as those that are running. For the `Win32_SystemDriver` class the relevant property is `State`. You can filter the system drivers, selecting only the running ones by typing:

PowerShell

```
Get-CimInstance -Class Win32_SystemDriver |
    Where-Object {$_ .State -eq 'Running'}
```

This still produces a long list. You may want to filter to only select the drivers set to start automatically by testing the `StartMode` value as well:

PowerShell

```
Get-CimInstance -Class Win32_SystemDriver |  
    Where-Object {$_._State -eq "Running"} |  
    Where-Object {$_._StartMode -eq "Auto"}
```

Output

```
DisplayName : RAS Asynchronous Media Driver  
Name       : AsyncMac  
State      : Running  
Status     : OK  
Started    : True  
  
DisplayName : Audio Stub Driver  
Name       : audstub  
State      : Running  
Status     : OK  
Started    : True  
...
```

This gives us a lot of information we no longer need because we know that the drivers are running. In fact, the only information we probably need at this point are the name and the display name. The following command includes only those two properties, resulting in much simpler output:

PowerShell

```
Get-CimInstance -Class Win32_SystemDriver |  
    Where-Object {$_._State -eq "Running"} |  
    Where-Object {$_._StartMode -eq "Manual"} |  
    Format-Table -Property Name, DisplayName
```

Output

Name	DisplayName
AsyncMac	RAS Asynchronous Media Driver
bindflt	Windows Bind Filter Driver
bowser	Browser
CompositeBus	Composite Bus Enumerator Driver
condrv	Console Driver
HdAudAddService	Microsoft 1.1 UAA Function Driver for High Definition
Audio Service	
HDAudBus	Microsoft UAA Bus Driver for High Definition Audio
HidUsb	Microsoft HID Class Driver
HTTP	HTTP Service
igfx	igfx
IntcDAud	Intel(R) Display Audio

There are two `Where-Object` elements in the above command, but they can be expressed in a single `Where-Object` element using the `-and` logical operator, like this:

PowerShell

```
Get-CimInstance -Class Win32_SystemDriver |  
    Where-Object {($_.State -eq 'Running') -and ($_.StartMode -eq 'Manual')}  
|  
    Format-Table -Property Name, DisplayName
```

The standard logical operators are listed in the following table.

[+] Expand table

Logical Operator	Meaning	Example (returns true)
<code>-and</code>	Logical and; true if both sides are true	<code>(1 -eq 1) -and (2 -eq 2)</code>
<code>-or</code>	Logical or; true if either side is true	<code>(1 -eq 1) -or (1 -eq 2)</code>
<code>-not</code>	Logical not; reverses true and false	<code>-not (1 -eq 2)</code>
<code>!</code>	Logical not; reverses true and false	<code>!(1 -eq 2)</code>

Sorting objects

Article • 12/09/2022

We can organize displayed data to make it easier to scan using the `Sort-Object` cmdlet. `Sort-Object` takes the name of one or more properties to sort on, and returns data sorted by the values of those properties.

Basic sorting

Consider the problem of listing subdirectories and files in the current directory. If we want to sort by `LastWriteTime` and then by `Name`, we can do it by typing:

PowerShell

```
Get-ChildItem |  
    Sort-Object -Property LastWriteTime, Name |  
    Format-Table -Property LastWriteTime, Name
```

Output

LastWriteTime	Name
11/6/2017 10:10:11 AM	.localization-config
11/6/2017 10:10:11 AM	.openpublishing.build.ps1
11/6/2017 10:10:11 AM	appveyor.yml
11/6/2017 10:10:11 AM	LICENSE
11/6/2017 10:10:11 AM	LICENSE-CODE
11/6/2017 10:10:11 AM	ThirdPartyNotices
11/6/2017 10:10:15 AM	tests
6/6/2018 7:58:59 PM	CONTRIBUTING.md
6/6/2018 7:58:59 PM	README.md
...	

You can also sort the objects in reverse order by specifying the `Descending` switch parameter.

PowerShell

```
Get-ChildItem |  
    Sort-Object -Property LastWriteTime, Name -Descending |  
    Format-Table -Property LastWriteTime, Name
```

Output

```
LastWriteTime          Name
-----
12/1/2018 10:13:50 PM  reference
12/1/2018 10:13:50 PM  dsc
...
6/6/2018 7:58:59 PM   README.md
6/6/2018 7:58:59 PM   CONTRIBUTING.md
11/6/2017 10:10:15 AM tests
11/6/2017 10:10:11 AM ThirdPartyNotices
11/6/2017 10:10:11 AM LICENSE-CODE

Using hash tables

You can sort different properties in different orders using hash tables in an array. Each hash table uses an **Expression** key to specify the property name as string and an **Ascending** or **Descending** key to specify the sort order by `$true` or `$false`. The **Expression** key is mandatory. The **Ascending** or **Descending** key is optional.

The following example sorts objects in descending **LastWriteTime** order and ascending **Name** order.

PowerShell

```
Get-ChildItem |
  Sort-Object -Property @{
    Expression = 'LastWriteTime'; Descending = $true
  },
    @{
      Expression = 'Name'; Ascending = $true
    } |
  Format-Table -Property LastWriteTime, Name
```

Output

```
LastWriteTime          Name
-----
12/1/2018 10:13:50 PM  dsc
12/1/2018 10:13:50 PM  reference
11/29/2018 6:56:01 PM  .openpublishing.redirection.json
11/29/2018 6:56:01 PM  gallery
11/24/2018 10:33:22 AM developer
11/20/2018 7:22:19 PM  .markdownlint.json
...
```

You can also set a scriptblock to the **Expression** key. When running the `Sort-Object` cmdlet, the scriptblock is executed and the result is used for sorting.

The following example sorts objects in descending order by the time span between **CreationTime** and **LastWriteTime**.

PowerShell

```
Get-ChildItem |  
    Sort-Object -Property @{ Exp = { $_.LastWriteTime - $_.CreationTime };  
    Desc = $true } |  
    Format-Table -Property LastWriteTime, CreationTime
```

Output

LastWriteTime	CreationTime
12/1/2018 10:13:50 PM	11/6/2017 10:10:11 AM
12/1/2018 10:13:50 PM	11/6/2017 10:10:11 AM
11/7/2018 6:52:24 PM	11/6/2017 10:10:11 AM
11/7/2018 6:52:24 PM	11/6/2017 10:10:15 AM
11/3/2018 9:58:17 AM	11/6/2017 10:10:11 AM
10/26/2018 4:50:21 PM	11/6/2017 10:10:11 AM
11/17/2018 1:10:57 PM	11/29/2017 5:48:30 PM
11/12/2018 6:29:53 PM	12/7/2017 7:57:07 PM
...	

Tips

You can omit the **Property** parameter name as following:

PowerShell

```
Sort-Object LastWriteTime, Name
```

Besides, you can refer to `Sort-Object` by its built-in alias, `sort`:

PowerShell

```
sort LastWriteTime, Name
```

The keys in the hash tables for sorting can be abbreviated as following:

PowerShell

```
Sort-Object @{ e = 'LastWriteTime'; d = $true }, @{ e = 'Name'; a = $true }
```

In this example, the **e** stands for **Expression**, the **d** stands for **Descending**, and the **a** stands for **Ascending**.

To improve readability, you can place the hash tables into a separate variable:

PowerShell

```
$order = @(  
    @{ Expression = 'LastWriteTime'; Descending = $true }  
    @{ Expression = 'Name'; Ascending = $true }  
)  
  
Get-ChildItem |  
    Sort-Object $order |  
    Format-Table LastWriteTime, Name
```

Creating .NET and COM objects

Article • 12/09/2022

This sample only runs on Windows platforms.

There are software components with .NET Framework and COM interfaces that enable you to perform many system administration tasks. PowerShell lets you use these components, so you aren't limited to the tasks that can be performed by using cmdlets. Many of the cmdlets in the initial release of PowerShell don't work against remote computers. We will demonstrate how to get around this limitation when managing event logs by using the .NET Framework `System.Diagnostics.EventLog` class directly from PowerShell.

Using New-Object for event log access

The .NET Framework Class Library includes a class named `System.Diagnostics.EventLog` that can be used to manage event logs. You can create a new instance of a .NET Framework class by using the `New-Object` cmdlet with the `TypeName` parameter. For example, the following command creates an event log reference:

PowerShell

```
New-Object -TypeName System.Diagnostics.EventLog
```

Output

Max(K)	Retain	OverflowAction	Entries	Name
-----	-----	-----	-----	-----

Although the command has created an instance of the `EventLog` class, the instance doesn't include any data. that's because we didn't specify a particular event log. How do you get a real event log?

Using constructors with New-Object

To refer to a specific event log, you need to specify the name of the log. `New-Object` has an `ArgumentList` parameter. The arguments you pass as values to this parameter are used by a special startup method of the object. The method is called a `constructor`

because it's used to construct the object. For example, to get a reference to the Application log, you specify the string 'Application' as an argument:

PowerShell

```
New-Object -TypeName System.Diagnostics.EventLog -ArgumentList Application
```

Output

Max(K)	Retain	OverflowAction	Entries	Name
-----	-----	-----	-----	-----
16,384	7	OverwriteOlder	2,160	Application

ⓘ Note

Since most of the .NET classes are contained in the **System** namespace, PowerShell automatically attempts to find classes you specify in the **System** namespace if it can't find a match for the typename you specify. This means that you can specify `Diagnostics.EventLog` instead of `System.Diagnostics.EventLog`.

Storing Objects in Variables

You might want to store a reference to an object, so you can use it in the current shell. Although PowerShell lets you do a lot of work with pipelines, lessening the need for variables, sometimes storing references to objects in variables makes it more convenient to manipulate those objects.

The output from any valid PowerShell command can be stored in a variable. Variable names always begin with `$`. If you want to store the Application log reference in a variable named `$AppLog`, type the name of the variable, followed by an equal sign and then type the command used to create the Application log object:

PowerShell

```
$AppLog = New-Object -TypeName System.Diagnostics.EventLog -ArgumentList Application
```

If you then type `$AppLog`, you can see that it contains the Application log:

PowerShell

```
$AppLog
```

Output

Max(K) Retain OverflowAction	Entries Name
-----	-----
16,384 7 OverwriteOlder	2,160 Application

Accessing a remote event log with New-Object

The commands used in the preceding section target the local computer; the `Get-EventLog` cmdlet can do that. To access the Application log on a remote computer, you must supply both the log name and a computer name (or IP address) as arguments.

PowerShell

```
$RemoteAppLog = New-Object -TypeName System.Diagnostics.EventLog  
Application, 192.168.1.81  
$RemoteAppLog
```

Output

Max(K) Retain OverflowAction	Entries Name
-----	-----
512 7 OverwriteOlder	262 Application

Now that we have a reference to an event log stored in the `$RemoteAppLog` variable, what tasks can we perform on it?

Clearing an event log with object methods

Objects often have methods that can be called to perform tasks. You can use `Get-Member` to display the methods associated with an object. The following command and selected output show some the methods of the `EventLog` class:

PowerShell

```
$RemoteAppLog | Get-Member -MemberType Method
```

Output

TypeName: System.Diagnostics.EventLog

Name	MemberType	Definition
---		-----
...		
Clear	Method	System.Void Clear()
Close	Method	System.Void Close()
...		
GetType	Method	System.Type GetType()
...		
ModifyOverflowPolicy	Method	System.Void
ModifyOverflowPolicy(Overfl...		
RegisterDisplayName	Method	System.Void RegisterDisplayName(String
...		
...		
ToString	Method	System.String ToString()
WriteEntry	Method	System.Void WriteEntry(String
message),...		
WriteEvent	Method	System.Void WriteEvent(EventInstance
in...		

The `Clear()` method can be used to clear the event log. When calling a method, you must always follow the method name by parentheses, even if the method doesn't require arguments. This lets PowerShell distinguish between the method and a potential property with the same name. Type the following to call the `Clear` method:

PowerShell

```
$RemoteAppLog.Clear()  
$RemoteAppLog
```

Output

Max(K)	Retain	OverflowAction	Entries	Name
-----	-----	-----	-----	-----
512	7	OverwriteOlder	0	Application

Notice that the event log was cleared and now has 0 entries instead of 262.

Creating COM objects with New-Object

You can use `New-Object` to work with Component Object Model (COM) components. Components range from the various libraries included with Windows Script Host (WSH) to ActiveX applications such as Internet Explorer that are installed on most systems.

`New-Object` uses .NET Framework Runtime-Callable Wrappers to create COM objects, so it has the same limitations that .NET Framework does when calling COM objects. To create a COM object, you need to specify the **ComObject** parameter with the Programmatic Identifier or **ProgId** of the COM class you want to use. A complete discussion of the limitations of COM use and determining what ProgIds are available on a system is beyond the scope of this user's guide, but most well-known objects from environments such as WSH can be used within PowerShell.

You can create the WSH objects by specifying these progids: **WScript.Shell**, **WScript.Network**, **Scripting.Dictionary**, and **Scripting.FileSystemObject**. The following commands create these objects:

PowerShell

```
New-Object -ComObject WScript.Shell  
New-Object -ComObject WScript.Network  
New-Object -ComObject Scripting.Dictionary  
New-Object -ComObject Scripting.FileSystemObject
```

Although most of the functionality of these classes is made available in other ways in Windows PowerShell, a few tasks such as shortcut creation are still easier to do using the WSH classes.

Creating a desktop shortcut with **WScript.Shell**

One task that can be performed quickly with a COM object is creating a shortcut. Suppose you want to create a shortcut on your desktop that links to the home folder for PowerShell. You first need to create a reference to **WScript.Shell**, which we will store in a variable named `$WshShell`:

PowerShell

```
$WshShell = New-Object -ComObject WScript.Shell
```

`Get-Member` works with COM objects, so you can explore the members of the object by typing:

PowerShell

```
$WshShell | Get-Member
```

Output

```
TypeName: System.__ComObject#{41904400-be18-11d3-a28b-00104bd35090}
```

Name	MemberType	Definition
AppActivate	Method	bool AppActivate (Variant,
Va...		
CreateShortcut	Method	IDispatch CreateShortcut
(str...		
...		

`Get-Member` has an optional `InputObject` parameter you can use instead of piping to provide input to `Get-Member`. You would get the same output as shown above if you instead used the command `Get-Member -InputObject $WshShell`. If you use `InputObject`, it treats its argument as a single item. This means that if you have several objects in a variable, `Get-Member` treats them as an array of objects. For example:

PowerShell

```
$a = 1,2,"three"  
Get-Member -InputObject $a
```

Output

TypeName: System.Object[]		
Name	MemberType	Definition
Count	AliasProperty	Count = Length
...		

The `WScript.Shell` `CreateShortcut` method accepts a single argument, the path to the shortcut file to create. We could type in the full path to the desktop, but there is an easier way. The desktop is normally represented by a folder named `Desktop` inside the home folder of the current user. Windows PowerShell has a variable `$HOME` that contains the path to this folder. We can specify the path to the home folder by using this variable, and then add the name of the `Desktop` folder and the name for the shortcut to create by typing:

PowerShell

```
$lnk = $WshShell.CreateShortcut("$HOME\Desktop\PSHome.lnk")
```

When you use something that looks like a variable name inside double-quotes, PowerShell tries to substitute a matching value. If you use single-quotes, PowerShell

doesn't try to substitute the variable value. For example, try typing the following commands:

PowerShell

```
"$HOME\Desktop\PSHome.lnk"
```

Output

```
C:\Documents and Settings\aka\Desktop\PSHome.lnk
```

PowerShell

```
'$HOME\Desktop\PSHome.lnk'
```

Output

```
$HOME\Desktop\PSHome.lnk
```

We now have a variable named `$lnk` that contains a new shortcut reference. If you want to see its members, you can pipe it to `Get-Member`. The output below shows the members we need to use to finish creating our shortcut:

PowerShell

```
$lnk | Get-Member
```

Output

```
TypeName: System.__ComObject#{f935dc23-1cf0-11d0-adb9-00c04fd58a0b}
Name          MemberType  Definition
----          -----      -----
...
Save          Method     void Save ()
...
TargetPath    Property   string TargetPath () {get} {set}
```

We need to specify the `TargetPath`, which is the application folder for PowerShell, and then save the shortcut by calling the `Save` method. The PowerShell application folder path is stored in the variable `$PSHOME`, so we can do this by typing:

PowerShell

```
$lnk.TargetPath = $PSHOME  
$lnk.Save()
```

Using Internet Explorer from PowerShell

Many applications, including the Microsoft Office family of applications and Internet Explorer, can be automated by using COM. The following examples illustrate some of the typical techniques and issues involved in working with COM-based applications.

You create an Internet Explorer instance by specifying the Internet Explorer ProgId, `InternetExplorer.Application`:

```
PowerShell  
  
$ie = New-Object -ComObject InternetExplorer.Application
```

This command starts Internet Explorer, but doesn't make it visible. If you type `Get-Process`, you can see that a process named `iexplore` is running. In fact, if you exit PowerShell, the process will continue to run. You must reboot the computer or use a tool like Task Manager to end the `iexplore` process.

① Note

COM objects that start as separate processes, commonly called *ActiveX executables*, may or may not display a user interface window when they start up. If they create a window but don't make it visible, like Internet Explorer, the focus usually moves to the Windows desktop. You must make the window visible to interact with it.

By typing `$ie | Get-Member`, you can view properties and methods for Internet Explorer. To see the Internet Explorer window, set the `Visible` property to `$true` by typing:

```
PowerShell  
  
$ie.Visible = $true
```

You can then navigate to a specific Web address using the `Navigate` method:

```
PowerShell  
  
$ie.Navigate("https://devblogs.microsoft.com/scripting/")
```

Using other members of the Internet Explorer object model, it's possible to retrieve text content from the Web page. The following command displays the HTML text in the body of the current Web page:

```
PowerShell  
  
$ie.Document.Body.InnerText
```

To close Internet Explorer from within PowerShell, call its `Quit()` method:

```
PowerShell  
  
$ie.Quit()
```

The `$ie` variable no longer contains a valid reference even though it still appears to be a COM object. If you attempt to use it, PowerShell returns an automation error:

```
PowerShell  
  
$ie | Get-Member
```

Output

```
Get-Member : Exception retrieving the string representation for property  
"Application" : "The object invoked has disconnected from its clients. (Exception  
from HRESULT: 0x80010108 (RPC_E_DISCONNECTED))"  
At line:1 char:16  
+ $ie | Get-Member <<<
```

You can either remove the remaining reference with a command like `$ie = $null`, or completely remove the variable by typing:

```
PowerShell  
  
Remove-Variable ie
```

ⓘ Note

There is no common standard for whether ActiveX executables exit or continue to run when you remove a reference to one. Depending on circumstances, such as whether the application is visible, whether an edited document is running in it, and

even whether PowerShell is still running, the application may or may not exit. For this reason, you should test termination behavior for each ActiveX executable you want to use in PowerShell.

Getting warnings about .NET Framework-wrapped COM objects

In some cases, a COM object might have an associated .NET Framework **Runtime-Callable Wrapper** (RCW) that's used by `New-Object`. Since the behavior of the RCW may be different from the behavior of the normal COM object, `New-Object` has a **Strict** parameter to warn you about RCW access. If you specify the **Strict** parameter and then create a COM object that uses an RCW, you get a warning message:

PowerShell

```
$xl = New-Object -ComObject Excel.Application -Strict
```

Output

```
New-Object : The object written to the pipeline is an instance of the type
"Microsoft.Office.Interop.Excel.ApplicationClass" from the component's primary
interop assembly. If
this type exposes different members than the IDispatch members , scripts
written to work with this
object might not work if the primary interop assembly isn't installed. At
line:1 char:17 + $xl =
New-Object <<< -ComObject Excel.Application -Strict
```

Although the object is still created, you are warned that it isn't a standard COM object.

Using static classes and methods

Article • 12/09/2022

Not all .NET Framework classes can be created using `New-Object`. For example, if you try to create a `System.Environment` or a `System.Math` object with `New-Object`, you will get the following error messages:

PowerShell

```
New-Object System.Environment
```

Output

```
New-Object : Constructor not found. Cannot find an appropriate constructor
for
type System.Environment.
At line:1 char:11
+ New-Object <<< System.Environment
```

PowerShell

```
New-Object System.Math
```

Output

```
New-Object : Constructor not found. Cannot find an appropriate constructor
for
type System.Math.
At line:1 char:11
+ New-Object <<< System.Math
```

These errors occur because there is no way to create a new object from these classes. These classes are reference libraries of methods and properties that don't change state. You don't need to create them, you simply use them. Classes and methods such as these are called *static classes* because they're not created, destroyed, or changed. To make this clear we will provide examples that use static classes.

Getting environment data with `System.Environment`

Usually, the first step in working with an object in Windows PowerShell is to use `Get-Member` to find out what members it contains. With static classes, the process is a little different because the actual class isn't an object.

Referring to the static `System.Environment` class

You can refer to a static class by surrounding the class name with square brackets. For example, you can refer to `System.Environment` by typing the name within brackets.

Doing so displays some generic type information:

PowerShell	Output								
[System.Environment]									
	<table><thead><tr><th>IsPublic</th><th>IsSerial</th><th>Name</th><th>BaseType</th></tr></thead><tbody><tr><td>True</td><td>False</td><td>Environment</td><td>System.Object</td></tr></tbody></table>	IsPublic	IsSerial	Name	BaseType	True	False	Environment	System.Object
IsPublic	IsSerial	Name	BaseType						
True	False	Environment	System.Object						

① Note

As we mentioned previously, Windows PowerShell automatically prepends '`System.`' to type names when you use `New-Object`. The same thing happens when using a bracketed type name, so you can specify `[System.Environment]` as `[Environment]`.

The `System.Environment` class contains general information about the working environment for the current process, which is `powershell.exe` when working within Windows PowerShell.

If you try to view details of this class by typing `[System.Environment] | Get-Member`, the object type is reported as being `System.RuntimeType`, not `System.Environment`:

PowerShell	Output
[System.Environment] <code>Get-Member</code>	
	TypeName: System.RuntimeType

To view static members with Get-Member, specify the **Static** parameter:

PowerShell

```
[System.Environment] | Get-Member -Static
```

Output

TypeName: System.Environment

Name	MemberType	Definition
-----	-----	-----
Equals	Method	static System.Boolean Equals(Object
ob...		
Exit	Method	static System.Void Exit(Int32
exitCode)		
...		
CommandLine	Property	static System.String CommandLine
{get;}		
CurrentDirectory	Property	static System.String CurrentDirectory
...		
ExitCode	Property	static System.Int32 ExitCode
{get;set;}		
HasShutdownStarted	Property	static System.Boolean
HasShutdownStart...		
MachineName	Property	static System.String MachineName
{get;}		
NewLine	Property	static System.String NewLine {get;}
OSVersion	Property	static System.OperatingSystem
OSVersio...		
ProcessorCount	Property	static System.Int32 ProcessorCount
{get;}		
StackTrace	Property	static System.String StackTrace {get;}
SystemDirectory	Property	static System.String SystemDirectory
{...		
TickCount	Property	static System.Int32 TickCount {get;}
UserDomainName	Property	static System.String UserDomainName
{g...		
UserInteractive	Property	static System.Boolean UserInteractive
...		
UserName	Property	static System.String UserName {get;}
Version	Property	static System.Version Version {get;}
WorkingSet	Property	static System.Int64 WorkingSet {get;}
TickCount		ExitCode

We can now select properties to view from System.Environment.

Displaying static properties of System.Environment

The properties of `System.Environment` are also static, and must be specified in a different way than normal properties. We use `::` to indicate to Windows PowerShell that we want to work with a static method or property. To see the command that was used to launch Windows PowerShell, we check the `CommandLine` property by typing:

PowerShell	[<code>System.Environment</code>]:: <code>CommandLine</code>
Output	"C:\Program Files\Windows PowerShell\v1.0\powershell.exe"

To check the operating system version, display the `OSVersion` property by typing:

PowerShell	[<code>System.Environment</code>]:: <code>OSVersion</code>												
Output	<table><thead><tr><th>Platform</th><th>ServicePack</th><th>Version</th><th>VersionString</th></tr></thead><tbody><tr><td>Win32NT</td><td>Service Pack 2</td><td>5.1.2600.131072</td><td>Microsoft</td></tr><tr><td>Windows...</td><td></td><td></td><td></td></tr></tbody></table>	Platform	ServicePack	Version	VersionString	Win32NT	Service Pack 2	5.1.2600.131072	Microsoft	Windows...			
Platform	ServicePack	Version	VersionString										
Win32NT	Service Pack 2	5.1.2600.131072	Microsoft										
Windows...													

We can check whether the computer is in the process of shutting down by displaying the `HasShutdownStarted` property:

PowerShell	[<code>System.Environment</code>]:: <code>HasShutdownStarted</code>
Output	False

Doing math with `System.Math`

The `System.Math` static class is useful for performing some mathematical operations. The class includes several useful methods, which we can display using `Get-Member`.

⚠ Note

System.Math has several methods with the same name, but they're distinguished by the type of their parameters.

Type the following command to list the methods of the **System.Math** class.

PowerShell

```
[System.Math] | Get-Member -Static -MemberType Methods
```

Output

TypeName: System.Math

Name	MemberType	Definition
Abs	Method	static System.Single Abs(Single value), static
Sy...		
Acos	Method	static System.Double Acos(Double d)
Asin	Method	static System.Double Asin(Double d)
Atan	Method	static System.Double Atan(Double d)
Atan2	Method	static System.Double Atan2(Double y, Double x)
BigMul	Method	static System.Int64 BigMul(Int32 a, Int32 b)
Ceiling	Method	static System.Double Ceiling(Double a), static
Sy...		
Cos	Method	static System.Double Cos(Double d)
Cosh	Method	static System.Double Cosh(Double value)
DivRem	Method	static System.Int32 DivRem(Int32 a, Int32 b,
Int3...		
Equals	Method	static System.Boolean Equals(Object objA, Object
...		
Exp	Method	static System.Double Exp(Double d)
Floor	Method	static System.Double Floor(Double d), static
Syst...		
IEEERemainder	Method	static System.Double IEEERemainder(Double x,
Doub...		
Log	Method	static System.Double Log(Double d), static
System...		
Log10	Method	static System.Double Log10(Double d)
Max	Method	static System.SByte Max(SByte val1, SByte val2),
...		
Min	Method	static System.SByte Min(SByte val1, SByte val2),
...		
Pow	Method	static System.Double Pow(Double x, Double y)
ReferenceEquals	Method	static System.Boolean ReferenceEquals(Object
objA...		
Round	Method	static System.Double Round(Double a), static
Syst...		
Sign	Method	static System.Int32 Sign(SByte value), static

```
Sys...
Sin           Method    static System.Double Sin(Double a)
Sinh          Method    static System.Double Sinh(Double value)
Sqrt          Method    static System.Double Sqrt(Double d)
Tan           Method    static System.Double Tan(Double a)
Tanh          Method    static System.Double Tanh(Double value)
Truncate      Method    static System.Decimal Truncate(Decimal d),
static...
```

This displays several mathematical methods. Here is a list of commands that demonstrate how some of the common methods work:

PowerShell

```
[System.Math]::Sqrt(9)
3
[System.Math]::Pow(2,3)
8
[System.Math]::Floor(3.3)
3
[System.Math]::Floor(-3.3)
-4
[System.Math]::Ceiling(3.3)
4
[System.Math]::Ceiling(-3.3)
-3
[System.Math]::Max(2,7)
7
[System.Math]::Min(2,7)
2
[System.Math]::Truncate(9.3)
9
[System.Math]::Truncate(-9.3)
-9
```

Getting WMI objects with Get-CimInstance

Article • 10/13/2023

This sample only applies to Windows platforms.

Windows Management Instrumentation (WMI) is a core technology for Windows system administration because it exposes a wide range of information in a uniform manner. Because of how much WMI makes possible, the PowerShell cmdlet for accessing WMI objects, `Get-CimInstance`, is one of the most useful for doing real work. We're going to discuss how to use the CIM cmdlets to access WMI objects and then how to use WMI objects to do specific things.

List WMI classes

The first problem most WMI users face is trying to find out what can be done with WMI. WMI classes describe the resources that can be managed. There are hundreds of WMI classes, some of which contain dozens of properties.

`Get-CimClass` addresses this problem by making WMI discoverable. You can get a list of the WMI classes available on the local computer by typing:

PowerShell

```
Get-CimClass -Namespace root/CIMV2 |  
    Where-Object CimClassName -Like Win32* |  
    Select-Object CimClassName
```

Output

```
CimClassName  
-----  
Win32_DeviceChangeEvent  
Win32_SystemConfigurationChangeEvent  
Win32_VolumeChangeEvent  
Win32_SystemTrace  
Win32_ProcessTrace  
Win32_ProcessStartTrace  
Win32_ProcessStopTrace  
Win32_ThreadTrace  
Win32_ThreadStartTrace
```

```
Win32_ThreadStopTrace
```

```
...
```

You can retrieve the same information from a remote computer using the **ComputerName** parameter, specifying a computer name or IP address:

```
PowerShell
```

```
Get-CimClass -Namespace root/CIMV2 -ComputerName 192.168.1.29
```

The class listing returned by remote computers may vary due to the specific operating system the computer is running and the particular WMI extensions are added by installed applications.

 **Note**

When using CIM cmdlets to connect to a remote computer, the remote computer must be running WMI and the account you are using must be in the local **Administrators** group on the remote computer. The remote system doesn't need to have PowerShell installed. This allows you to administer operating systems that aren't running PowerShell, but do have WMI available.

Displaying WMI class details

If you already know the name of a WMI class, you can use it to get information immediately. For example, one of the WMI classes commonly used for retrieving information about a computer is **Win32_OperatingSystem**.

```
PowerShell
```

```
Get-CimInstance -Class Win32_OperatingSystem
```

Output

SystemDirectory Version	Organization	BuildNumber	RegisteredUser	SerialNumber
C:\WINDOWS\system32 10.0.22621	Microsoft	22621	USER1	00330-80000- 0000-AA175

Although we're showing all of the parameters, the command can be expressed in a more succinct way. The **ComputerName** parameter isn't necessary when connecting to the local system. We show it to demonstrate the most general case and remind you about the parameter. The **Namespace** defaults to **root/CIMV2**, and can be omitted as well. Finally, most cmdlets allow you to omit the name of common parameters. With `Get-CimInstance`, if no name is specified for the first parameter, PowerShell treats it as the **Class** parameter. This means the last command could have been issued by typing:

PowerShell

```
Get-CimInstance Win32_OperatingSystem
```

The **Win32_OperatingSystem** class has many more properties than those displayed here. You can use `Get-Member` to see all the properties. The properties of a WMI class are automatically available like other object properties:

PowerShell

```
Get-CimInstance -Class Win32_OperatingSystem | Get-Member -MemberType Property
```

Output

Type	Name	MemberType	Definition
Property	BootDevice	string	BootDevice
Property	BuildNumber	string	BuildNumber
Property	BuildType	string	BuildType {get;}
Property	Caption	string	Caption {get;}
Property	CodeSet	string	CodeSet {get;}
Property	CountryCode	string	CountryCode {get;}
Property	CreationClassName	string	
Property	CreationClassName {get;}		
Property	CSCreationClassName	string	
Property	CSCreationClassName {get;}		
Property	CSDVersion	string	CSDVersion {get;}
Property	CSName	string	CSName {get;}
Property	CurrentTimeZone	int16	CurrentTimeZone {get;}
Property	DataExecutionPrevention_32BitApplications	bool	
Property	DataExecutionPrevention_32BitApplications {get;}		

```
DataExecutionPrevention_Available      Property   bool  
DataExecutionPrevention_Available {get;}  
...
```

Displaying non-default properties with Format cmdlets

If you want the information contained in the **Win32_OperatingSystem** class that isn't displayed by default, you can display it by using the **Format** cmdlets. For example, if you want to display available memory data, type:

PowerShell

```
Get-CimInstance -Class Win32_OperatingSystem | Format-Table -Property  
TotalVirtualMemorySize, TotalVisibleMemorySize, FreePhysicalMemory,  
FreeVirtualMemory, FreeSpaceInPagingFiles
```

Output

TotalVirtualMemorySize	TotalVisibleMemorySize	FreePhysicalMemory
41787920	16622096	9537952
-----	-----	-----
33071884	25056628	

ⓘ Note

Wildcards work with property names in **Format-Table**, so the final pipeline element can be reduced to **Format-Table -Property Total*Memory*, Free***

The memory data might be more readable if you format it as a list by typing:

PowerShell

```
Get-CimInstance -Class Win32_OperatingSystem | Format-List Total*Memory*,  
Free*
```

Output

TotalVirtualMemorySize :	41787920
TotalVisibleMemorySize :	16622096
FreePhysicalMemory :	9365296

```
FreeSpaceInPagingFiles : 25042952
FreeVirtualMemory      : 33013484
Name                  : Microsoft Windows 11
Pro|C:\Windows|\Device\Harddisk0\Partition2
```

Manipulating items directly

Article • 11/06/2024

The elements that you see in PowerShell drives, such as the files and folders or registry keys, are called *Items* in PowerShell. The cmdlets for working with them item have the noun **Item** in their names.

The output of the `Get-Command -Noun Item` command shows that there are nine PowerShell item cmdlets.

```
PowerShell
Get-Command -Noun Item

Output
CommandType      Name                           Definition
----           ----
Cmdlet          Clear-Item                   Clear-Item [-Path]
<String[]>...
Cmdlet          Copy-Item                   Copy-Item [-Path]
<String[]>...
Cmdlet          Get-Item                    Get-Item [-Path] <String[]>
...
Cmdlet          Invoke-Item                 Invoke-Item [-Path]
<String[]>...
Cmdlet          Move-Item                  Move-Item [-Path]
<String[]>...
Cmdlet          New-Item                   New-Item [-Path] <String[]>
...
Cmdlet          Remove-Item                Remove-Item [-Path]
<String[]>...
Cmdlet          Rename-Item                Rename-Item [-Path]
<String>...
Cmdlet          Set-Item                   Set-Item [-Path] <String[]>
...
```

Creating new items

To create a new item in the filesystem, use the `New-Item` cmdlet. Include the **Path** parameter with path to the item, and the **ItemType** parameter with a value of `File` or `Directory`.

For example, to create a new directory named `New.Directory` in the `C:\Temp` directory, type:

PowerShell

```
New-Item -Path C:\temp\New.Directory -ItemType Directory
```

Output

```
Directory: Microsoft.PowerShell.Core\FileSystem::C:\temp
```

Mode	LastWriteTime	Length	Name
----	-----	-----	-----
d---	2006-05-18 11:29 AM		New.Directory

To create a file, change the value of the `ItemType` parameter to `File`. For example, to create a file named `file1.txt` in the `New.Directory` directory, type:

PowerShell

```
New-Item -Path C:\temp\New.Directory\file1.txt -ItemType File
```

Output

```
Directory: Microsoft.PowerShell.Core\FileSystem::C:\temp\New.Directory
```

Mode	LastWriteTime	Length	Name
----	-----	-----	-----
-a--	2006-05-18 11:44 AM	0	file1

You can use the same technique to create a new registry key. In fact, a registry key is easier to create because the only item type in the Windows registry is a key. (Registry entries are item *properties*.) For example, to create a key named `_Test` in the `CurrentVersion` subkey, type:

PowerShell

```
New-Item -Path HKLM:\SOFTWARE\Microsoft\Windows\CurrentVersion\_Test
```

Output

```
Hive:  
Microsoft.PowerShell.Core\Registry::HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows\CurrentVersion
```

SKC	VC	Name	Property
-----	----	------	----------

```
---  ---  ---  
0  0 _Test
```

```
{}
```

When typing a registry path, be sure to include the colon (:) in the PowerShell drive names, `HKLM:` and `HKCU:`. Without the colon, PowerShell doesn't recognize the drive name in the path.

Why registry values aren't items

When you use the `Get-ChildItem` cmdlet to find the items in a registry key, you will never see actual registry entries or their values.

For example, the registry key

`HKEY_LOCAL_MACHINE\Software\Microsoft\Windows\CurrentVersion\Run` usually contains several registry entries that represent applications that run when the system starts.

However, when you use `Get-ChildItem` to look for child items in the key, all you will see is the `OptionalComponents` subkey of the key:

PowerShell

```
Get-ChildItem HKLM:\Software\Microsoft\Windows\CurrentVersion\Run
```

Output

```
Hive:  
Microsoft.PowerShell.Core\Registry::HKEY_LOCAL_MACHINE\Software\Microsoft\Wi  
ndows\CurrentVersion\Run  
SKC  VC Name          Property  
---  --  ---  
3    0  OptionalComponents  {}
```

Although it would be convenient to treat registry entries as items, you can't specify a path to a registry entry in a way that ensures that it's unique. The path notation doesn't distinguish between the registry subkey named **Run** and the **(Default)** registry entry in the **Run** subkey. Furthermore, because registry entry names can contain the backslash character (\), if registry entries were items, then you couldn't use the path notation to distinguish a registry entry named `Windows\CurrentVersion\Run` from the subkey that's located in that path.

Renaming existing items

To change the name of a file or folder, use the `Rename-Item` cmdlet. The following command changes the name of the `file1.txt` file to `fileOne.txt`.

PowerShell

```
Rename-Item -Path C:\temp\New.Directory\file1.txt fileOne.txt
```

The `Rename-Item` cmdlet can change the name of a file or a folder, but it can't move an item. The following command fails because it attempts to move the file from the `New.Directory` directory to the Temp directory.

PowerShell

```
Rename-Item -Path C:\temp\New.Directory\fileOne.txt C:\temp\fileOne.txt
```

Output

```
Rename-Item : can't rename because the target specified isn't a path.  
At line:1 char:12  
+ Rename-Item <<< -Path C:\temp\New.Directory\fileOne C:\temp\fileOne.txt
```

Moving items

To move a file or folder, use the `Move-Item` cmdlet.

For example, the following command moves the `New.Directory` directory from the `C:\temp` directory to the root of the `C:` drive. To verify that the item was moved, include the `PassThru` parameter of the `Move-Item` cmdlet. Without `PassThru`, the `Move-Item` cmdlet doesn't display any results.

PowerShell

```
Move-Item -Path C:\temp\New.Directory -Destination C:\ -PassThru
```

Output

```
Directory: Microsoft.PowerShell.Core\FileSystem::C:\
```

Mode	LastWriteTime	Length	Name
----	-----	-----	-----
d----	2006-05-18 12:14 PM		New.Directory

Copying items

If you are familiar with the copy operations in other shells, you might find the behavior of the `Copy-Item` cmdlet in PowerShell to be unusual. When you copy an item from one location to another, `Copy-Item` doesn't copy its contents by default.

For example, if you copy the `New.Directory` directory from the C: drive to the `C:\temp` directory, the command succeeds, but the files in the `New.Directory` directory aren't copied.

PowerShell

```
Copy-Item -Path C:\New.Directory -Destination C:\temp
```

If you display the contents of `C:\temp\New.Directory`, you will find that it contains no files:

```
PS> Get-ChildItem -Path C:\temp\New.Directory  
PS>
```

Why doesn't the `Copy-Item` cmdlet copy the contents to the new location?

The `Copy-Item` cmdlet was designed to be generic; it isn't just for copying files and folders. Also, even when copying files and folders, you might want to copy only the container and not the items within it.

To copy all of the contents of a folder, include the `Recurse` parameter of the `Copy-Item` cmdlet in the command. If you have already copied the directory without its contents, add the `Force` parameter, which allows you to overwrite the empty folder.

PowerShell

```
Copy-Item -Path C:\New.Directory -Destination C:\temp -Recurse -Force -  
PassThru
```

Output

```
Directory: Microsoft.PowerShell.Core\FileSystem::C:\temp
```

Mode	LastWriteTime	Length	Name
----	-----	-----	---
d----	2006-05-18	1:53 PM	New.Directory

```
Directory: Microsoft.PowerShell.Core\FileSystem::C:\temp\New.Directory
```

Mode	LastWriteTime	Length	Name
-	-----	-----	-----
-a--	2006-05-18 11:44 AM	0	file1

Deleting items

To delete files and folders, use the `Remove-Item` cmdlet. PowerShell cmdlets, such as `Remove-Item`, that can make significant, irreversible changes will often prompt for confirmation when you enter its commands. For example, if you try to remove the `New.Directory` folder, you will be prompted to confirm the command, because the folder contains files:

PowerShell

```
Remove-Item C:\temp\New.Directory
```

Output

Confirm

The item at C:\temp\New.Directory has children and the -Recurse parameter was not specified. If you continue, all children will be removed with the item. Are you sure you want to continue?
[Y] Yes [A] Yes to All [N] No [L] No to All [S] Suspend [?] Help (default is "Y"):

Because `Yes` is the default response, to delete the folder and its files, press the `Enter` key. To remove the folder without confirming, use the `Recurse` parameter.

PowerShell

```
Remove-Item C:\temp\New.Directory -Recurse
```

Executing items

PowerShell uses the `Invoke-Item` cmdlet to perform a default action for a file or folder. This default action is determined by the default application handler in the registry; the effect is the same as if you double-click the item in File Explorer.

For example, suppose you run the following command:

```
PowerShell
```

```
Invoke-Item C:\WINDOWS
```

An Explorer window that's located in `C:\Windows` appears, just as if you had double-clicked the `C:\Windows` folder.

If you invoke the `Boot.ini` file on a system prior to Windows Vista:

```
PowerShell
```

```
Invoke-Item C:\boot.ini
```

If the `.ini` file type is associated with Notepad, the `boot.ini` file opens in Notepad.

Changing computer state

Article • 12/18/2023

This sample only applies to Windows platforms.

To reset a computer in PowerShell, use either a standard command-line tool, WMI, or a CIM class. Although you are using PowerShell only to run the tool, learning how to change a computer's power state in PowerShell illustrates some of the important details about working with external tools in PowerShell.

Locking a computer

The only way to lock a computer directly with the standard available tools is to call the `LockWorkstation()` function in `user32.dll`:

```
PowerShell  
rundll32.exe user32.dll,LockWorkStation
```

This command immediately locks the workstation. It uses `rundll32.exe` to call the `LockWorkStation` function in `user32.dll`.

When you lock a workstation while Fast User Switching is enabled, such as on Windows XP, the computer displays the user logon screen rather than starting the current user's screensaver.

To shut down particular sessions on a Terminal Server, use the `tsshutdn.exe` command-line tool.

Logging off the current session

You can use several different techniques to log off of a session on the local system. The simplest way is to use the Remote Desktop/Terminal Services command-line tool, `logoff.exe` (For details, at the PowerShell prompt, type `logoff /?`). To log off the current active session, type `logoff` with no arguments.

You can also use the `shutdown.exe` tool with its `logoff` option:

```
PowerShell
```

```
shutdown.exe -1
```

Another option is to use WMI. The **Win32_OperatingSystem** class has a **Shutdown** method. Invoking the method with the 0 flag initiates logoff:

For more information, see the [Shutdown method](#) of the **Win32_OperatingSystem** class.

PowerShell

```
Get-CimInstance -ClassName Win32_OperatingSystem | Invoke-CimMethod -  
MethodName Shutdown
```

Shutting down or restarting a computer

Shutting down and restarting computers are similar tasks. Most command-line tools support both actions. Windows includes two command-line tools for restarting a computer. Use either `tsshutdn.exe` or `shutdown.exe` with appropriate arguments. You can get detailed usage information from `tsshutdn.exe /?` or `shutdown.exe /?`.

You can also perform shutdown and restart operations directly from PowerShell.

To shut down the computer, use the `Stop-Computer` command

PowerShell

```
Stop-Computer
```

To restart the operating system, use the `Restart-Computer` command

PowerShell

```
Restart-Computer
```

To force an immediate restart of the computer, use the `-Force` parameter.

PowerShell

```
Restart-Computer -Force
```

Collecting information about computers

Article • 12/09/2022

This sample only applies to Windows platforms.

Cmdlets from **CimCmdlets** module are the most important cmdlets for general system management tasks. All critical subsystem settings are exposed through WMI. Furthermore, WMI treats data as objects that are in collections of one or more items. Because PowerShell also works with objects and has a pipeline that allows you to treat single or multiple objects in the same way, generic WMI access allows you to perform some advanced tasks with very little work.

Listing desktop settings

We'll begin with a command that collects information about the desktops on the local computer.

PowerShell

```
Get-CimInstance -ClassName Win32/Desktop
```

This returns information for all desktops, whether they're in use or not.

ⓘ Note

Information returned by some WMI classes can be very detailed, and often include metadata about the WMI class.

Because most of these metadata properties have names that begin with **Cim**, you can filter the properties using `Select-Object`. Specify the `-ExcludeProperty` parameter with "`Cim*`" as the value. For example:

PowerShell

```
Get-CimInstance -ClassName Win32/Desktop | Select-Object -ExcludeProperty "CIM*"
```

To filter out the metadata, use a pipeline operator (`|`) to send the results of the `Get-CimInstance` command to `Select-Object -ExcludeProperty "CIM*"`.

Listing BIOS Information

The WMI `Win32_BIOS` class returns fairly compact and complete information about the system BIOS on the local computer:

PowerShell

```
Get-CimInstance -ClassName Win32_BIOS
```

Listing Processor Information

You can retrieve general processor information by using WMI's `Win32_Processor` class, although you will likely want to filter the information:

PowerShell

```
Get-CimInstance -ClassName Win32_Processor | Select-Object -ExcludeProperty "CIM*"
```

For a generic description string of the processor family, you can just return the `SystemType` property:

PowerShell

```
Get-CimInstance -ClassName Win32_ComputerSystem | Select-Object -Property SystemType  
SystemType  
-----  
X86-based PC
```

Listing computer manufacturer and model

Computer model information is also available from `Win32_ComputerSystem`. The standard displayed output will not need any filtering to provide OEM data:

PowerShell

```
Get-CimInstance -ClassName Win32_ComputerSystem
```

Output

Name	PrimaryOwnerName	Domain	TotalPhysicalMemory	Model
Manufacturer				
MyPC	Jane Doe	WORKGROUP	804765696	DA243A-ABA 6415c1 NA910
Compaq	Presario	06		

Your output from commands such as this, which return information directly from some hardware, is only as good as the data you have. Some information isn't correctly configured by hardware manufacturers and may therefore be unavailable.

Listing installed hotfixes

You can list all installed hotfixes by using `Win32_QuickFixEngineering`:

PowerShell

```
Get-CimInstance -ClassName Win32_QuickFixEngineering
```

This class returns a list of hotfixes that looks like this:

Output

Source	Description	HotFixID	InstalledBy	InstalledOn	PSComputerName
Security Update	KB4048951	Administrator	12/16/2017	.	

For more succinct output, you may want to exclude some properties. Although you can use the `Get-CimInstance`'s **Property** parameter to choose only the **HotFixID**, doing so will actually return more information, because all the metadata is displayed by default:

PowerShell

```
Get-CimInstance -ClassName Win32_QuickFixEngineering -Property HotFixID
```

Output

InstalledOn	:
Caption	:
Description	:
InstallDate	:
Name	:
Status	:
CSName	:

```
FixComments      :  
HotFixID        : KB4533002  
InstalledBy     :  
ServicePackInEffect :  
PSCoputerName   :  
CimClass         : root/cimv2:Win32_QuickFixEngineering  
CimInstanceProperties : {Caption, Description, InstallDate, Name...}  
CimSystemProperties  :  
Microsoft.Management.Infrastructure.CimSystemProperties  
...
```

The additional data is returned, because the **Property** parameter in `Get-CimInstance` restricts the properties returned from WMI class instances, not the object returned to PowerShell. To reduce the output, use `Select-Object`:

PowerShell

```
Get-CimInstance -ClassName Win32_QuickFixEngineering -Property HotFixId |  
    Select-Object -Property HotFixId
```

Output

```
HotFixId  
-----  
KB4048951
```

Listing operating system version information

The **Win32_OperatingSystem** class properties include version and service pack information. You can explicitly select only these properties to get a version information summary from **Win32_OperatingSystem**:

PowerShell

```
Get-CimInstance -ClassName Win32_OperatingSystem |  
    Select-Object -Property  
BuildNumber, BuildType, OSType, ServicePackMajorVersion, ServicePackMinorVersion
```

You can also use wildcards with the **Property** parameter. Because all the properties beginning with either **Build** or **ServicePack** are important to use here, we can shorten this to the following form:

PowerShell

```
Get-CimInstance -ClassName Win32_OperatingSystem |  
    Select-Object -Property Build*,OSType,ServicePack*
```

Output

```
BuildNumber      : 18362  
BuildType       : Multiprocessor Free  
OSType          : 18  
ServicePackMajorVersion : 0  
ServicePackMinorVersion : 0
```

Listing local users and owner

General information about local users can be found with a selection of **Win32_OperatingSystem** class properties. You can explicitly select the properties to display like this:

PowerShell

```
Get-CimInstance -ClassName Win32_OperatingSystem |  
    Select-Object -Property NumberOfLicensedUsers, NumberOfUsers,  
    RegisteredUser
```

A more succinct version using wildcards is:

PowerShell

```
Get-CimInstance -ClassName Win32_OperatingSystem | Select-Object -Property  
*user*
```

Getting available disk space

To see the disk space and free space for local drives, you can use the **Win32_LogicalDisk** class. You need to see only instances with a **DriveType** of 3, the value WMI uses for fixed hard disks.

PowerShell

```
Get-CimInstance -ClassName Win32_LogicalDisk -Filter "DriveType=3"
```

Output

DeviceID	DriveType	ProviderName	VolumeName	Size	FreeSpace
PSComputerName					
C:	3		Local Disk	203912880128	65541357568 .
Q:	3		New Volume	122934034432	44298250240 .

PowerShell

```
Get-CimInstance -ClassName Win32_LogicalDisk -Filter "DriveType=3" |  
    Measure-Object -Property FreeSpace,Size -Sum |  
    Select-Object -Property Property,Sum
```

Output

Property	Sum
FreeSpace	109839607808
Size	326846914560

Getting logon session information

You can get general information about logon sessions associated with users through the **Win32_LogonSession** WMI class:

PowerShell

```
Get-CimInstance -ClassName Win32_LogonSession
```

Getting the user logged on to a computer

You can display the user logged on to a particular computer system using **Win32_ComputerSystem**. This command returns only the user logged on to the system desktop:

PowerShell

```
Get-CimInstance -ClassName Win32_ComputerSystem -Property UserName
```

Getting local time from a computer

You can retrieve the current local time on a specific computer using the **Win32_LocalTime** WMI class.

PowerShell

```
Get-CimInstance -ClassName Win32_LocalTime
```

Output

```
Day          : 23
DayOfWeek    : 1
Hour         : 8
Milliseconds : 
Minute        : 52
Month         : 12
Quarter       : 4
Second        : 55
WeekInMonth   : 4
Year          : 2019
PSComputerName :
```

Displaying service status

To view the status of all services on a specific computer, you can locally use the **Get-Service** cmdlet. For remote systems, you can use the **Win32_Service** WMI class. If you also use **Select-Object** to filter the results to **Status**, **Name**, and **DisplayName**, the output format is almost identical to that from **Get-Service**:

PowerShell

```
Get-CimInstance -ClassName Win32_Service |
    Select-Object -Property Status,Name,DisplayName
```

To allow the complete display of names for services with long names, use the **AutoSize** and **Wrap** parameters of **Format-Table**. These parameters optimize column width and allow long names to wrap instead of being truncated:

PowerShell

```
Get-CimInstance -ClassName Win32_Service |
    Format-Table -Property Status, Name, DisplayName -AutoSize -Wrap
```

Creating Get-WinEvent queries with FilterHashtable

Article • 06/28/2023

This sample only applies to Windows platforms.

To read the original June 3, 2014 [Scripting Guy](#) blog post, see [Use FilterHashTable to Filter Event Log with PowerShell ↴](#).

This article is an excerpt of the original blog post and explains how to use the `Get-WinEvent` cmdlet's `FilterHashtable` parameter to filter event logs. PowerShell's `Get-WinEvent` cmdlet is a powerful method to filter Windows event and diagnostic logs. Performance improves when a `Get-WinEvent` query uses the `FilterHashtable` parameter.

When you work with large event logs, it's not efficient to send objects down the pipeline to a `Where-Object` command. Prior to PowerShell 6, the `Get-EventLog` cmdlet was another option to get log data. For example, the following commands are inefficient to filter the **Microsoft-Windows-Defrag** logs:

```
PowerShell

Get-EventLog -LogName Application | Where-Object Source -Match defrag

Get-WinEvent -LogName Application | Where-Object { $_.ProviderName -match
'defrag' }
```

The following command uses a hash table that improves the performance:

```
PowerShell

Get-WinEvent -FilterHashtable @{
    LogName='Application'
    ProviderName='*defrag'
}
```

Blog posts about enumeration

This article presents information about how to use enumerated values in a hash table. For more information about enumeration, read these [Scripting Guy](#) blog posts. To

create a function that returns the enumerated values, see [Enumerations and Values](#). For more information, see the [Scripting Guy series of blog posts about enumeration](#).

Hash table key-value pairs

To build efficient queries, use the `Get-WinEvent` cmdlet with the **FilterHashtable** parameter. **FilterHashtable** accepts a hash table as a filter to get specific information from Windows event logs. A hash table uses **key-value** pairs. For more information about hash tables, see [about_Hash_Tables](#).

If the **key-value** pairs are on the same line, they must be separated by a semicolon. If each **key-value** pair is on a separate line, the semicolon isn't needed. For example, this article places **key-value** pairs on separate lines and doesn't use semicolons.

This sample uses several of the **FilterHashtable** parameter's **key-value** pairs. The completed query includes **LogName**, **ProviderName**, **Keywords**, **Id**, and **Level**.

The accepted **key-value** pairs are shown in the following table and are included in the documentation for the [Get-WinEvent FilterHashtable](#) parameter.

The following table displays the key names, data types, and whether wildcard characters are accepted for a data value.

[] Expand table

Key name	Value data type	Accepts wildcard characters?
LogName	<code><String[]></code>	Yes
ProviderName	<code><String[]></code>	Yes
Path	<code><String[]></code>	No
Keywords	<code><Long[]></code>	No
ID	<code><Int32[]></code>	No
Level	<code><Int32[]></code>	No
StartTime	<code><DateTime></code>	No
EndTime	<code><DateTime></code>	No
UserID	<code><SID></code>	No
Data	<code><String[]></code>	No

Key name	Value data type	Accepts wildcard characters?
<named-data>	<String[]>	No

The <named-data> key represents a named event data field. For example, the Perflib event 1008 can contain the following event data:

XML

```
<EventData>
  <Data Name="Service">BITS</Data>
  <Data Name="Library">C:\Windows\System32\bitsperf.dll</Data>
  <Data Name="Win32Error">2</Data>
</EventData>
```

You can query for these events using the following command:

PowerShell

```
Get-WinEvent -FilterHashtable @{LogName='Application'; 'Service'='Bits'}
```

ⓘ Note

The ability to query for <named-data> was added in PowerShell 6.

Building a query with a hash table

To verify results and troubleshoot problems, it helps to build the hash table one **key-value** pair at a time. The query gets data from the **Application** log. The hash table is equivalent to `Get-WinEvent -LogName Application`.

To begin, create the `Get-WinEvent` query. Use the `FilterHashtable` parameter's **key-value** pair with the key, **LogName**, and the value, **Application**.

PowerShell

```
Get-WinEvent -FilterHashtable @{
    LogName='Application'
}
```

Continue to build the hash table with the **ProviderName** key. Usually, the **ProviderName** is the name that appears in the **Source** field in the **Windows Event Viewer**. For example,

.NET Runtime in the following screenshot:

Image of Windows Event Viewer sources

Update the hash table and include the key-value pair with the key, **ProviderName**, and the value, .NET Runtime.

PowerShell

```
Get-WinEvent -FilterHashtable @{
    LogName='Application'
    ProviderName='.NET Runtime'
}
```

ⓘ Note

For some event providers, the correct **ProviderName** can be obtained by looking on the **Details** tab in **Event Properties**. For example, events where the **Source** field shows **Defrag**, the correct **ProviderName** is **Microsoft-Windows-Defrag**.

If your query needs to get data from archived event logs, use the **Path** key. The **Path** value specifies the full path to the log file. For more information, see the **Scripting Guy** blog post, [Use PowerShell to Parse Saved Event Logs for Errors ↗](#).

Using enumerated values in a hash table

Keywords is the next key in the hash table. The **Keywords** data type is an array of the **[long]** value type that holds a large number. Use the following command to find the maximum value of **[long]**:

PowerShell

```
[long]::MaxValue
```

Output

```
9223372036854775807
```

For the **Keywords** key, PowerShell uses a number, not a string such as **Security**. **Windows Event Viewer** displays the **Keywords** as strings, but they're enumerated values. In the hash table, if you use the **Keywords** key with a string value, an error message is displayed.

Open the **Windows Event Viewer** and from the **Actions** pane, click on **Filter current log**.

The **Keywords** drop-down menu displays the available keywords, as shown in the following screenshot:

[Image of Windows Event Viewer keywords](#)

Use the following command to display the `StandardEventKeywords` property names.

```
PowerShell

[System.Diagnostics.Eventing.Reader.StandardEventKeywords] |
    Get-Member -Static -MemberType Property

Output

TypeName: System.Diagnostics.Eventing.Reader.StandardEventKeywords
Name           MemberType Definition
--           -- -- -
AuditFailure   Property  static
System.Diagnostics.Eventing.Reader.StandardEventKey...
AuditSuccess   Property  static
System.Diagnostics.Eventing.Reader.StandardEventKey...
CorrelationHint Property  static
System.Diagnostics.Eventing.Reader.StandardEventKey...
CorrelationHint2 Property static
System.Diagnostics.Eventing.Reader.StandardEventKey...
EventLogClassic Property static
System.Diagnostics.Eventing.Reader.StandardEventKey...
None          Property  static
System.Diagnostics.Eventing.Reader.StandardEventKey...
ResponseTime   Property  static
System.Diagnostics.Eventing.Reader.StandardEventKey...
Sqm            Property  static
System.Diagnostics.Eventing.Reader.StandardEventKey...
WdiContext     Property  static
System.Diagnostics.Eventing.Reader.StandardEventKey...
WdiDiagnostic  Property  static
System.Diagnostics.Eventing.Reader.StandardEventKey...
```

The enumerated values are documented in the [.NET Framework](#). For more information, see [StandardEventKeywords Enumeration](#).

The **Keywords** names and enumerated values are as follows:

[+] [Expand table](#)

Name	Value
AuditFailure	4503599627370496
AuditSuccess	9007199254740992
CorrelationHint2	18014398509481984
EventLogClassic	36028797018963968
Sqm	2251799813685248
WdiDiagnostic	1125899906842624
WdiContext	562949953421312
ResponseTime	281474976710656
None	0

Update the hash table and include the **key-value** pair with the key, **Keywords**, and the **EventLogClassic** enumeration value, **36028797018963968**.

PowerShell

```
Get-WinEvent -FilterHashtable @{
    LogName='Application'
    ProviderName='.NET Runtime'
    Keywords=36028797018963968
}
```

Keywords static property value (optional)

The **Keywords** key is enumerated, but you can use a static property name in the hash table query. Rather than using the returned string, the property name must be converted to a value with the **value__** property.

For example, the following script uses the **value__** property.

PowerShell

```
$C =
[System.Diagnostics.Eventing.Reader.StandardEventKeywords]::EventLogClassic
Get-WinEvent -FilterHashtable @{
    LogName='Application'
    ProviderName='.NET Runtime'
    Keywords=$C.value__}
```

Filtering by Event Id

To get more specific data, the query's results are filtered by **Event Id**. The **Event Id** is referenced in the hash table as the key **Id** and the value is a specific **Event Id**. The **Windows Event Viewer** displays the **Event Id**. This example uses **Event Id 1023**.

Update the hash table and include the **key-value** pair with the key, **Id** and the value, **1023**.

PowerShell

```
Get-WinEvent -FilterHashtable @{
    LogName='Application'
    ProviderName='.NET Runtime'
    Keywords=36028797018963968
    ID=1023
}
```

Filtering by Level

To further refine the results and include only events that are errors, use the **Level** key. **Windows Event Viewer** displays the **Level** as string values, but they're enumerated values. In the hash table, if you use the **Level** key with a string value, an error message is displayed.

Level has values such as **Error**, **Warning**, or **Informational**. Use the following command to display the **StandardEventLevel** property names.

PowerShell

```
[System.Diagnostics.Eventing.Reader.StandardEventLevel] |
    Get-Member -Static -MemberType Property
```

Output

```
Type Name: System.Diagnostics.Eventing.Reader.StandardEventLevel
```

Name	MemberType	Definition
Critical	Property	static System.Diagnostics.Eventing.Reader.StandardEventLevel Critical {get;}
Error	Property	static System.Diagnostics.Eventing.Reader.StandardEventLevel Error {get;}
Informational	Property	static System.Diagnostics.Eventing.Reader.StandardEventLevel Informational {get;}
LogAlways	Property	static

```
System.Diagnostics.Eventing.Reader.StandardEventLevel LogAlways {get;}  
Verbose      Property static  
System.Diagnostics.Eventing.Reader.StandardEventLevel Verbose {get;}  
Warning      Property static  
System.Diagnostics.Eventing.Reader.StandardEventLevel Warning {get;}
```

The enumerated values are documented in the [.NET Framework](#). For more information, see [StandardEventLevel Enumeration](#).

The **Level** key's names and enumerated values are as follows:

[+] Expand table

Name	Value
Verbose	5
Informational	4
Warning	3
Error	2
Critical	1
LogAlways	0

The hash table for the completed query includes the key, **Level**, and the value, **2**.

PowerShell

```
Get-WinEvent -FilterHashtable @{  
    LogName='Application'  
    ProviderName='.NET Runtime'  
    Keywords=36028797018963968  
    ID=1023  
    Level=2  
}
```

Level static property in enumeration (optional)

The **Level** key is enumerated, but you can use a static property name in the hash table query. Rather than using the returned string, the property name must be converted to a value with the **value__** property.

For example, the following script uses the **value__** property.

PowerShell

```
$C = [System.Diagnostics.Eventing.Reader.StandardEventLevel]::Informational
Get-WinEvent -FilterHashtable @{
    LogName='Application'
    ProviderName='.NET Runtime'
    Keywords=36028797018963968
    ID=1023
    Level=$C.value__
}
```

Managing processes with Process cmdlets

Article • 12/09/2022

This sample only applies to Windows PowerShell 5.1.

You can use the Process cmdlets in PowerShell to manage local and remote processes in PowerShell.

Getting processes

To get the processes running on the local computer, run a `Get-Process` with no parameters.

You can get particular processes by specifying their process names or process IDs. The following command gets the Idle process:

PowerShell

```
Get-Process -Id 0
```

Output

Handles	NPM(K)	PM(K)	WS(K)	VM(M)	CPU(s)	Id	ProcessName
0	0	0	16	0		0	Idle

Although it's normal for cmdlets to return no data in some situations, when you specify a process by its `ProcessId`, `Get-Process` generates an error if it finds no matches, because the usual intent is to retrieve a known running process. If there is no process with that ID, it's likely that the ID is incorrect or that the process of interest has already exited:

PowerShell

```
Get-Process -Id 99
```

Output

```
Get-Process : No process with process ID 99 was found.  
At line:1 char:12  
+ Get-Process <<< -Id 99
```

You can use the `Name` parameter of the `Get-Process` cmdlet to specify a subset of processes based on the process name. The `Name` parameter can take multiple names in a comma-separated list and it supports the use of wildcards, so you can type name patterns.

For example, the following command gets process whose names begin with "ex."

PowerShell

```
Get-Process -Name ex*
```

Output

Handles	NPM(K)	PM(K)	WS(K)	VM(M)	CPU(s)	Id	ProcessName
234	7	5572	12484	134	2.98	1684	EXCEL
555	15	34500	12384	134	105.25	728	explorer

Because the .NET `System.Diagnostics.Process` class is the foundation for PowerShell processes, it follows some of the conventions used by `System.Diagnostics.Process`. One of those conventions is that the process name for an executable never includes the `.exe` at the end of the executable name.

`Get-Process` also accepts multiple values for the `Name` parameter.

PowerShell

```
Get-Process -Name exp*,power*
```

Output

Handles	NPM(K)	PM(K)	WS(K)	VM(M)	CPU(s)	Id	ProcessName
540	15	35172	48148	141	88.44	408	explorer
605	9	30668	29800	155	7.11	3052	powershell

You can use the `ComputerName` parameter of `Get-Process` to get processes on remote computers. For example, the following command gets the PowerShell processes on the local computer (represented by "localhost") and on two remote computers.

PowerShell

```
Get-Process -Name powershell -ComputerName localhost, Server01, Server02
```

Output

Handles	NPM(K)	PM(K)	WS(K)	VM(M)	CPU(s)	Id	ProcessName
258	8	29772	38636	130		3700	powershell
398	24	75988	76800	572		5816	powershell
605	9	30668	29800	155	7.11	3052	powershell

The computer names aren't evident in this display, but they're stored in the **MachineName** property of the process objects that `Get-Process` returns. The following command uses the `Format-Table` cmdlet to display the process **Id**, **ProcessName** and **MachineName** (ComputerName) properties of the process objects.

PowerShell

```
Get-Process -Name powershell -ComputerName localhost, Server01, Server02 |  
Format-Table -Property Id, ProcessName, MachineName
```

Output

Id	ProcessName	MachineName
3700	powershell	Server01
3052	powershell	Server02
5816	powershell	localhost

This more complex command adds the **MachineName** property to the standard `Get-Process` display.

PowerShell

```
Get-Process powershell -ComputerName localhost, Server01, Server02 |  
Format-Table -Property Handles,  
@{Label="NPM(K)";Expression={[int]($_.NPM/1024)}},  
@{Label="PM(K)";Expression={[int]($_.PM/1024)}},  
@{Label="WS(K)";Expression={[int]($_.WS/1024)}},  
@{Label="VM(M)";Expression={[int]($_.VM/1MB)}},  
@{Label="CPU(s)";Expression={if ($_.CPU -ne $())  
{$_.CPU.ToString("N")}}},  
Id, ProcessName, MachineName -Auto
```

Output

Handles	NPM(K)	PM(K)	WS(K)	VM(M)	CPU(s)	Id	ProcessName	MachineName
258	8	29772	38636	130		3700	powershell	Server01
398	24	75988	76800	572		5816	powershell	localhost
605	9	30668	29800	155	7.11	3052	powershell	Server02

Stopping processes

PowerShell gives you flexibility for listing processes, but what about stopping a process?

The `Stop-Process` cmdlet takes a **Name** or **Id** to specify a process you want to stop. Your ability to stop processes depends on your permissions. Some processes can't be stopped. For example, if you try to stop the idle process, you get an error:

PowerShell

```
Stop-Process -Name Idle
```

Output

```
Stop-Process : Process 'Idle (0)' cannot be stopped due to the following
error:
Access is denied
At line:1 char:13
+ Stop-Process <<< -Name Idle
```

You can also force prompting with the **Confirm** parameter. This parameter is particularly useful if you use a wildcard when specifying the process name, because you may accidentally match some processes you don't want to stop:

PowerShell

```
Stop-Process -Name t*,e* -Confirm
```

Output

```
Confirm
Are you sure you want to perform this action?
Performing operation "Stop-Process" on Target "explorer (408)".
[Y] Yes [A] Yes to All [N] No [L] No to All [S] Suspend [?] Help
(default is "Y"):n
Confirm
Are you sure you want to perform this action?
```

```
Performing operation "Stop-Process" on Target "taskmgr (4072)".  
[Y] Yes [A] Yes to All [N] No [L] No to All [S] Suspend [?] Help  
(default is "Y"):n
```

Complex process manipulation is possible by using some of the object filtering cmdlets. Because a Process object has a **Responding** property that's true when it's no longer responding, you can stop all nonresponsive applications with the following command:

PowerShell

```
Get-Process | Where-Object -FilterScript {$_.Responding -eq $false} | Stop-  
Process
```

You can use the same approach in other situations. For example, suppose a secondary notification area application automatically runs when users start another application. You may find that this doesn't work correctly in Terminal Services sessions, but you still want to keep it in sessions that run on the physical computer console. Sessions connected to the physical computer desktop always have a session ID of 0, so you can stop all instances of the process that are in other sessions by using `Where-Object` and the process, `SessionId`:

PowerShell

```
Get-Process -Name BadApp | Where-Object -FilterScript {$_.SessionId -neq 0}  
| Stop-Process
```

The `Stop-Process` cmdlet doesn't have a `ComputerName` parameter. Therefore, to run a stop process command on a remote computer, you need to use the `Invoke-Command` cmdlet. For example, to stop the PowerShell process on the Server01 remote computer, type:

PowerShell

```
Invoke-Command -ComputerName Server01 {Stop-Process PowerShell}
```

Stopping All Other PowerShell Sessions

It may occasionally be useful to be able to stop all running PowerShell sessions other than the current session. If a session is using too many resources or is inaccessible (it may be running remotely or in another desktop session), you may not be able to directly stop it. If you try to stop all running sessions, however, the current session may be terminated instead.

Each PowerShell session has an environment variable PID that contains the Id of the Windows PowerShell process. You can check the \$PID against the Id of each session and terminate only Windows PowerShell sessions that have a different Id. The following pipeline command does this and returns the list of terminated sessions (because of the use of the **PassThru** parameter):

PowerShell

```
Get-Process -Name powershell | Where-Object -FilterScript {$_._Id -ne $PID} | Stop-Process -PassThru
```

Output

Handles	NPM(K)	PM(K)	WS(K)	VM(M)	CPU(s)	Id	ProcessName
334	9	23348	29136	143	1.03	388	powershell
304	9	23152	29040	143	1.03	632	powershell
302	9	20916	26804	143	1.03	1116	powershell
335	9	25656	31412	143	1.09	3452	powershell
303	9	23156	29044	143	1.05	3608	powershell
287	9	21044	26928	143	1.02	3672	powershell

Starting, debugging, and waiting for processes

PowerShell also comes with cmdlets to start (or restart), debug a process, and wait for a process to complete before running a command. For information about these cmdlets, see the cmdlet help topic for each cmdlet.

Managing services

Article • 12/09/2022

This sample only applies to Windows PowerShell 5.1.

There are eight core **Service** cmdlets, designed for a wide range of service tasks . This article only looks at listing and changing running state for services. You can get a list of service cmdlets using `Get-Command *-Service`. You can find information about each cmdlet by using `Get-Help <Cmdlet-Name>`, such as `Get-Help New-Service`.

Getting services

You can get the services on a local or remote computer by using the `Get-Service` cmdlet. As with `Get-Process`, using the `Get-Service` command without parameters returns all services. You can filter by name, even using an asterisk as a wildcard:

```
PowerShell

PS> Get-Service -Name se*

Status      Name            DisplayName
----      ----            -----
Running    seclogon        Secondary Logon
Running    SENS            System Event Notification
Stopped   ServiceLayer    ServiceLayer
```

Because it isn't always apparent what the real name for the service is, you may find you need to find services by display name. You can search by specific name, use wildcards, or provide a list of display names:

```
PowerShell

PS> Get-Service -DisplayName se*

Status      Name            DisplayName
----      ----            -----
Running    lanmanserver    Server
Running    SamSs           Security Accounts Manager
Running    seclogon        Secondary Logon
Stopped   ServiceLayer    ServiceLayer
Running    wscsvc          Security Center

PS> Get-Service -DisplayName ServiceLayer, Server
```

Status	Name	DisplayName
Running	lanmanserver	Server
Stopped	ServiceLayer	ServiceLayer

Getting remote services

With Windows PowerShell, you can use the `ComputerName` parameter of the `Get-Service` cmdlet to get the services on remote computers. The `ComputerName` parameter accepts multiple values and wildcard characters, so you can get the services on multiple computers with a single command. For example, the following command gets the services on the `Server01` remote computer.

```
PowerShell
```

```
Get-Service -ComputerName Server01
```

Starting in PowerShell 6.0, the `*-Service` cmdlets don't have the `ComputerName` parameter. You can still get services on remote computers with PowerShell remoting. For example, the following command gets the services on the `Server02` remote computer.

```
PowerShell
```

```
Invoke-Command -ComputerName Server02 -ScriptBlock { Get-Service }
```

You can also manage services with the other `*-Service` cmdlets. For more information on PowerShell remoting, see [about_Remote](#).

Getting required and dependent services

The `Get-Service` cmdlet has two parameters that are very useful in service administration. The `DependentServices` parameter gets services that depend on the service.

The `RequiredServices` parameter gets services upon which the `LanmanWorkstation` service depends.

```
PowerShell
```

```
PS> Get-Service -Name LanmanWorkstation -RequiredServices
```

Status	Name	DisplayName
-----	-----	-----

Running	MRxSmb20	SMB 2.0 MiniRedirector
Running	bowser	Bowser
Running	MRxSmb10	SMB 1.x MiniRedirector
Running	NSI	Network Store Interface Service

The **DependentServices** parameter gets services that require the LanmanWorkstation service.

PowerShell

```
PS> Get-Service -Name LanmanWorkstation -DependentServices
```

Status	Name	DisplayName
Running	SessionEnv	Terminal Services Configuration
Running	Netlogon	Netlogon
Stopped	Browser	Computer Browser
Running	BITS	Background Intelligent Transfer Ser...

The following command gets all services that have dependencies. The **Format-Table** cmdlet to display the **Status**, **Name**, **RequiredServices**, and **DependentServices** properties of the services.

PowerShell

```
Get-Service -Name * | Where-Object {$_._RequiredServices -or
$_._DependentServices} |
Format-Table -Property Status, Name, RequiredServices, DependentServices -
Auto
```

Stopping, starting, suspending, and restarting services

The Service cmdlets all have the same general form. Services can be specified by common name or display name, and take lists and wildcards as values. To stop the print spooler, use:

PowerShell

```
Stop-Service -Name spooler
```

To start the print spooler after it's stopped, use:

PowerShell

```
Start-Service -Name spooler
```

To suspend the print spooler, use:

PowerShell

```
Suspend-Service -Name spooler
```

The `Restart-Service` cmdlet works in the same manner as the other Service cmdlets:

PowerShell

```
PS> Restart-Service -Name spooler
```

```
WARNING: Waiting for service 'Print Spooler (Spooler)' to finish starting...
WARNING: Waiting for service 'Print Spooler (Spooler)' to finish starting...
PS>
```

Notice that you get a repeated warning message about the Print Spooler starting up. When you perform a service operation that takes some time, PowerShell notifies you that it's still attempting to perform the task.

If you want to restart multiple services, you can get a list of services, filter them, and then perform the restart:

PowerShell

```
PS> Get-Service | Where-Object -FilterScript {$_._CanStop} | Restart-Service

WARNING: Waiting for service 'Computer Browser (Browser)' to finish
stopping...
WARNING: Waiting for service 'Computer Browser (Browser)' to finish
stopping...
Restart-Service : can't stop service 'Logical Disk Manager (dmserver)'
because
    it has dependent services. It can only be stopped if the Force flag is set.
At line:1 char:57
+ Get-Service | Where-Object -FilterScript {$_._CanStop} | Restart-Service
<<<
WARNING: Waiting for service 'Print Spooler (Spooler)' to finish starting...
WARNING: Waiting for service 'Print Spooler (Spooler)' to finish starting...
```

These Service cmdlets don't have a `ComputerName` parameter, but you can run them on a remote computer by using the `Invoke-Command` cmdlet. For example, the following command restarts the Spooler service on the Server01 remote computer.

PowerShell

```
Invoke-Command -ComputerName Server01 {Restart-Service Spooler}
```

Setting service properties

The `Set-Service` cmdlet changes the properties of a service on a local or remote computer. Because the service status is a property, you can use this cmdlet to start, stop, and suspend a service. The Set-Service cmdlet also has a `StartupType` parameter that lets you change the service startup type.

To use `Set-Service` on Windows Vista and later versions of Windows, open PowerShell with the **Run as administrator** option.

For more information, see [Set-Service](#)

Working with printers in Windows

Article • 12/09/2022

This sample only applies to Windows platforms.

You can use PowerShell to manage printers using WMI and the `WScript.Network` COM object from WSH.

Listing printer connections

The simplest way to list the printers installed on a computer is to use the WMI `Win32_Printer` class:

PowerShell

```
Get-CimInstance -Class Win32_Printer
```

You can also list the printers using the `WScript.Network` COM object that's typically used in WSH scripts:

PowerShell

```
(New-Object -ComObject WScript.Network).EnumPrinterConnections()
```

Because this command returns a simple string collection of port names and printer device names without any distinguishing labels, it isn't easy to interpret.

Adding a network printer

To add a new network printer, use `WScript.Network`:

PowerShell

```
(New-Object -ComObject  
WScript.Network).AddWindowsPrinterConnection("\\\Printserver01\Xerox5")
```

Setting a default printer

To use WMI to set the default printer, find the printer in the `Win32_Printer` collection and then invoke the `SetDefaultPrinter` method:

PowerShell

```
$printer = Get-CimInstance -Class Win32_Printer -Filter "Name='HP LaserJet 5Si'"  
Invoke-CimMethod -InputObject $printer -MethodName SetDefaultPrinter
```

`WScript.Network` is a little simpler to use, because it has a `SetDefaultPrinter` method that takes only the printer name as an argument:

PowerShell

```
(New-Object -ComObject WScript.Network).SetDefaultPrinter('HP LaserJet 5Si')
```

Removing a printer connection

To remove a printer connection, use the `WScript.Network RemovePrinterConnection` method:

PowerShell

```
(New-Object -ComObject  
WScript.Network).RemovePrinterConnection("\Printserver01\Xerox5")
```

Performing networking tasks

Article • 02/12/2025

This sample only applies to Windows platforms.

Because TCP/IP is the most commonly used network protocol, most low-level network protocol administration tasks involve TCP/IP. In this section, we use PowerShell and WMI to do these tasks.

Listing IP addresses for a computer

To get all IP addresses in use on the local computer, use the following command:

PowerShell

```
Get-CimInstance -Class Win32_NetworkAdapterConfiguration -Filter  
IPEnabled=$true |  
Select-Object -ExpandProperty IPAddress
```

Since the **IPAddress** property of a **Win32_NetworkAdapterConfiguration** object is an array, you must use the **ExpandProperty** parameter of **Select-Object** to see the entire list of addresses.

Output

```
10.0.0.1  
fe80::60ea:29a7:a233:7cb7  
2601:600:a27f:a470:f532:6451:5630:ec8b  
2601:600:a27f:a470:e167:477d:6c5c:342d  
2601:600:a27f:a470:b021:7f0d:eab9:6299  
2601:600:a27f:a470:a40e:ebce:1a8c:a2f3  
2601:600:a27f:a470:613c:12a2:e0e0:bd89  
2601:600:a27f:a470:444f:17ec:b463:7edd  
2601:600:a27f:a470:10fd:7063:28e9:c9f3  
2601:600:a27f:a470:60ea:29a7:a233:7cb7  
2601:600:a27f:a470::2ec1
```

Using the **Get-Member** cmdlet, you can see that the **IPAddress** property is an array:

PowerShell

```
Get-CimInstance -Class Win32_NetworkAdapterConfiguration -Filter  
IPEnabled=$true |
```

```
Get-Member -Name IPAddress
```

Output

```
TypeName:  
Microsoft.Management.Infrastructure.CimInstance#root/cimv2/Win32_NetworkAdapterConfiguration  
  
Name      MemberType Definition  
----      -----  
IPAddress Property   string[] IPAddress {get;}
```

The **IPAddress** property for each network adapter is actually an array. The braces in the definition indicate that **IPAddress** isn't a **System.String** value, but an array of **System.String** values.

Listing IP configuration data

To display detailed IP configuration data for each network adapter, use the following command:

PowerShell

```
Get-CimInstance -Class Win32_NetworkAdapterConfiguration -Filter  
IPEnabled=$true
```

The default display for the network adapter configuration object is a very reduced set of the available information. For in-depth inspection and troubleshooting, use **Select-Object** or a formatting cmdlet, such as **Format-List**, to specify the properties to be displayed.

In modern TCP/IP networks you are probably not interested in IPX or WINS properties. You can use the **ExcludeProperty** parameter of **Select-Object** to hide properties with names that begin with "WINS" or "IPX".

PowerShell

```
Get-CimInstance -Class Win32_NetworkAdapterConfiguration -Filter  
IPEnabled=$true |  
Select-Object -ExcludeProperty IPX*,WINS*
```

This command returns detailed information about DHCP, DNS, routing, and other minor IP configuration properties.

Pinging computers

You can perform a simple ping against a computer by using `Win32_PingStatus`. The following command performs the ping, but returns lengthy output:

PowerShell

```
Get-CimInstance -Class Win32_PingStatus -Filter "Address='127.0.0.1'"
```

The response from `Win32_PingStatus` contains 29 properties. You can use `Format-Table` to select the properties that are most interesting to you. The `AutoSize` parameter of `Format-Table` resizes the table columns so that they display properly in PowerShell.

PowerShell

```
Get-CimInstance -Class Win32_PingStatus -Filter "Address='127.0.0.1'" | Format-Table -Property Address,ResponseTime,StatusCode -AutoSize
```

Output

Address	ResponseTime	StatusCode
127.0.0.1	0	0

A `StatusCode` of 0 indicates a successful ping.

You can use an array to ping multiple computers with a single command. Because there is more than one address, use the `ForEach-Object` to ping each address separately:

PowerShell

```
'127.0.0.1','localhost','bing.com' | ForEach-Object -Process { Get-CimInstance -Class Win32_PingStatus -Filter ("Address='$_'") | Select-Object -Property Address,ResponseTime,StatusCode }
```

You can use the same command format to ping all the addresses on a subnet, such as a private network that uses network number 192.168.1.0 and a standard Class C subnet mask (255.255.255.0). Only addresses in the range of 192.168.1.1 through 192.168.1.254 are legitimate local addresses (0 is always reserved for the network number and 255 is a subnet broadcast address).

To represent an array of the numbers from 1 through 254 in PowerShell, use the expression `1..254`. A complete subnet ping can be performed by adding each value in the range to a partial address in the ping statement:

```
PowerShell

1..254 | ForEach-Object -Process {
    Get-CimInstance -Class Win32_PingStatus -Filter ("Address='192.168.1.$_''")
} |
    Select-Object -Property Address,ResponseTime,StatusCode
```

Note that this technique for generating a range of addresses can be used elsewhere as well. You can generate a complete set of addresses in this way:

```
PowerShell

$ips = 1..254 | ForEach-Object -Process {'192.168.1.' + $_}
```

Retrieving network adapter properties

Earlier, we mentioned that you could retrieve general configuration properties using the **Win32_NetworkAdapterConfiguration** class. Although not strictly TCP/IP information, network adapter information such as MAC addresses and adapter types can be useful for understanding what's going on with a computer. To get a summary of this information, use the following command:

```
PowerShell

Get-CimInstance -Class Win32_NetworkAdapter -ComputerName .
```

Assigning the DNS domain for a network adapter

To assign the DNS domain for automatic name resolution, use the **SetDNSDomain** method of the **Win32_NetworkAdapterConfiguration**. The **Query** parameter of **Invoke-CimMethod** takes a WQL query string. The cmdlet calls the method specified on each instance returned by the query.

```
PowerShell
```

```
$wql = 'SELECT * FROM Win32_NetworkAdapterConfiguration WHERE  
IPEnabled=True'  
$args = @{ DnsDomain = 'fabrikam.com'}  
Invoke-CimMethod -MethodName SetDNSDomain -Arguments $args -Query $wql
```

Filtering on `IPEnabled=True` is necessary, because even on a network that uses only TCP/IP, several of the network adapter configurations on a computer aren't true TCP/IP adapters. They're general software elements supporting RAS, VPN, QoS, and other services for all adapters and thus don't have an address of their own.

Performing DHCP configuration tasks

Modifying DHCP details involves working with a set of network adapters, just as the DNS configuration does. There are several distinct actions you can perform using WMI.

Finding DHCP-enabled adapters

To find the DHCP-enabled adapters on a computer, use the following command:

PowerShell

```
Get-CimInstance -Class Win32_NetworkAdapterConfiguration -Filter  
"DHCPEnabled=$true"
```

To exclude adapters with IP configuration problems, you can retrieve only IP-enabled adapters:

PowerShell

```
Get-CimInstance -Class Win32_NetworkAdapterConfiguration -Filter  
"IPEnabled=$true and DHCPEnabled=$true"
```

Retrieving DHCP properties

Because DHCP-related properties for an adapter generally begin with `DHCP`, you can use the `Property` parameter of `Format-Table` to display only those properties:

PowerShell

```
Get-CimInstance -Class Win32_NetworkAdapterConfiguration -Filter  
"IPEnabled=$true and DHCPEnabled=$true" |
```

```
Format-Table -Property DHCP*
```

Enabling DHCP on each adapter

To enable DHCP on all adapters, use the following command:

PowerShell

```
$wql = 'SELECT * from Win32_NetworkAdapterConfiguration WHERE IPEnabled=True  
and DHCPEnabled=False'  
Invoke-CimMethod -MethodName ReleaseDHCPLease -Query $wql
```

Using the filter statement `IPEnabled=True and DHCPEnabled=False` avoids enabling DHCP where it's already enabled.

Releasing and renewing DHCP leases on specific adapters

Instances of the `Win32_NetworkAdapterConfiguration` class has `ReleaseDHCPLease` and `RenewDHCPLease` methods. Both are used in the same way. In general, use these methods if you only need to release or renew addresses for an adapter on a specific subnet. The easiest way to filter adapters on a subnet is to choose only the adapter configurations that use the gateway for that subnet. For example, the following command releases all DHCP leases on adapters on the local computer that are obtaining DHCP leases from 192.168.1.254:

PowerShell

```
$wql = 'SELECT * from Win32_NetworkAdapterConfiguration WHERE  
DHCPServer="192.168.1.1"'  
Invoke-CimMethod -MethodName ReleaseDHCPLease -Query $wql
```

The only change for renewing a DHCP lease is to use the `RenewDHCPLease` method instead of the `ReleaseDHCPLease` method:

PowerShell

```
$wql = 'SELECT * from Win32_NetworkAdapterConfiguration WHERE  
DHCPServer="192.168.1.1"'  
Invoke-CimMethod -MethodName RenewDHCPLease -Query $wql
```

ⓘ Note

When using these methods on a remote computer, be aware that you can lose access to the remote system if you are connected to it through the adapter with the released or renewed lease.

Releasing and renewing DHCP leases on all adapters

You can perform global DHCP address releases or renewals on all adapters by using the `Win32_NetworkAdapterConfiguration` methods, `ReleaseDHCPLeaseAll` and `RenewDHCPLeaseAll`. However, the command must apply to the WMI class, rather than a particular adapter, because releasing and renewing leases globally is performed on the class, not on a specific adapter. The `Invoke-CimMethod` cmdlet can call the methods of a class.

PowerShell

```
Invoke-CimMethod -ClassName Win32_NetworkAdapterConfiguration -MethodName ReleaseDHCPLeaseAll
```

You can use the same command format to invoke the `RenewDHCPLeaseAll` method:

PowerShell

```
Invoke-CimMethod -ClassName Win32_NetworkAdapterConfiguration -MethodName RenewDHCPLeaseAll
```

Creating a network share

To create a network share, use the `Create` method of `Win32_Share`:

PowerShell

```
Invoke-CimMethod -ClassName Win32_Share -MethodName Create -Arguments @{
    Path = 'C:\temp'
    Name = 'TempShare'
    Type = [uint32]0 #Disk Drive
    MaximumAllowed = [uint32]25
    Description = 'test share of the temp folder'
}
```

This is equivalent to the following `net share` command on Windows:

PowerShell

```
net share tempshare=C:\temp /users:25 /remark:"test share of the temp folder"
```

To call a method of a WMI class that takes parameters you must know what parameters are available and the types of those parameters. For example, you can list the methods of the **Win32_Class** with the following commands:

PowerShell

```
(Get-CimClass -ClassName Win32_Share).CimClassMethods
```

Output

Name	ReturnType	Parameters
Qualifiers		
-----	-----	-----

Create	UInt32	{Access, Description, MaximumAllowed, Name...}
	{Constructor, Implemented, MappingStrings, Stati...	
SetShareInfo	UInt32	{Access, Description, MaximumAllowed}
	{Implemented, MappingStrings}	
GetAccessMask	UInt32	{}
	{Implemented, MappingStrings}	
Delete	UInt32	{}
	{Destructor, Implemented, MappingStrings}	

Use the following command to list the parameters of the `Create` method.

PowerShell

```
(Get-CimClass -ClassName Win32_Share).CimClassMethods['Create'].Parameters
```

Output

Name	CimType	Qualifiers
ReferenceClassName		
-----	-----	-----

Access	Instance	{EmbeddedInstance, ID, In, MappingStrings...}
Description	String	{ID, In, MappingStrings, Optional}
MaximumAllowed	UInt32	{ID, In, MappingStrings, Optional}
Name	String	{ID, In, MappingStrings}
Password	String	{ID, In, MappingStrings, Optional}
Path	String	{ID, In, MappingStrings}
Type	UInt32	{ID, In, MappingStrings}

You can also read the documentation for [Create](#) method of the `Win32_Share` class.

Removing a network share

You can remove a network share with `Win32_Share`, but the process is slightly different from creating a share, because you need to retrieve the specific instance to be removed, rather than the `Win32_Share` class. The following example deletes the share `TempShare`:

PowerShell

```
$wql = 'SELECT * from Win32_Share WHERE Name="TempShare"'
Invoke-CimMethod -MethodName Delete -Query $wql
```

Connecting a Windows-accessible network drive

The `New-PSDrive` cmdlet can create a PowerShell drive that's mapped to a network share.

PowerShell

```
New-PSDrive -Name "X" -PSProvider "FileSystem" -Root "\\\Server01\Public"
```

However, drives created this way are only available to PowerShell session where they're created. To map a drive that's available outside of PowerShell (or to other PowerShell sessions), you must use the `Persist` parameter.

PowerShell

```
New-PSDrive -Persist -Name "X" -PSProvider "FileSystem" -Root
"\\\Server01\Public"
```

ⓘ Note

Persistently mapped drives may not be available when running in an elevated context. This is the default behavior of Windows UAC. For more information, see the following article:

- [Mapped drives aren't available from an elevated prompt when UAC is configured to Prompt for credentials](#)

Working with software installations

Article • 03/17/2023

Applications installed with the Windows Installer can be found through WMI's queries, but not all applications use the Windows Installer. The specific techniques for finding applications installed with other tools depends on the installer software.

For example, applications installed by copying the files to a folder on the computer usually can't be managed using techniques discussed here. You can manage these applications as files and folders using the techniques discussed in [Working With Files and Folders](#).

For software installed using an installer package, the Windows Installer can be found using the `Win32Reg_AddRemovePrograms` or the `Win32_Product` classes. However, both of these have problems. The `Win32Reg_AddRemovePrograms` is only available if you are using System Center Configuration Manager (SCCM). And the `Win32_Product` class can be slow and has side effects.

⊗ Caution

The `Win32_Product` class isn't query optimized. Queries that use wildcard filters cause WMI to use the MSI provider to enumerate all installed products then parse the full list sequentially to handle the filter. This also initiates a consistency check of packages installed, verifying and repairing the install. The validation is a slow process and may result in errors in the event logs. For more information seek [KB article 974524](#).

This article provides an alternative method for finding installed software.

Querying the Uninstall registry key to find installed software

Because most standard applications register an uninstaller with Windows, we can work with those locally by finding them in the Windows registry. There is no guaranteed way to find every application on a system. However, it's possible to find all programs with listings displayed in **Add or Remove Programs** in the following registry key:

`HKEY_LOCAL_MACHINE\Software\Microsoft\Windows\CurrentVersion\Uninstall`.

We can find the number of installed applications by counting the number of registry keys:

PowerShell

```
$UninstallPath = 'HKLM:\Software\Microsoft\Windows\CurrentVersion\Uninstall'  
(Get-ChildItem -Path $UninstallPath).Count
```

Output

```
459
```

We can search this list of applications further using a variety of techniques. To display the values of the registry values in the registry keys under `Uninstall`, use the `GetValue()` method of the registry keys. The value of the method is the name of the registry entry. For example, to find the display names of applications in the `Uninstall` key, use the following command:

PowerShell

```
Get-ChildItem -Path $UninstallPath |  
ForEach-Object -Process { $_.GetValue('DisplayName') } |  
Sort-Object
```

ⓘ Note

There is no guarantee that the `DisplayName` values are unique.

The following example produces output similar to the `Win32Reg_AddRemovePrograms` class:

PowerShell

```
Get-ChildItem $UninstallPath |  
ForEach-Object {  
    $ProdID = ($_.Name -split '\\')[-1]  
    Get-ItemProperty -Path "$UninstallPath\$ProdID" -ea SilentlyContinue  
    |  
        Select-Object -Property DisplayName, InstallDate, @{n='ProdID'; e={$ProdID}}, Publisher, DisplayVersion  
    } | Select-Object -First 3
```

For the sake of brevity, this example uses `Select-Object` to limit the number of items returned to three.

Output

```
DisplayName      : 7-Zip 22.01 (x64)
InstallDate     :
ProdID          : 7-Zip
Publisher        : Igor Pavlov
DisplayVersion   : 22.01

DisplayName      : AutoHotkey 1.1.33.10
InstallDate     :
ProdID          : AutoHotkey
Publisher        : Lexikos
DisplayVersion   : 1.1.33.10

DisplayName      : Beyond Compare 4.4.6
InstallDate     : 20230310
ProdID          : BeyondCompare4_is1
Publisher        : Scooter Software
DisplayVersion   : 4.4.6.27483
```

Decode a PowerShell command from a running process

Article • 12/09/2022

This sample only runs on Windows platforms.

At times, you may have a PowerShell process running that's taking up a large amount of resources. This process could be running in the context of a [Task Scheduler](#) job or a [SQL Server Agent](#) job. Where there are multiple PowerShell processes running, it can be difficult to know which process represents the problem. This article shows how to decode a script block that a PowerShell process is currently running.

Create a long running process

To demonstrate this scenario, open a new PowerShell window and run the following code. It executes a PowerShell command that outputs a number every minute for 10 minutes.

```
PowerShell

powershell.exe -Command {
    $i = 1
    while ( $i -le 10 )
    {
        Write-Output -InputObject $i
        Start-Sleep -Seconds 60
        $i++
    }
}
```

View the process

The body of the command that PowerShell is executing is stored in the **CommandLine** property of the [Win32_Process](#) class. If the command is an encoded command, the **CommandLine** property contains the string "EncodedCommand". Using this information, the encoded command can be de-obfuscated via the following process.

Start PowerShell as Administrator. It's vital that PowerShell is running as administrator, otherwise no results are returned when querying the running processes.

Execute the following command to get all the PowerShell processes that have an encoded command:

```
PowerShell

$powerShellProcesses = Get-CimInstance -ClassName Win32_Process -Filter
'CommandLine LIKE "%EncodedCommand%"'
```

The following command creates a custom PowerShell object that contains the process ID and the encoded command.

```
PowerShell

$commandDetails = $powerShellProcesses | Select-Object -Property ProcessId,
@{
    Name      = 'EncodedCommand'
    Expression = {
        if ( $_.CommandLine -match 'encodedCommand (.*) -inputFormat' )
        {
            return $Matches[1]
        }
    }
}
```

Now the encoded command can be decoded. The following snippet iterates over the command details object, decodes the encoded command, and adds the decoded command back to the object for further investigation.

```
PowerShell

$commandDetails | ForEach-Object -Process {
    # Get the current process
    $currentProcess = $_

    # Convert the Base 64 string to a Byte Array
    $commandBytes =
[System.Convert]::FromBase64String($currentProcess.EncodedCommand)

    # Convert the Byte Array to a string
    $decodedCommand =
[System.Text.Encoding]::Unicode.GetString($commandBytes)

    # Add the decoded command back to the object
    $commandDetails |
        Where-Object -FilterScript { $_.ProcessId -eq
$currentProcess.ProcessId } |
            Add-Member -MemberType NoteProperty -Name DecodedCommand -Value
$decodedCommand
```

```
}
```

```
$commandDetails[0] | Format-List -Property *
```

The decoded command can now be reviewed by selecting the decoded command property.

Output

```
ProcessId      : 8752
EncodedCommand :
IAAKAAoACgAgAAoAIAAgACAAIAAkAGkAIAA9ACAAMQAgAAoACgAKACAAcGAgACAAIAAgAHcAaABp

AAIAAgACAAIAAgACQAaQArACsA
IAAKAAoACgAgAAoAIAAgACAAIAB9ACAAcGAKAAoAIAAKAA==

DecodedCommand :
    $i = 1
    while ( $i -le 10 )
    {
        Write-Output -InputObject $i
        Start-Sleep -Seconds 60
        $i++
    }
```

Redirecting output

Article • 05/14/2024

PowerShell provides several cmdlets that let you control data output directly. These cmdlets share two important characteristics.

First, they generally transform data to some form of text. They do this because they output the data to system components that require text input. This means they need to represent the objects as text. Therefore, the text is formatted as you see it in the PowerShell console window.

Second, these cmdlets use the PowerShell verb **Out** because they send information out from PowerShell to somewhere else.

Console output

By default, PowerShell sends data to the host window, which is exactly what the `Out-Host` cmdlet does. The primary use for the `Out-Host` cmdlet is paging. For example, the following command uses `Out-Host` to page the output of the `Get-Command` cmdlet:

```
PowerShell  
  
Get-Command | Out-Host -Paging
```

The host window display is outside of PowerShell. This is important because when data is sent out of PowerShell, it's actually removed. You can see this if you try to create a pipeline that pages data to the host window, and then attempt to format it as a list, as shown here:

```
PowerShell  
  
Get-Process | Out-Host -Paging | Format-List
```

You might expect the command to display pages of process information in list format. Instead, it displays the default tabular list:

Handles	NPM(K)	PM(K)	WS(K)	VM(M)	CPU(s)	Id	ProcessName
101	5	1076	3316	32	0.05	2888	alg
...							

```
618      18    39348      51108   143    211.20    740 explorer
257      8     9752       16828    79     3.02     2560 explorer
...
<SPACE> next page; <CR> next line; Q quit
...
```

The `Out-Host` cmdlet sends the data directly to the console, so the `Format-List` command never receives anything to format.

The correct way to structure this command is to put the `Out-Host` cmdlet at the end of the pipeline as shown below. This causes the process data to be formatted in a list before being paged and displayed.

```
PowerShell
Get-Process | Format-List | Out-Host -Paging
```

Output

```
Id      : 2888
Handles : 101
CPU     : 0.046875
Name    : alg
...

Id      : 740
Handles : 612
CPU     : 211.703125
Name    : explorer

Id      : 2560
Handles : 257
CPU     : 3.015625
Name    : explorer
...
<SPACE> next page; <CR> next line; Q quit
...
```

This applies to all of the `Out` cmdlets. An `Out` cmdlet should always appear at the end of the pipeline.

ⓘ Note

All the `Out` cmdlets render output as text, using the formatting in effect for the console window, including line length limits.

Discarding output

The `Out-Null` cmdlet is designed to immediately discard any input it receives. This is useful for discarding unnecessary data that you get as a side-effect of running a command. When type the following command, you don't get anything back from the command:

```
PowerShell
```

```
Get-Command | Out-Null
```

The `Out-Null` cmdlet doesn't discard error output. For example, if you enter the following command, a message is displayed informing you that PowerShell doesn't recognize `Is-NotACommand`:

```
PS> Get-Command Is-NotACommand | Out-Null
Get-Command : 'Is-NotACommand' isn't recognized as a cmdlet, function,
operable program, or script file.
At line:1 char:12
+ Get-Command <<< Is-NotACommand | Out-Null
```

Printing data

`Out-Printer` is only available on Windows platforms.

You can print data using the `Out-Printer` cmdlet. The `Out-Printer` cmdlet uses your default printer if you don't provide a printer name. You can use any Windows-based printer by specifying its display name. There is no need for any kind of printer port mapping or even a real physical printer. For example, if you have the Microsoft Office document imaging tools installed, you can send the data to an image file by typing:

```
PowerShell
```

```
Get-Command -Name Get-* | Out-Printer -Name 'Microsoft Office Document Image
Writer'
```

Saving data

You can send output to a file instead of the console window using the `Out-File` cmdlet.

The following command line sends a list of processes to the file

```
C:\temp\processlist.txt:
```

```
PowerShell
```

```
Get-Process | Out-File -FilePath C:\temp\processlist.txt
```

The results of using the `Out-File` cmdlet may not be what you expect if you are used to traditional output redirection. To understand its behavior, you must be aware of the context in which the `Out-File` cmdlet operates.

On Window PowerShell 5.1, the `Out-File` cmdlet creates a Unicode file. Some tools, that expect ASCII files, don't work correctly with the default output format. You can change the default output format to ASCII using the `Encoding` parameter:

```
PowerShell
```

```
Get-Process | Out-File -FilePath C:\temp\processlist.txt -Encoding ascii
```

`Out-File` formats file contents to look like console output. This causes the output to be truncated just as it's in a console window in most circumstances. For example, if you run the following command:

```
PowerShell
```

```
Get-Command | Out-File -FilePath C:\temp\output.txt
```

The output will look like this:

```
Output
```

CommandType	Name	Definition
Cmdlet	Add-Content	Add-Content [-Path]
<String[...]		
Cmdlet	Add-History	Add-History [[-InputObject]
...		
...		

To get output that doesn't force line wraps to match the screen width, you can use the `Width` parameter to specify line width. Because `Width` is a 32-bit integer parameter, the maximum value it can have is 2147483647. Type the following to set the line width to this maximum value:

PowerShell

```
Get-Command | Out-File -FilePath C:\temp\output.txt -Width 2147483647
```

The `Out-File` cmdlet is most useful when you want to save output as it would have displayed on the console.

Using Format commands to change output view

Article • 12/09/2022

PowerShell has a set of cmdlets that allow you to control how properties are displayed for particular objects. The names of all the cmdlets begin with the verb `Format`. They let you select which properties you want to show.

PowerShell			
<code>Get-Command -Verb Format -Module Microsoft.PowerShell.Utility</code>			
Output			
CommandType	Name	Version	Source
-----	----	-----	-----
Cmdlet	Format-Custom	6.1.0.0	Microsoft.PowerShell.Utility
Cmdlet	Format-Hex	6.1.0.0	Microsoft.PowerShell.Utility
Cmdlet	Format-List	6.1.0.0	Microsoft.PowerShell.Utility
Cmdlet	Format-Table	6.1.0.0	Microsoft.PowerShell.Utility
Cmdlet	Format-Wide	6.1.0.0	Microsoft.PowerShell.Utility

This article describes the `Format-Wide`, `Format-List`, and `Format-Table` cmdlets.

Each object type in PowerShell has default properties that are used when you don't select the properties to display. Each cmdlet uses the same `Property` parameter to specify which properties you want displayed. Because `Format-Wide` only shows a single property, its `Property` parameter only takes a single value, but the `Property` parameter of `Format-List` and `Format-Table` accepts a list of property names.

In this example, the default output of `Get-Process` cmdlet shows that we've two instances of Internet Explorer running.

PowerShell			
<code>Get-Process -Name iexplore</code>			
The default format for <code>Process</code> objects displays the properties shown here:			

Output						
NPM(K)	PM(M)	WS(M)	CPU(s)	Id	SI	ProcessName
-----	-----	-----	-----	--	--	-----

32	25.52	10.25	13.11	12808	1	iexplore
52	11.46	26.46	3.55	21748	1	iexplore

Using Format-Wide for single-item output

The `Format-Wide` cmdlet, by default, displays only the default property of an object. The information associated with each object is displayed in a single column:

PowerShell

```
Get-Command -Verb Format | Format-Wide
```

Output

Format-Custom	Format-Hex
Format-List	Format-Table
Format-Wide	

You can also specify a non-default property:

PowerShell

```
Get-Command -Verb Format | Format-Wide -Property Noun
```

Output

Custom	Hex
List	Table
Wide	

Controlling Format-Wide display with column

With the `Format-Wide` cmdlet, you can only display a single property at a time. This makes it useful for displaying large lists in multiple columns.

PowerShell

```
Get-Command -Verb Format | Format-Wide -Property Noun -Column 3
```

Output

Custom
Table

Hex
Wide

List

Using Format-List for a list view

The `Format-List` cmdlet displays an object in the form of a listing, with each property labeled and displayed on a separate line:

PowerShell

```
Get-Process -Name iexplore | Format-List
```

Output

```
Id      : 12808
Handles : 578
CPU     : 13.140625
SI      : 1
Name    : iexplore

Id      : 21748
Handles : 641
CPU     : 3.59375
SI      : 1
Name    : iexplore
```

You can specify as many properties as you want:

PowerShell

```
Get-Process -Name iexplore | Format-List -Property
ProcessName,FileVersion,StartTime,Id
```

Output

```
ProcessName : iexplore
FileVersion : 11.00.18362.1 (WinBuild.160101.0800)
StartTime   : 10/22/2019 11:23:58 AM
Id         : 12808

ProcessName : iexplore
FileVersion : 11.00.18362.1 (WinBuild.160101.0800)
StartTime   : 10/22/2019 11:23:57 AM
Id         : 21748
```

Getting detailed information using Format-List with wildcards

The `Format-List` cmdlet lets you use a wildcard as the value of its `Property` parameter. This lets you display detailed information. Often, objects include more information than you need, which is why PowerShell doesn't show all property values by default. To show all properties of an object, use the `Format-List -Property *` command. The following command generates more than 60 lines of output for a single process:

PowerShell

```
Get-Process -Name iexplore | Format-List -Property *
```

Although the `Format-List` command is useful for showing detail, if you want an overview of output that includes many items, a simpler tabular view is often more useful.

Using Format-Table for tabular output

If you use the `Format-Table` cmdlet with no property names specified to format the output of the `Get-Process` command, you get exactly the same output as you do without a `Format` cmdlet. By default, PowerShell displays `Process` objects in a tabular format.

PowerShell

```
Get-Service -Name win* | Format-Table
```

Output

Status	Name	DisplayName
Running	WinDefend	Windows Defender Antivirus Service
Running	WinHttpAutoProxy	WinHTTP Web Proxy Auto-Discovery Se...
Running	Winmgmt	Windows Management Instrumentation
Running	WinRM	Windows Remote Management (WS-Manag...

Note

`Get-Service` is only available on Windows platforms.

Improving Format-Table output

Although a tabular view is useful for displaying lots of information, it may be difficult to interpret if the display is too narrow for the data. In the previous example, the output is truncated. If you specify the `AutoSize` parameter when you run the `Format-Table` command, PowerShell calculates column widths based on the actual data displayed. This makes the columns readable.

PowerShell

```
Get-Service -Name win* | Format-Table -AutoSize
```

Output

Status	Name	DisplayName
Running	WinDefend	Windows Defender Antivirus Service
Running	WinHttpAutoProxySvc	WinHTTP Web Proxy Auto-Discovery Service
Running	Winmgmt	Windows Management Instrumentation
Running	WinRM	Windows Remote Management (WS-Management)

The `Format-Table` cmdlet might still truncate data, but it only truncates at the end of the screen. Properties, other than the last one displayed, are given as much size as they need for their longest data element to display correctly.

PowerShell

```
Get-Service -Name win* |  
    Format-Table -Property Name, Status, StartType, DisplayName,  
    DependentServices -AutoSize
```

Output

Name	Status	StartType	DisplayName
ces	Running	Automatic	Windows Defender Antivirus Service
{} WinHttpAutoProxySvc	Running	Manual	WinHTTP Web Proxy Auto-Discovery Service {NcaSvc, iphl...
Winmgmt	Running	Automatic	Windows Management Instrumentation {vmmms, TPHKLO...

```
WinRM          Running Automatic Windows Remote Management (WS-
Management) {}
```

The `Format-Table` command assumes that properties are listed in order of importance. The cmdlet attempts to fully display the properties nearest the beginning. If the `Format-Table` command can't display all the properties, it removes some columns from the display. You can see this behavior in the `DependentServices` property previous example.

Wrapping Format-Table output in columns

You can force lengthy `Format-Table` data to wrap within its display column using the `Wrap` parameter. Using the `Wrap` parameter may not do what you expect, since it uses default settings if you don't also specify `AutoSize`:

PowerShell

```
Get-Service -Name win* |
    Format-Table -Property Name, Status, StartType, DisplayName,
    DependentServices -Wrap
```

Output

Name	Status	StartType	DisplayName
DependentServices			
ces			
---	-----	-----	-----

WinDefend	Running	Automatic	Windows Defender Antivirus Service
{}			
WinHttpAutoProxySvc	Running	Manual	WinHTTP Web Proxy Auto-Discovery
Service {NcaSvc,			
iphlpsvc}			
Winmgmt	Running	Automatic	Windows Management Instrumentation
{vmmms,			
TPHKLOAD,			
SUService,			
smstsmsgr...}			
WinRM	Running	Automatic	Windows Remote Management (WS-
Management) {}			

Using the `Wrap` parameter by itself doesn't slow down processing very much. However, using `AutoSize` to format a recursive file listing of a large directory structure can take a

long time and use lots of memory before displaying the first output items.

If you aren't concerned about system load, then **AutoSize** works well with the **Wrap** parameter. The initial columns still use as much width as needed to display items on one line, but the final column is wrapped, if necessary.

 **Note**

Some columns may not be displayed when you specify the widest columns first. For best results, specify the smallest data elements first.

In the following example, we specify the widest properties first.

PowerShell

```
Get-Process -Name iexplore |  
    Format-Table -Wrap -AutoSize -Property FileVersion, Path, Name, Id
```

Even with wrapping, the final **Id** column is omitted:

Output

FileVersion	Path
Nam	
e	
-----	----

11.00.18362.1 (WinBuild.160101.0800)	C:\Program Files (x86)\Internet
Explorer\IEXPLORE.EXE	iex

plo

re

11.00.18362.1 (WinBuild.160101.0800)	C:\Program Files\Internet
Explorer\iexplore.exe	iex

plo

re

Organizing table output

Another useful parameter for tabular output control is **GroupBy**. Longer tabular listings in particular may be hard to compare. The **GroupBy** parameter groups output based on

a property value. For example, we can group services by **StartType** for easier inspection, omitting the **StartType** value from the property listing:

PowerShell

```
Get-Service -Name win* | Sort-Object StartType | Format-Table -GroupBy StartType
```

Output

StartType: Automatic		
Status	Name	DisplayName
-----	---	-----
Running	WinDefend	Windows Defender Antivirus Service
Running	Winmgmt	Windows Management Instrumentation
Running	WinRM	Windows Remote Management (WS-Managem...

StartType: Manual		
Status	Name	DisplayName
-----	---	-----
Running	WinHttpAutoProxyS...	WinHTTP Web Proxy Auto-Discovery Serv...

Managing current location

Article • 12/18/2023

When navigating folder systems in File Explorer, you usually have a specific working location - namely, the current open folder. Items in the current folder can be manipulated easily by clicking them. For command-line interfaces such as Cmd.exe, when you are in the same folder as a particular file, you can access it by specifying a relatively short name, rather than needing to specify the entire path to the file. The current directory is called the working directory.

PowerShell uses the noun **Location** to refer to the working directory, and implements a family of cmdlets to examine and manipulate your location.

Getting your current location (Get-Location)

To determine the path of your current directory location, enter the `Get-Location` command:

```
PowerShell
Get-Location
Output
Path
-----
C:\Documents and Settings\PowerUser
```

ⓘ Note

The `Get-Location` cmdlet is similar to the `pwd` command in the BASH shell. The `Set-Location` cmdlet is similar to the `cd` command in Cmd.exe.

Setting your current location (Set-Location)

The `Get-Location` command is used with the `Set-Location` command. The `Set-Location` command allows you to specify your current directory location.

```
PowerShell
```

```
Set-Location -Path C:\Windows
```

After you enter the command, notice that you don't receive any direct feedback about the effect of the command. Most PowerShell commands that perform an action produce little or no output because the output isn't always useful. To verify that a successful directory change has occurred when you enter the `Set-Location` command, include the `PassThru` parameter when you enter the `Set-Location` command:

PowerShell

```
Set-Location -Path C:\Windows -PassThru
```

Output

Path

C:\WINDOWS

The `PassThru` parameter can be used with many Set commands in PowerShell to return information about the result for cases in which there is no default output.

You can specify paths relative to your current location in the same way as you would in most Unix and Windows command shells. In standard notation for relative paths, a period (.) represents your current folder, and a doubled period (...) represents the parent directory of your current location.

For example, if you are in the `C:\Windows` folder, a period (.) represents `C:\Windows` and double periods (...) represent `C:.` You can change from your current location to the root of the `C:` drive by typing:

PowerShell

```
Set-Location -Path .. -PassThru
```

Output

Path

C:\

The same technique works on PowerShell drives that aren't file system drives, such as `HKLM:.` You can set your location to the `HKLM\Software` key in the registry by typing:

```
PowerShell
```

```
Set-Location -Path HKLM:\SOFTWARE -PassThru
```

```
Output
```

```
Path
```

```
----
```

```
HKLM:\SOFTWARE
```

You can then change the directory location to the parent directory, using a relative path:

```
PowerShell
```

```
Set-Location -Path .. -PassThru
```

```
Output
```

```
Path
```

```
----
```

```
HKLM:\
```

You can type `Set-Location` or use any of the built-in PowerShell aliases for `Set-Location` (`cd`, `chdir`, `sl`). For example:

```
PowerShell
```

```
cd -Path C:\Windows
```

```
PowerShell
```

```
chdir -Path .. -PassThru
```

```
PowerShell
```

```
sl -Path HKLM:\SOFTWARE -PassThru
```

Saving and recalling recent locations (Push-Location and Pop-Location)

When changing locations, it's helpful to keep track of where you have been and to be able to return to your previous location. The `Push-Location` cmdlet in PowerShell creates an ordered history (a "stack") of directory paths where you have been, and you can step back through the history of directory paths using the `Pop-Location` cmdlet.

For example, PowerShell typically starts in the user's home directory.

```
PowerShell  
  
Get-Location  
  
Path  
----  
C:\Documents and Settings\PowerUser
```

① Note

The word **stack** has a special meaning in many programming settings, including .NET Framework. Like a physical stack of items, the last item you put onto the stack is the first item that you can pull off the stack. Adding an item to a stack is colloquially known as "pushing" the item onto the stack. Pulling an item off the stack is colloquially known as "popping" the item off the stack.

To push the current location onto the stack, and then move to the Local Settings folder, type:

```
PowerShell  
  
Push-Location -Path "Local Settings"
```

You can then push the Local Settings location onto the stack and move to the Temp folder by typing:

```
PowerShell  
  
Push-Location -Path Temp
```

You can verify that you changed directories by entering the `Get-Location` command:

```
PowerShell  
  
Get-Location
```

Output

Path

C:\Documents and Settings\PowerUser\Local Settings\Temp

You can then pop back into the most recently visited directory by entering the `Pop-Location` command, and verify the change by entering the `Get-Location` command:

PowerShell

`Pop-Location`

`Get-Location`

Output

Path

C:\Documents and Settings\me\Local Settings

Just as with the `Set-Location` cmdlet, you can include the `PassThru` parameter when you enter the `Pop-Location` cmdlet to display the directory that you entered:

PowerShell

`Pop-Location -PassThru`

Output

Path

C:\Documents and Settings\PowerUser

You can also use the Location cmdlets with network paths. If you have a server named FS01 with a share named Public, you can change your location by typing

PowerShell

`Set-Location \\FS01\Public`

or

PowerShell

```
Push-Location \\FS01\Public
```

You can use the `Push-Location` and `Set-Location` commands to change the location to any available drive. For example, if you have a local CD-ROM drive with drive letter D that contains a data CD, you can change the location to the CD drive by entering the `Set-Location D:` command.

If the drive is empty, you get the following error message:

PowerShell

```
Set-Location D:
```

Output

```
Set-Location : Cannot find path 'D:\' because it does not exist.
```

When you are using a command-line interface, it's not convenient to use File Explorer to examine the available physical drives. Also, File Explorer would not show you the all the PowerShell drives. PowerShell provides a set of commands for manipulating PowerShell drives.

Managing PowerShell drives

Article • 12/19/2023

This sample only applies to Windows platforms.

A *PowerShell drive* is a data store location that you can access like a filesystem drive in PowerShell. The PowerShell providers create some drives for you, such as the file system drives (including `C:` and `D:`), the registry drives (`HKCU:` and `HKLM:`), and the certificate drive (`Cert:`), and you can create your own PowerShell drives. These drives are useful, but they're available only within PowerShell. You can't access them using other Windows tools, such as File Explorer or `Cmd.exe`.

PowerShell uses the noun, **PSDrive**, for commands that work with PowerShell drives. For a list of the PowerShell drives in your PowerShell session, use the `Get-PSDrive` cmdlet.

```
PowerShell
Get-PSDrive

Output
Name      Provider      Root
CurrentLocation
----      -----      ---
A          FileSystem    A:\                                 . . .
Alias     Alias
C          FileSystem    C:\                               . . .
Settings\me
cert      Certificate   \
D          FileSystem    D:\
Env       Environment
Function   Function
HKCU      Registry      HKEY_CURRENT_USER
HKLM      Registry      HKEY_LOCAL_MACHINE
Variable   Variable
```

Although the drives in the display vary with the drives on your system, yours should look similar to the output of the `Get-PSDrive` command shown above.

filesystem drives are a subset of the PowerShell drives. You can identify the filesystem drives by the `FileSystem` entry in the `Provider` column. The filesystem drives in PowerShell are supported by the PowerShell `FileSystem` provider.

To see the syntax of the `Get-PSDrive` cmdlet, type a `Get-Command` command with the **Syntax** parameter:

PowerShell

```
Get-Command -Name Get-PSDrive -Syntax
```

Output

```
Get-PSDrive [[-Name] <String[]>] [-Scope <String>] [-PSProvider <String[]>]
[-V
erbose] [-Debug] [-ErrorAction <ActionPreference>] [-ErrorVariable <String>]
[-
OutVariable <String>] [-OutBuffer <Int32>]
```

The **PSProvider** parameter lets you display only the PowerShell drives that are supported by a particular provider. For example, to display only the PowerShell drives that are supported by the PowerShell FileSystem provider, type a `Get-PSDrive` command with the **PSProvider** parameter and the **FileSystem** value:

PowerShell

```
Get-PSDrive -PSProvider FileSystem
```

Output

Name	Provider	Root	CurrentLocation
A	FileSystem	A:\	
C	FileSystem	C:\	...nd
Settings\PowerUser			
D	FileSystem	D:\	

To view the PowerShell drives that represent registry hives, use the **PSProvider** parameter to display only the PowerShell drives that are supported by the PowerShell Registry provider:

PowerShell

```
Get-PSDrive -PSProvider Registry
```

Output

Name	Provider	Root	
CurrentLocation			-----
---	-----	-----	-----
HKCU	Registry	HKEY_CURRENT_USER	
HKLM	Registry	HKEY_LOCAL_MACHINE	

You can also use the standard Location cmdlets with the PowerShell drives:

PowerShell

```
Set-Location HKLM:\SOFTWARE
Push-Location .\Microsoft
Get-Location
```

Output

Path

```
-----
```

```
HKLM:\SOFTWARE\Microsoft
```

Adding new PowerShell drives

You can add your own PowerShell drives by using the `New-PSDrive` command. To get the syntax for the `New-PSDrive` command, enter the `Get-Command` command with the `Syntax` parameter:

PowerShell

```
Get-Command -Name New-PSDrive -Syntax
```

Output

```
New- [-Description <String>] [-Scope <String>] [-Credential <PSCredential>]
[-Verbose] [-Debug ]
[-ErrorAction <ActionPreference>] [-ErrorVariable <String>] [-OutVariable
<String>]
[-OutBuffer <Int32>] [-WhatIf] [-Confirm]
```

To create a new PowerShell drive, you must supply three parameters:

- A name for the drive (you can use any valid PowerShell name)

- The PSProvider - use `FileSystem` for filesystem locations and `Registry` for registry locations
- The root, that is, the path to the root of the new drive

For example, you can create a drive named `Office` that's mapped to the folder that contains the Microsoft Office applications on your computer, such as `C:\Program Files\Microsoft Office\OFFICE11`. To create the drive, type the following command:

PowerShell

```
New-PSDrive -Name Office -PSProvider FileSystem -Root "C:\Program Files\Microsoft Office\OFFICE11"
```

Output

Name	Provider	Root
CurrentLocation		
Office	FileSystem	C:\Program Files\Microsoft Offic...

① Note

In general, paths aren't case-sensitive.

A PowerShell drive is accessed using its name followed by a colon (:).

A PowerShell drive can make many tasks much simpler. For example, some of the most important keys in the Windows registry have extremely long paths, making them cumbersome to access and difficult to remember. Critical configuration information resides under `HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows\CurrentVersion`. To view and change items in the CurrentVersion registry key, you can create a PowerShell drive that's rooted in that key by typing:

PowerShell

```
New-PSDrive -Name cvkey -PSProvider Registry -Root HKLM\Software\Microsoft\Windows\CurrentVersion
```

Output

Name	Provider	Root
CurrentLocation		

```
---- ----- ----  
---  
cvkey Registry HKLM\Software\Microsoft\Windows\...
```

You can then change location to the `cvkey:` drive as you would any other drive:

```
PowerShell
```

```
cd cvkey:
```

or:

```
PowerShell
```

```
Set-Location cvkey: -PassThru
```

```
Output
```

```
Path
```

```
----
```

```
cvkey:\
```

The `New-PSDrive` cmdlet adds the new drive only to the current PowerShell session. If you close the PowerShell window, the new drive is lost. To save a PowerShell drive, use the `Export-Console` cmdlet to export the current PowerShell session, and then use the `powershell.exe PSConsoleFile` parameter to import it. Or, add the new drive to your Windows PowerShell profile.

Deleting PowerShell drives

You can delete drives from PowerShell using the `Remove-PSDrive` cmdlet. For example, if you added the `Office:` PowerShell drive, as shown in the `New-PSDrive` topic, you can delete it by typing:

```
PowerShell
```

```
Remove-PSDrive -Name Office
```

To delete the `cvkey:` PowerShell drive, use the following command:

```
PowerShell
```

```
Remove-PSDrive -Name cvkey
```

However, you can't delete it while you are in the drive. For example:

PowerShell

```
cd office:  
Remove-PSDrive -Name Office
```

Output

```
Remove-PSDrive : Cannot remove drive 'Office' because it is in use.  
At line:1 char:15  
+ Remove-PSDrive <<< -Name Office
```

Adding and removing drives outside PowerShell

PowerShell detects filesystem drives that are added or removed in Windows, including:

- network drives that are mapped
- USB drives that are attached
- Drives that are deleted using the `net use` command or from a Windows Script Host (WSH) script

Working with files and folders

Article • 10/18/2023

Navigating through PowerShell drives and manipulating the items on them is similar to manipulating files and folders on Windows disk drives. This article discusses how to deal with specific file and folder manipulation tasks using PowerShell.

List all files and folders within a folder

You can get all items directly within a folder using `Get-ChildItem`. Add the optional **Force** parameter to display hidden or system items. For example, this command displays the direct contents of PowerShell Drive `c:`.

```
PowerShell
```

```
Get-ChildItem -Path C:\ -Force
```

The command lists only the directly contained items, much like using the `dir` command in `cmd.exe` or `ls` in a Unix shell. To show items in subfolder, you need to specify the **Recurse** parameter. The following command lists everything on the `c:` drive:

```
PowerShell
```

```
Get-ChildItem -Path C:\ -Force -Recurse
```

`Get-ChildItem` can filter items with its **Path**, **Filter**, **Include**, and **Exclude** parameters, but those are typically based only on name. You can perform complex filtering based on other properties of items using `Where-Object`.

The following command finds all executables within the Program Files folder that were last modified after October 1, 2005 and that are neither smaller than 1 megabyte nor larger than 10 megabytes:

```
PowerShell
```

```
Get-ChildItem -Path $Env:ProgramFiles -Recurse -Include *.exe |  
    Where-Object -FilterScript {  
        ($_.LastWriteTime -gt '2005-10-01') -and ($_.Length -ge 1mb) -and  
        ($_.Length -le 10mb)  
    }
```

Copying files and folders

Copying is done with `Copy-Item`. The following command backs up your PowerShell profile script:

```
PowerShell

if (Test-Path -Path $PROFILE) {
    Copy-Item -Path $PROFILE -Destination $($PROFILE -replace 'ps1$', 'bak')
}
```

The `Test-Path` command checks whether the profile script exists.

If the destination file already exists, the copy attempt fails. To overwrite a pre-existing destination, use the `Force` parameter:

```
PowerShell

if (Test-Path -Path $PROFILE) {
    Copy-Item -Path $PROFILE -Destination $($PROFILE -replace 'ps1$', 'bak') -
    Force
}
```

This command works even when the destination is read-only.

Folder copying works the same way. This command copies the folder `C:\temp\test1` to the new folder `C:\temp\DeleteMe` recursively:

```
PowerShell

Copy-Item C:\temp\test1 -Recurse C:\temp\DeleteMe
```

You can also copy a selection of items. The following command copies all `.txt` files contained anywhere in `C:\data` to `C:\temp\text`:

```
PowerShell

Copy-Item -Filter *.txt -Path C:\data -Recurse -Destination C:\temp\text
```

You can still run native commands like `xcopy.exe` and `robocopy.exe` to copy files.

Creating files and folders

Creating new items works the same on all PowerShell providers. If a PowerShell provider has more than one type of item—for example, the FileSystem PowerShell provider distinguishes between directories and files—you need to specify the item type.

This command creates a new folder `C:\temp\New Folder`:

```
PowerShell  
  
New-Item -Path 'C:\temp\New Folder' -ItemType Directory
```

This command creates a new empty file `C:\temp\New Folder\file.txt`

```
PowerShell  
  
New-Item -Path 'C:\temp\New Folder\file.txt' -ItemType File
```

Important

When using the `Force` switch with the `New-Item` command to create a folder, and the folder already exists, it *won't* overwrite or replace the folder. It will simply return the existing folder object. However, if you use `New-Item -Force` on a file that already exists, the file is overwritten.

Removing all files and folders within a folder

You can remove contained items using `Remove-Item`, but you will be prompted to confirm the removal if the item contains anything else. For example, if you attempt to delete the folder `C:\temp\DeleteMe` that contains other items, PowerShell prompts you for confirmation before deleting the folder:

```
PowerShell  
  
Remove-Item -Path C:\temp\DeleteMe
```

Output

Confirm
The item at `C:\temp\DeleteMe` has children and the `Recurse` parameter wasn't specified. If you continue, all children will be removed with the item. Are you sure you want to continue?

```
[Y] Yes [A] Yes to All [N] No [L] No to All [S] Suspend [?] Help  
(default is "Y"):
```

If you don't want to be prompted for each contained item, specify the **Recurse** parameter:

```
PowerShell
```

```
Remove-Item -Path C:\temp\DeleteMe -Recurse
```

Mapping a local folder as a drive

You can also map a local folder, using the `New-PSDrive` command. The following command creates a local drive `P:` rooted in the local Program Files directory, visible only from the PowerShell session:

```
PowerShell
```

```
New-PSDrive -Name P -Root $Env:ProgramFiles -PSProvider FileSystem
```

Just as with network drives, drives mapped within PowerShell are immediately visible to the PowerShell shell. To create a mapped drive visible from File Explorer, use the **Persist** parameter. However, only remote paths can be used with **Persist**.

Reading a text file into an array

One of the more common storage formats for text data is in a file with separate lines treated as distinct data elements. The `Get-Content` cmdlet can be used to read an entire file in one step, as shown here:

```
PowerShell
```

```
Get-Content -Path $PROFILE  
# Load modules and change to the PowerShell-Docs repository folder  
Import-Module posh-git  
Set-Location C:\Git\PowerShell-Docs
```

`Get-Content` treats the data read from the file as an array, with one element per line of file content. You can confirm this by checking the **Length** of the returned content:

```
PowerShell
```

```
PS> (Get-Content -Path $PROFILE).Length
```

```
3
```

This command is most useful for getting lists of information into PowerShell. For example, you might store a list of computer names or IP addresses in the file `C:\temp\domainMembers.txt`, with one name on each line of the file. You can use `Get-Content` to retrieve the file contents and put them in the variable `$Computers`:

```
PowerShell
```

```
$Computers = Get-Content -Path C:\temp\DomainMembers.txt
```

`$Computers` is now an array containing a computer name in each element.

Working with files, folders and registry keys

Article • 12/09/2022

This sample only applies to Windows platforms.

PowerShell uses the noun **Item** to refer to items found on a PowerShell drive. When dealing with the PowerShell FileSystem provider, an **Item** might be a file, a folder, or the PowerShell drive. Listing and working with these items is a critical basic task in most administrative settings, so we want to discuss these tasks in detail.

Enumerating files, folders, and registry keys

Since getting a collection of items from a particular location is such a common task, the `Get-ChildItem` cmdlet is designed specifically to return all items found within a container such as a folder.

If you want to return all files and folders that are contained directly within the folder `C:\Windows`, type:

```
PS> Get-ChildItem -Path C:\Windows
Directory: Microsoft.PowerShell.Core\FileSystem::C:\Windows

Mode          LastWriteTime    Length Name
----          -----        ---- 
-a---  2006-05-16 8:10 AM      0 0.log
-a---  2005-11-29 3:16 PM     97 acc1.txt
-a---  2005-10-23 11:21 PM   3848 actsetup.log
...
```

The listing looks similar to what you would see when you enter the `dir` command in `cmd.exe`, or the `ls` command in a Unix command shell.

You can perform complex listings using parameters of the `Get-ChildItem` cmdlet. You can see the syntax the `Get-ChildItem` cmdlet by typing:

```
PowerShell
Get-Command -Name Get-ChildItem -Syntax
```

These parameters can be mixed and matched to get highly customized output.

Listing all contained items

To see both the items inside a Windows folder and any items that are contained within the subfolders, use the **Recurse** parameter of `Get-ChildItem`. The listing displays everything within the Windows folder and the items in its subfolders. For example:

```
PS> Get-ChildItem -Path C:\WINDOWS -Recurse

    Directory: Microsoft.PowerShell.Core\FileSystem::C:\WINDOWS
    Directory: Microsoft.PowerShell.Core\FileSystem::C:\WINDOWS\AppPatch
Mode           LastWriteTime      Length Name
----           -----          -----
-a---       2004-08-04   8:00 AM     1852416 AcGenral.dll
...
...
```

Filtering items by name

To display only the names of items, use the **Name** parameter of `Get-ChildItem`:

```
PS> Get-ChildItem -Path C:\WINDOWS -Name
addons
AppPatch
assembly
...
...
```

Forcibly listing hidden items

Items that are hidden in File Explorer or `cmd.exe` aren't displayed in the output of a `Get-ChildItem` command. To display hidden items, use the **Force** parameter of `Get-ChildItem`. For example:

```
PowerShell
Get-ChildItem -Path C:\Windows -Force
```

This parameter is named **Force** because you can forcibly override the normal behavior of the `Get-ChildItem` command. **Force** is a widely used parameter that forces an action

that a cmdlet wouldn't normally perform, although it can't perform any action that compromises the security of the system.

Matching item names with wildcards

The `Get-ChildItem` command accepts wildcards in the path of the items to list.

Because wildcard matching is handled by the PowerShell engine, all cmdlets that accept wildcards use the same notation and have the same matching behavior. The PowerShell wildcard notation includes:

- Asterisk (*) matches zero or more occurrences of any character.
- Question mark (?) matches exactly one character.
- Left bracket ([]) character and right bracket (]) character surround a set of characters to be matched.

Here are some examples of how wildcard specification works.

To find all files in the Windows directory with the suffix `.log` and exactly five characters in the base name, enter the following command:

```
PS> Get-ChildItem -Path C:\Windows\?????.log

    Directory: Microsoft.PowerShell.Core\FileSystem::C:\Windows
Mode           LastWriteTime      Length Name
----           -----          ---- 
...
-a---   2006-05-11  6:31 PM     204276 ocgen.log
-a---   2006-05-11  6:31 PM     22365 ocmsn.log
...
-a---   2005-11-11  4:55 AM       64 setup.log
-a---   2005-12-15  2:24 PM    17719 VxSDM.log
...
```

To find all files that begin with the letter `x` in the Windows directory, type:

```
PowerShell
Get-ChildItem -Path C:\Windows\x*
```

To find all files whose names begin with "x" or "z", type:

```
PowerShell
```

```
Get-ChildItem -Path C:\Windows\[xz]*
```

For more information about wildcards, see [about_Wildcards](#).

Excluding items

You can exclude specific items using the **Exclude** parameter of `Get-ChildItem`. This lets you perform complex filtering in a single statement.

For example, suppose you are trying to find the Windows Time Service DLL in the `System32` folder, and all you can remember about the DLL name is that it begins with "W" and has "32" in it.

An expression like `w*32*.dll` will find all DLLs that satisfy the conditions, but you may want to further filter out the files and omit any `win32` files. You can omit these files using the **Exclude** parameter with the pattern `win*`:

```
PS> Get-ChildItem -Path C:\WINDOWS\System32\w*32*.dll -Exclude win*
```

```
Directory: C:\WINDOWS\System32
```

Mode	LastWriteTime	Length	Name
----	-----	-----	-----
-a--	3/18/2019 9:43 PM	495616	w32time.dll
-a--	3/18/2019 9:44 PM	35328	w32topl.dll
-a--	1/24/2020 5:44 PM	401920	Wldap32.dll
-a--	10/10/2019 5:40 PM	442704	ws2_32.dll
-a--	3/18/2019 9:44 PM	66048	wsnmp32.dll
-a--	3/18/2019 9:44 PM	18944	wsock32.dll
-a--	3/18/2019 9:44 PM	64792	wtsapi32.dll

Mixing `Get-ChildItem` parameters

You can use several of the parameters of the `Get-ChildItem` cmdlet in the same command. Before you mix parameters, be sure that you understand wildcard matching. For example, the following command returns no results:

```
PowerShell
```

```
Get-ChildItem -Path C:\Windows\*.dll -Recurse -Exclude [a-y]*.dll
```

There are no results, even though there are two DLLs that begin with the letter "z" in the Windows folder.

No results were returned because we specified the wildcard as part of the path. Even though the command was recursive, the `Get-ChildItem` cmdlet restricted the items to those that are in the Windows folder with names ending with `.dll`.

To specify a recursive search for files whose names match a special pattern, use the **Include** parameter.

```
PS> Get-ChildItem -Path C:\Windows -Include *.dll -Recurse -Exclude [a-y]*.dll

    Directory:
Microsoft.PowerShell.Core\FileSystem::C:\Windows\System32\Setup

Mode           LastWriteTime      Length Name
----           -----          ----- 
-a-- 2004-08-04 8:00 AM        8261 zoneoc.dll

    Directory: Microsoft.PowerShell.Core\FileSystem::C:\Windows\System32

Mode           LastWriteTime      Length Name
----           -----          ----- 
-a-- 2004-08-04 8:00 AM       337920 zipfldr.dll
```

Working with registry entries

Article • 07/31/2024

This sample only applies to Windows platforms.

Because registry entries are properties of keys and, as such, can't be directly browsed, we need to take a slightly different approach when working with them.

Listing registry entries

There are many different ways to examine registry entries. The simplest way is to get the property names associated with a key. For example, to see the names of the entries in the registry key `HKEY_LOCAL_MACHINE\Software\Microsoft\Windows\CurrentVersion`, use `Get-Item`. Registry keys have a property with the generic name of "Property" that's a list of registry entries in the key. The following command selects the `Property` property and expands the items so that they're displayed in a list:

PowerShell

```
Get-Item -Path  
Registry::HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows\CurrentVersion |  
    Select-Object -ExpandProperty Property
```

Output

```
DevicePath  
MediaPathUnexpanded  
ProgramFilesDir  
CommonFilesDir  
ProductId
```

To view the registry entries in a more readable form, use `Get-ItemProperty`:

PowerShell

```
Get-ItemProperty -Path  
Registry::HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows\CurrentVersion
```

Output

ProgramFilesDir	: C:\Program Files
CommonFilesDir	: C:\Program Files\Common Files

```
ProgramFilesDir (x86)      : C:\Program Files (x86)
CommonFilesDir (x86)        : C:\Program Files (x86)\Common Files
CommonW6432Dir              : C:\Program Files\Common Files
DevicePath                  : C:\WINDOWS\inf
MediaPathUnexpanded          : C:\WINDOWS\Media
ProgramFilesPath             : C:\Program Files
ProgramW6432Dir              : C:\Program Files
SM_ConfigureProgramsName    : Set Program Access and Defaults
SM_GamesName                 : Games
PSPath                      :
Microsoft.PowerShell.Core\Registry::HKEY_LOCAL_MACHINE\SOFTWA
                                RE\Microsoft\Windows\CurrentVersion
PSParentPath                 :
Microsoft.PowerShell.Core\Registry::HKEY_LOCAL_MACHINE\SOFTWA
                                RE\Microsoft\Windows
PSChildName                  : CurrentVersion
PSDrive                      : HKLM
PSProvider                   : Microsoft.PowerShell.Core\Registry
```

The Windows PowerShell-related properties for the key are all prefixed with "PS", such as **PSPath**, **PSParentPath**, **PSChildName**, and **PSProvider**.

You can use the `*.*` notation for referring to the current location. You can use `Set-Location` to change to the **CurrentVersion** registry container first:

```
PowerShell

Set-Location -Path
Registry::HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows\CurrentVersion
```

Alternatively, you can use the built-in `HKLM:` PSDrive with `Set-Location`:

```
PowerShell

Set-Location -Path HKLM:\SOFTWARE\Microsoft\Windows\CurrentVersion
```

You can then use the `.` notation for the current location to list the properties without specifying a full path:

```
PowerShell

Get-ItemProperty -Path .
```

```
Output

...
DevicePath      : C:\WINDOWS\inf
```

```
MediaPathUnexpanded : C:\WINDOWS\Media
ProgramFilesDir      : C:\Program Files
...
```

Path expansion works the same as it does within the filesystem, so from this location you can get the **ItemProperty** listing for `HKLM:\SOFTWARE\Microsoft\Windows\Help` using `Get-ItemProperty -Path ..\Help`.

Getting a single registry entry

If you want to retrieve a specific entry in a registry key, you can use one of several possible approaches. This example finds the value of **DevicePath** in `HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows\CurrentVersion`.

Using `Get-ItemProperty`, use the **Path** parameter to specify the name of the key, and the **Name** parameter to specify the name of the **DevicePath** entry.

PowerShell

```
Get-ItemProperty -Path HKLM:\Software\Microsoft\Windows\CurrentVersion -Name
DevicePath
```

Output

```
DevicePath    : C:\WINDOWS\inf
PSPath        :
Microsoft.PowerShell.Core\Registry::HKEY_LOCAL_MACHINE\Software\Microsoft\Wi
ndows\CurrentVersion
PSParentPath  :
Microsoft.PowerShell.Core\Registry::HKEY_LOCAL_MACHINE\Software\Microsoft\Wi
ndows
PSChildName   : CurrentVersion
PSDrive       : HKLM
PSProvider    : Microsoft.PowerShell.Core\Registry
```

This command returns the standard Windows PowerShell properties as well as the **DevicePath** property.

ⓘ Note

Although `Get-ItemProperty` has **Filter**, **Include**, and **Exclude** parameters, they can't be used to filter by property name. These parameters refer to registry keys, which are item paths and not registry entries, which are item properties.

Another option is to use the `reg.exe` command line tool. For help with `reg.exe`, type `reg.exe /?` at a command prompt. To find the **DevicePath** entry, use `reg.exe` as shown in the following command:

PowerShell

```
reg query HKLM\SOFTWARE\Microsoft\Windows\CurrentVersion /v DevicePath
```

Output

```
! REG.EXE VERSION 3.0
```

```
HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Windows\CurrentVersion  
    DevicePath  REG_EXPAND_SZ  %SystemRoot%\inf
```

You can also use the **WshShell** COM object to find some registry entries, although this method doesn't work with large binary data or with registry entry names that include characters such as backslash (\). Append the property name to the item path with a \ separator:

PowerShell

```
(New-Object -ComObject  
WScript.Shell).RegRead("HKLM\SOFTWARE\Microsoft\Windows\CurrentVersion\DevicePath")
```

Output

```
%SystemRoot%\inf
```

Setting a single registry entry

If you want to change a specific entry in a registry key, you can use one of several possible approaches. This example modifies the **Path** entry under `HKEY_CURRENT_USER\Environment`. The **Path** entry specifies where to find executable files.

1. Retrieve the current value of the **Path** entry using `Get-ItemProperty`.
2. Add the new value, separating it with a ;.
3. Use `Set-ItemProperty` with the specified key, entry name, and value to modify the registry entry.

PowerShell

```
$value = Get-ItemProperty -Path HKCU:\Environment -Name Path  
$newpath = $value.Path += ";C:\src\bin\"  
Set-ItemProperty -Path HKCU:\Environment -Name Path -Value $newpath
```

ⓘ Note

Although `Set-ItemProperty` has `Filter`, `Include`, and `Exclude` parameters, they can't be used to filter by property name. These parameters refer to registry keys—which are item paths—and not registry entries—which are item properties.

Another option is to use the `Reg.exe` command line tool. For help with `reg.exe`, type `reg.exe /?` at a command prompt.

The following example changes the `Path` entry by removing the path added in the example above. `Get-ItemProperty` is still used to retrieve the current value to avoid having to parse the string returned from `reg query`. The `SubString` and `LastIndexOf` methods are used to retrieve the last path added to the `Path` entry.

PowerShell

```
$value = Get-ItemProperty -Path HKCU:\Environment -Name Path  
$newpath = $value.Path.SubString(0, $value.Path.LastIndexOf(';'))  
reg add HKCU\Environment /v Path /d $newpath /f
```

Output

The operation completed successfully.

Creating new registry entries

To add a new entry named "PowerShellPath" to the `CurrentVersion` key, use `New-ItemProperty` with the path to the key, the entry name, and the value of the entry. For this example, we will take the value of the Windows PowerShell variable `$PSHOME`, which stores the path to the installation directory for Windows PowerShell.

You can add the new entry to the key using the following command, and the command also returns information about the new entry:

PowerShell

```
$newItemPropertySplat = @{
    Path = 'HKLM:\SOFTWARE\Microsoft\Windows\CurrentVersion'
    Name = 'PowerShellPath'
    PropertyType = 'String'
    Value = $PSHOME
}
New-ItemProperty @newItemPropertySplat
```

Output

```
PSPath      :
Microsoft.PowerShell.Core\Registry::HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Wi
ndows\CurrentVersion
PSParentPath  :
Microsoft.PowerShell.Core\Registry::HKEY_LOCAL_MACHINE\SOFTWARE\Microsoft\Wi
ndows
PSChildName   : CurrentVersion
PSDrive       : HKLM
PSProvider     : Microsoft.PowerShell.Core\Registry
PowerShellPath : C:\Program Files\Windows PowerShell\v1.0
```

The **.PropertyType** must be the name of a **Microsoft.Win32.RegistryValueKind** enumeration member from the following table:

- **String** - Used for REG_SZ values. Pass a **[System.String]** object to the **Value** parameter.
- **ExpandString** - Used for REG_EXPAND_SZ values. Pass a **[System.String]** object to the **Value** parameter. The string should contain unexpanded references to environment variables that are expanded when the value is retrieved.
- **Binary** - Used for REG_BINARY values. Pass a **[System.Byte[]]** object to the **Value** parameter.
- **DWord** - Used for REG_DWORD values. Pass a **[System.Int32]** object to the **Value** parameter.
- **MultiString** - Used for REG_MULTI_SZ values. Pass a **[System.String[]]** object to the **Value** parameter.
- **QWord** - Used for REG_QWORD values. Pass a **[System.Int64]** object to the **Value** parameter.

You can add a registry entry to multiple locations by specifying an array of values for the **Path** parameter:

PowerShell

```
$newItemPropertySplat = @{
    Name = 'PowerShellPath'
```

```
.PropertyType = 'String'
Value = $PSHOME
Path = 'HKLM:\SOFTWARE\Microsoft\Windows\CurrentVersion',
      'HKCU:\SOFTWARE\Microsoft\Windows\CurrentVersion'
}
New-ItemProperty @newItemPropertySplat
```

You can also overwrite a pre-existing registry entry value by adding the **Force** parameter to any `New-ItemProperty` command.

The following examples show how to create new registry entries of various types. The registry values are created in a new key named **MySoftwareKey** under `HKEY_CURRENT_USER\Software`. The `$key` variable is used to store the new key object.

PowerShell

```
$key = New-Item -Path HKCU:\Software -Name MySoftwareKey
$newItemPropertySplat = @{
    Path = $key.PSPath
    Name = 'DefaultFolders'
    PropertyType = 'MultiString'
    Value = 'Home', 'Temp', 'Publish'
}
New-ItemProperty @newItemPropertySplat
```

Output

```
DefaultFolders : {Home, Temp, Publish}
PSPath         :
Microsoft.PowerShell.Core\Registry::HKEY_CURRENT_USER\Software\MySoftwareKey
PSParentPath   :
Microsoft.PowerShell.Core\Registry::HKEY_CURRENT_USER\Software
PSChildName   : MySoftwareKey
PSProvider     : Microsoft.PowerShell.Core\Registry
```

You can use the **PSPath** property of the key object in subsequent commands.

PowerShell

```
New-ItemProperty -Path $key.PSPath -Name MaxAllowed -PropertyType QWord -
Value 1024
```

Output

```
MaxAllowed   : 1024
PSPath       :
Microsoft.PowerShell.Core\Registry::HKEY_CURRENT_USER\Software\MySoftwareKey
```

```
PSParentPath :  
Microsoft.PowerShell.Core\Registry::HKEY_CURRENT_USER\Software  
PSChildName  : MySoftwareKey  
PSPrinter     : Microsoft.PowerShell.Core\Registry
```

You can also pipe `$key` to `New-ItemProperty` to add a value to the key.

PowerShell

```
$date = Get-Date -Format 'dd-MMM-yyyy'  
$newItemPropertySplat = @{  
    Name = 'BinaryDate'  
    PropertyType = 'Binary'  
    Value = ([System.Text.Encoding]::UTF8.GetBytes($date))  
}  
$key | New-ItemProperty @newItemPropertySplat
```

Output

```
BinaryDate    : {51, 49, 45, 74...}  
PSPath        :  
Microsoft.PowerShell.Core\Registry::HKEY_CURRENT_USER\Software\MySoftwareKey  
PSParentPath :  
Microsoft.PowerShell.Core\Registry::HKEY_CURRENT_USER\Software  
PSChildName  : MySoftwareKey  
PSPrinter     : Microsoft.PowerShell.Core\Registry
```

Displaying the content of `$key` shows the new entries.

PowerShell

```
$key
```

Output

```
Hive: HKEY_CURRENT_USER\Software
```

Name	Property
---	-----
MySoftwareKey	DefaultFolders : {Home, Temp, Publish} MaxAllowed : 1024 BinaryDate : {51, 49, 45, 74...}

The following example shows the value type for each kind of registry entry:

PowerShell

```
$key.GetValueNames() | Select-Object @{n='ValueName';e={$_.}},  
@{n='ValueKind';e={$key.GetValueKind($_)}},  
@{n='Type';e={$key.GetValue($_).GetType()}},  
@{n='Value';e={$key.GetValue($_)}}
```

Output

ValueName	ValueKind	Type	Value
DefaultFolders	MultiString	System.String[]	{Home, Temp, Publish}
MaxAllowed	QWord	System.Int64	1024
BinaryDate	Binary	System.Byte[]	{51, 49, 45, 74...}

Renaming registry entries

To rename the **PowerShellPath** entry to "PSHome," use `Rename-ItemProperty`:

PowerShell

```
$renameItemPropertySplat = @{  
    Path = 'HKLM:\SOFTWARE\Microsoft\Windows\CurrentVersion'  
    Name = 'PowerShellPath'  
    NewName = 'PSHome'  
}  
Rename-ItemProperty @renameItemPropertySplat
```

To display the renamed value, add the **PassThru** parameter to the command.

PowerShell

```
$renameItemPropertySplat = @{  
    Path = 'HKLM:\SOFTWARE\Microsoft\Windows\CurrentVersion'  
    Name = 'PowerShellPath'  
    NewName = 'PSHome'  
    PassThru = $true  
}  
Rename-ItemProperty @renameItemPropertySplat
```

Deleting registry entries

To delete both the PSHome and PowerShellPath registry entries, use `Remove-ItemProperty`:

PowerShell

```
Remove-ItemProperty -Path HKLM:\SOFTWARE\Microsoft\Windows\CurrentVersion -  
Name PSHome  
Remove-ItemProperty -Path HKCU:\SOFTWARE\Microsoft\Windows\CurrentVersion -  
Name PowerShellPath
```

Working with registry keys

Article • 12/09/2022

This sample only applies to Windows platforms.

Because registry keys are items on PowerShell drives, working with them is very similar to working with files and folders. One critical difference is that every item on a registry-based PowerShell drive is a container, just like a folder on a file system drive. However, registry entries and their associated values are properties of the items, not distinct items.

Listing all subkeys of a registry key

You can show all items directly within a registry key using `Get-ChildItem`. Add the optional **Force** parameter to display hidden or system items. For example, this command displays the items directly within PowerShell drive `HKCU:`, which corresponds to the `HKEY_CURRENT_USER` registry hive:

PowerShell

```
Get-ChildItem -Path HKCU:\ | Select-Object Name
```

Output

Hive: Microsoft.PowerShell.Core\Registry::HKEY_CURRENT_USER

Name

HKEY_CURRENT_USER\AppEvents
HKEY_CURRENT_USER\Console
HKEY_CURRENT_USER\Control Panel
HKEY_CURRENT_USER\DirectShow
HKEY_CURRENT_USER\dummy
HKEY_CURRENT_USER\Environment
HKEY_CURRENT_USER\EUDC
HKEY_CURRENT_USER\Keyboard Layout
HKEY_CURRENT_USER\MediaFoundation
HKEY_CURRENT_USER\Microsoft
HKEY_CURRENT_USER\Network
HKEY_CURRENT_USER\Printers
HKEY_CURRENT_USER\Software
HKEY_CURRENT_USER\System
HKEY_CURRENT_USER\Uninstall
HKEY_CURRENT_USER\WXP
HKEY_CURRENT_USER\Volatile Environment

These are the top-level keys visible under `HKEY_CURRENT_USER` in the Registry Editor (`regedit.exe`).

You can also specify this registry path by specifying the Registry provider's name, followed by `:::`. The Registry provider's full name is `Microsoft.PowerShell.Core\Registry`, but this can be shortened to just `Registry`. Any of the following commands will list the contents directly under `HKCU::`.

PowerShell

```
Get-ChildItem -Path Registry::HKEY_CURRENT_USER
Get-ChildItem -Path Microsoft.PowerShell.Core\Registry::HKEY_CURRENT_USER
Get-ChildItem -Path Registry::HKCU
Get-ChildItem -Path Microsoft.PowerShell.Core\Registry::HKCU
Get-ChildItem HKCU:
```

These commands list only the directly contained items, much like using `DIR` in `cmd.exe` or `ls` in a Unix shell. To show contained items, you need to specify the `Recurse` parameter. To list all registry keys in `HKCU::`, use the following command.

PowerShell

```
Get-ChildItem -Path HKCU:\ -Recurse
```

`Get-ChildItem` can perform complex filtering capabilities through its `Path`, `Filter`, `Include`, and `Exclude` parameters, but those parameters are typically based only on name. You can perform complex filtering based on other properties of items using the `Where-Object` cmdlet. The following command finds all keys within `HKCU:\Software` that have no more than one subkey and also have exactly four values:

PowerShell

```
Get-ChildItem -Path HKCU:\Software -Recurse |
  Where-Object {($_.SubKeyCount -le 1) -and ($_.ValueCount -eq 4) }
```

Copying keys

Copying is done with `Copy-Item`. The following example copies the `CurrentVersion` subkey of `HKLM:\SOFTWARE\Microsoft\Windows\` and all of its properties to `HKCU:\`.

PowerShell

```
Copy-Item -Path 'HKLM:\SOFTWARE\Microsoft\Windows\CurrentVersion' -  
Destination HKCU:
```

If you examine this new key in the registry editor or using `Get-ChildItem`, you notice that you don't have copies of the contained subkeys in the new location. In order to copy all of the contents of a container, you need to specify the `Recurse` parameter. To make the preceding copy command recursive, you would use this command:

PowerShell

```
Copy-Item -Path 'HKLM:\SOFTWARE\Microsoft\Windows\CurrentVersion' -  
Destination HKCU: -Recurse
```

You can still use other tools you already have available to perform filesystem copies. Any registry editing tools—including `reg.exe`, `regini.exe`, `regedit.exe`, and COM objects that support registry editing, such as `WScript.Shell` and WMI's `StdRegProv` class can be used from within PowerShell.

Creating keys

Creating new keys in the registry is simpler than creating a new item in a file system. Because all registry keys are containers, you don't need to specify the item type. Just provide an explicit path, such as:

PowerShell

```
New-Item -Path HKCU:\Software_DeleteMe
```

You can also use a provider-based path to specify a key:

PowerShell

```
New-Item -Path Registry::HKCU\Software_DeleteMe
```

Deleting keys

Deleting items is essentially the same for all providers. The following commands silently remove items:

PowerShell

```
Remove-Item -Path HKCU:\Software_DeleteMe
Remove-Item -Path 'HKCU:\key with spaces in the name'
```

Removing all keys under a specific key

You can remove contained items using `Remove-Item`, but you will be prompted to confirm the removal if the item contains anything else. For example, if we attempt to delete the `HKCU:\CurrentVersion` subkey we created, we see this:

PowerShell

```
Remove-Item -Path HKCU:\CurrentVersion
```

Output

Confirm

The item at `HKCU:\CurrentVersion\AdminDebug` has children and the `Recurse` parameter was not specified. If you continue, all children will be removed with

the item. Are you sure you want to continue?

[Y] Yes [A] Yes to All [N] No [L] No to All [S] Suspend [?] Help
(default is "Y"):

To delete contained items without prompting, specify the `Recurse` parameter:

PowerShell

```
Remove-Item -Path HKCU:\CurrentVersion -Recurse
```

If you wanted to remove all items within `HKCU:\CurrentVersion` but not `HKCU:\CurrentVersion` itself, you could instead use:

PowerShell

```
Remove-Item -Path HKCU:\CurrentVersion\* -Recurse
```

Creating a custom input box

Article • 12/09/2022

This sample only applies to Windows platforms.

Script a graphical custom input box using Microsoft .NET Framework form-building features in Windows PowerShell 3.0 and later releases.

Create a custom, graphical input box

Copy and then paste the following into Windows PowerShell ISE, and then save it as a PowerShell script (.ps1) file.

PowerShell

```
Add-Type -AssemblyName System.Windows.Forms
Add-Type -AssemblyName System.Drawing

$form = New-Object System.Windows.Forms.Form
$form.Text = 'Data Entry Form'
$form.Size = New-Object System.Drawing.Size(300,200)
$form.StartPosition = 'CenterScreen'

$okButton = New-Object System.Windows.Forms.Button
$okButton.Location = New-Object System.Drawing.Point(75,120)
$okButton.Size = New-Object System.Drawing.Size(75,23)
$okButton.Text = 'OK'
$okButton.DialogResult = [System.Windows.Forms.DialogResult]::OK
$form.AcceptButton = $okButton
$form.Controls.Add($okButton)

$cancelButton = New-Object System.Windows.Forms.Button
$cancelButton.Location = New-Object System.Drawing.Point(150,120)
$cancelButton.Size = New-Object System.Drawing.Size(75,23)
$cancelButton.Text = 'Cancel'
$cancelButton.DialogResult = [System.Windows.Forms.DialogResult]::Cancel
$form.CancelButton = $cancelButton
$form.Controls.Add($cancelButton)

$label = New-Object System.Windows.Forms.Label
$label.Location = New-Object System.Drawing.Point(10,20)
$label.Size = New-Object System.Drawing.Size(280,20)
$label.Text = 'Please enter the information in the space below:'
$form.Controls.Add($label)

$textBox = New-Object System.Windows.Forms.TextBox
$textBox.Location = New-Object System.Drawing.Point(10,40)
$textBox.Size = New-Object System.Drawing.Size(260,20)
```

```
$form.Controls.Add($textBox)

$form.Topmost = $true

$form.Add_Shown({$textBox.Select()})
$result = $form.ShowDialog()

if ($result -eq [System.Windows.Forms.DialogResult]::OK)
{
    $x = $textBox.Text
    $x
}
```

The script begins by loading two .NET Framework classes: **System.Drawing** and **System.Windows.Forms**. You then start a new instance of the .NET Framework class **System.Windows.Forms.Form**. That provides a blank form or window to which you can start adding controls.

PowerShell

```
$form = New-Object System.Windows.Forms.Form
```

After you create an instance of the Form class, assign values to three properties of this class.

- **Text**. This becomes the title of the window.
- **Size**. This is the size of the form, in pixels. The preceding script creates a form that's 300 pixels wide by 200 pixels tall.
- **StartPosition**. This optional property is set to **CenterScreen** in the preceding script. If you don't add this property, Windows selects a location when the form is opened. By setting the **StartPosition** to **CenterScreen**, you're automatically displaying the form in the middle of the screen each time it loads.

PowerShell

```
$form.Text = 'Data Entry Form'
$form.Size = New-Object System.Drawing.Size(300,200)
$form.StartPosition = 'CenterScreen'
```

Next, create an **OK** button for your form. Specify the size and behavior of the **OK** button. In this example, the button position is 120 pixels from the form's top edge, and 75 pixels from the left edge. The button height is 23 pixels, while the button length is 75 pixels. The script uses predefined Windows Forms types to determine the button behaviors.

PowerShell

```
$okButton = New-Object System.Windows.Forms.Button
$okButton.Location = New-Object System.Drawing.Point(75,120)
$okButton.Size = New-Object System.Drawing.Size(75,23)
$okButton.Text = 'OK'
$okButton.DialogResult = [System.Windows.Forms.DialogResult]::OK
$form.AcceptButton = $okButton
$form.Controls.Add($okButton)
```

Similarly, you create a **Cancel** button. The **Cancel** button is 120 pixels from the top, but 150 pixels from the left edge of the window.

PowerShell

```
$cancelButton = New-Object System.Windows.Forms.Button
$cancellationToken.Location = New-Object System.Drawing.Point(150,120)
$cancellationToken.Size = New-Object System.Drawing.Size(75,23)
$cancellationToken.Text = 'Cancel'
$cancellationToken.DialogResult = [System.Windows.Forms.DialogResult]::Cancel
$form.CancelButton = $cancelButton
$form.Controls.Add($cancelButton)
```

Next, provide label text on your window that describes the information you want users to provide.

PowerShell

```
$label = New-Object System.Windows.Forms.Label
$label.Location = New-Object System.Drawing.Point(10,20)
$label.Size = New-Object System.Drawing.Size(280,20)
$label.Text = 'Please enter the information in the space below:'
$form.Controls.Add($label)
```

Add the control (in this case, a text box) that lets users provide the information you've described in your label text. There are many other controls you can apply besides text boxes. For more controls, see [System.Windows.Forms Namespace](#).

PowerShell

```
$textBox = New-Object System.Windows.Forms.TextBox
$textBox.Location = New-Object System.Drawing.Point(10,40)
$textBox.Size = New-Object System.Drawing.Size(260,20)
$form.Controls.Add($textBox)
```

Set the **Topmost** property to **\$true** to force the window to open atop other open windows and dialog boxes.

```
PowerShell
```

```
$form.Topmost = $true
```

Next, add this line of code to activate the form, and set the focus to the text box that you created.

```
PowerShell
```

```
$form.Add_Shown({$textBox.Select()})
```

Add the following line of code to display the form in Windows.

```
PowerShell
```

```
$result = $form.ShowDialog()
```

Finally, the code inside the `if` block instructs Windows what to do with the form after users provide text in the text box, and then click the **OK** button or press the **Enter** key.

```
PowerShell
```

```
if ($result -eq [System.Windows.Forms.DialogResult]::OK) {  
    $x = $textBox.Text  
    $x  
}
```

Creating a graphical date picker

Article • 12/09/2022

This sample only applies to Windows platforms.

Use Windows PowerShell 3.0 and later releases to create a form with a graphical, calendar-style control that lets users select a day of the month.

Create a graphical date-picker control

Copy and then paste the following into Windows PowerShell ISE, and then save it as a PowerShell script (.ps1) file.

PowerShell

```
Add-Type -AssemblyName System.Windows.Forms
Add-Type -AssemblyName System.Drawing

$form = New-Object Windows.Forms.Form -Property @{
    StartPosition = [Windows.Forms.FormStartPosition]::CenterScreen
    Size          = New-Object Drawing.Size 243, 230
    Text          = 'Select a Date'
    Topmost       = $true
}

$calendar = New-Object Windows.Forms.MonthCalendar -Property @{
    ShowTodayCircle = $false
    MaxSelectionCount = 1
}
$form.Controls.Add($calendar)

$okButton = New-Object Windows.Forms.Button -Property @{
    Location      = New-Object Drawing.Point 38, 165
    Size          = New-Object Drawing.Size 75, 23
    Text          = 'OK'
    DialogResult = [Windows.Forms.DialogResult]::OK
}
$form.AcceptButton = $okButton
$form.Controls.Add($okButton)

$cancelButton = New-Object Windows.Forms.Button -Property @{
    Location      = New-Object Drawing.Point 113, 165
    Size          = New-Object Drawing.Size 75, 23
    Text          = 'Cancel'
    DialogResult = [Windows.Forms.DialogResult]::Cancel
}
$form.CancelButton = $cancelButton
$form.Controls.Add($cancelButton)
```

```
$result = $form.ShowDialog()

if ($result -eq [Windows.Forms.DialogResult]::OK) {
    $date = $calendar.SelectionStart
    Write-Host "Date selected: $($date.ToString())"
}
```

The script begins by loading two .NET Framework classes: `System.Drawing` and `System.Windows.Forms`. You then start a new instance of the .NET Framework class `Windows.Forms.Form`. That provides a blank form or window to which you can start adding controls.

PowerShell

```
$form = New-Object Windows.Forms.Form -Property @{
    StartPosition = [Windows.Forms.FormStartPosition]::CenterScreen
    Size          = New-Object Drawing.Size 243, 230
    Text          = 'Select a Date'
    Topmost       = $true
}
```

This example assigns values to four properties of this class by using the `Property` property and hashtable.

1. **StartPosition:** If you don't add this property, Windows selects a location when the form is opened. By setting this property to `CenterScreen`, you're automatically displaying the form in the middle of the screen each time it loads.
2. **Size:** This is the size of the form, in pixels. The preceding script creates a form that's 243 pixels wide by 230 pixels tall.
3. **Text:** This becomes the title of the window.
4. **Topmost:** By setting this property to `$true`, you can force the window to open atop other open windows and dialog boxes.

Next, create and then add a calendar control in your form. In this example, the current day isn't highlighted or circled. Users can select only one day on the calendar at one time.

PowerShell

```
$calendar = New-Object Windows.Forms.MonthCalendar -Property @{
    ShowTodayCircle = $false
    MaxSelectionCount = 1
```

```
}
```

```
$form.Controls.Add($calendar)
```

Next, create an **OK** button for your form. Specify the size and behavior of the **OK** button. In this example, the button position is 165 pixels from the form's top edge, and 38 pixels from the left edge. The button height is 23 pixels, while the button length is 75 pixels. The script uses predefined Windows Forms types to determine the button behaviors.

PowerShell

```
$okButton = New-Object Windows.Forms.Button -Property @{
    Location      = New-Object Drawing.Point 38, 165
    Size          = New-Object Drawing.Size 75, 23
    Text          = 'OK'
    DialogResult = [Windows.Forms.DialogResult]::OK
}
$form.AcceptButton = $okButton
$form.Controls.Add($okButton)
```

Similarly, you create a **Cancel** button. The **Cancel** button is 165 pixels from the top, but 113 pixels from the left edge of the window.

PowerShell

```
$cancelButton = New-Object Windows.Forms.Button -Property @{
    Location      = New-Object Drawing.Point 113, 165
    Size          = New-Object Drawing.Size 75, 23
    Text          = 'Cancel'
    DialogResult = [Windows.Forms.DialogResult]::Cancel
}
$form.CancelButton = $cancelButton
$form.Controls.Add($cancelButton)
```

Add the following line of code to display the form in Windows.

PowerShell

```
$result = $form.ShowDialog()
```

Finally, the code inside the `if` block instructs Windows what to do with the form after users select a day on the calendar, and then click the **OK** button or press the **Enter** key. Windows PowerShell displays the selected date to users.

PowerShell

```
if ($result -eq [Windows.Forms.DialogResult]::OK) {  
    $date = $calendar.SelectionStart  
    Write-Host "Date selected: $($date.ToString())"  
}
```

Multiple-selection list boxes

Article • 12/09/2022

This sample only applies to Windows platforms.

Use Windows PowerShell 3.0 and later releases to create a multiple-selection list box control in a custom Windows Form.

Create list box controls that allow multiple selections

Copy and then paste the following into Windows PowerShell ISE, and then save it as a PowerShell script (.ps1) file.

PowerShell

```
Add-Type -AssemblyName System.Windows.Forms
Add-Type -AssemblyName System.Drawing

$form = New-Object System.Windows.Forms.Form
$form.Text = 'Data Entry Form'
$form.Size = New-Object System.Drawing.Size(300,200)
$form.StartPosition = 'CenterScreen'

$OKButton = New-Object System.Windows.Forms.Button
$OKButton.Location = New-Object System.Drawing.Point(75,120)
$OKButton.Size = New-Object System.Drawing.Size(75,23)
$OKButton.Text = 'OK'
$OKButton.DialogResult = [System.Windows.Forms.DialogResult]::OK
$form.AcceptButton = $OKButton
$form.Controls.Add($OKButton)

$CancelButton = New-Object System.Windows.Forms.Button
$CancelButton.Location = New-Object System.Drawing.Point(150,120)
$CancelButton.Size = New-Object System.Drawing.Size(75,23)
$CancelButton.Text = 'Cancel'
$CancelButton.DialogResult = [System.Windows.Forms.DialogResult]::Cancel
$form.CancelButton = $CancelButton
$form.Controls.Add($CancelButton)

$label = New-Object System.Windows.Forms.Label
$label.Location = New-Object System.Drawing.Point(10,20)
$label.Size = New-Object System.Drawing.Size(280,20)
$label.Text = 'Please make a selection from the list below:'
$form.Controls.Add($label)

$listBox = New-Object System.Windows.Forms.ListBox
$listBox.Location = New-Object System.Drawing.Point(10,50)
$listBox.Size = New-Object System.Drawing.Size(280,150)
$listBox.SelectionMode = 'MultipleExtended'
$form.Controls.Add($listBox)
```

```

$listBox.Location = New-Object System.Drawing.Point(10,40)
$listBox.Size = New-Object System.Drawing.Size(260,20)

$listBox.SelectionMode = 'MultiExtended'

[void] $listBox.Items.Add('Item 1')
[void] $listBox.Items.Add('Item 2')
[void] $listBox.Items.Add('Item 3')
[void] $listBox.Items.Add('Item 4')
[void] $listBox.Items.Add('Item 5')

$listBox.Height = 70
$form.Controls.Add($listBox)
$form.Topmost = $true

$result = $form.ShowDialog()

if ($result -eq [System.Windows.Forms.DialogResult]::OK)
{
    $x = $listBox.SelectedItems
    $x
}

```

The script begins by loading two .NET Framework classes: `System.Drawing` and `System.Windows.Forms`. You then start a new instance of the .NET Framework class `System.Windows.Forms.Form`. That provides a blank form or window to which you can start adding controls.

PowerShell

```
$form = New-Object System.Windows.Forms.Form
```

After you create an instance of the `Form` class, assign values to three properties of this class.

- **Text**. This becomes the title of the window.
- **Size**. This is the size of the form, in pixels. The preceding script creates a form that's 300 pixels wide by 200 pixels tall.
- **StartPosition**. This optional property is set to `CenterScreen` in the preceding script. If you don't add this property, Windows selects a location when the form is opened. By setting the `StartPosition` to `CenterScreen`, you're automatically displaying the form in the middle of the screen each time it loads.

PowerShell

```
$form.Text = 'Data Entry Form'
$form.Size = New-Object System.Drawing.Size(300,200)
```

```
$form.StartPosition = 'CenterScreen'
```

Next, create an **OK** button for your form. Specify the size and behavior of the **OK** button. In this example, the button position is 120 pixels from the form's top edge, and 75 pixels from the left edge. The button height is 23 pixels, while the button length is 75 pixels. The script uses predefined Windows Forms types to determine the button behaviors.

PowerShell

```
$OKButton = New-Object System.Windows.Forms.Button
$OKButton.Location = New-Object System.Drawing.Size(75,120)
$OKButton.Size = New-Object System.Drawing.Size(75,23)
$OKButton.Text = 'OK'
$OKButton.DialogResult = [System.Windows.Forms.DialogResult]::OK
$form.AcceptButton = $OKButton
$form.Controls.Add($OKButton)
```

Similarly, you create a **Cancel** button. The **Cancel** button is 120 pixels from the top, but 150 pixels from the left edge of the window.

PowerShell

```
$CancelButton = New-Object System.Windows.Forms.Button
$CancelButton.Location = New-Object System.Drawing.Point(150,120)
$CancelButton.Size = New-Object System.Drawing.Size(75,23)
$CancelButton.Text = 'Cancel'
$CancelButton.DialogResult = [System.Windows.Forms.DialogResult]::Cancel
$form.CancelButton = $CancelButton
$form.Controls.Add($CancelButton)
```

Next, provide label text on your window that describes the information you want users to provide.

PowerShell

```
$label = New-Object System.Windows.Forms.Label
$label.Location = New-Object System.Drawing.Point(10,20)
$label.Size = New-Object System.Drawing.Size(280,20)
$label.Text = 'Please make a selection from the list below:'
$form.Controls.Add($label)
```

Add the control (in this case, a list box) that lets users provide the information you've described in your label text. There are many other controls you can apply besides text boxes; for more controls, see [System.Windows.Forms Namespace](#).

PowerShell

```
$listBox = New-Object System.Windows.Forms.ListBox  
$listBox.Location = New-Object System.Drawing.Point(10,40)  
$listBox.Size = New-Object System.Drawing.Size(260,20)
```

Here's how you specify that you want to allow users to select multiple values from the list.

PowerShell

```
$listBox.SelectionMode = 'MultiExtended'
```

In the next section, you specify the values you want the list box to display to users.

PowerShell

```
[void] $listBox.Items.Add('Item 1')  
[void] $listBox.Items.Add('Item 2')  
[void] $listBox.Items.Add('Item 3')  
[void] $listBox.Items.Add('Item 4')  
[void] $listBox.Items.Add('Item 5')
```

Specify the maximum height of the list box control.

PowerShell

```
$listBox.Height = 70
```

Add the list box control to your form, and instruct Windows to open the form atop other windows and dialog boxes when it's opened.

PowerShell

```
$form.Controls.Add($listBox)  
$form.Topmost = $true
```

Add the following line of code to display the form in Windows.

PowerShell

```
$result = $form.ShowDialog()
```

Finally, the code inside the `if` block instructs Windows what to do with the form after users select one or more options from the list box, and then click the **OK** button or press

the **Enter** key.

PowerShell

```
if ($result -eq [System.Windows.Forms.DialogResult]::OK)
{
    $x = $listBox.SelectedItems
    $x
}
```

Selecting items from a list box

Article • 12/09/2022

This sample only applies to Windows platforms.

Use Windows PowerShell 3.0 and later releases to create a dialog box that lets users select items from a list box control.

Create a list box control, and select items from it

Copy and then paste the following into Windows PowerShell ISE, and then save it as a PowerShell script (.ps1) file.

PowerShell

```
Add-Type -AssemblyName System.Windows.Forms
Add-Type -AssemblyName System.Drawing

$form = New-Object System.Windows.Forms.Form
$form.Text = 'Select a Computer'
$form.Size = New-Object System.Drawing.Size(300,200)
$form.StartPosition = 'CenterScreen'

$okButton = New-Object System.Windows.Forms.Button
$okButton.Location = New-Object System.Drawing.Point(75,120)
$okButton.Size = New-Object System.Drawing.Size(75,23)
$okButton.Text = 'OK'
$okButton.DialogResult = [System.Windows.Forms.DialogResult]::OK
$form.AcceptButton = $okButton
$form.Controls.Add($okButton)

$cancelButton = New-Object System.Windows.Forms.Button
$cancelButton.Location = New-Object System.Drawing.Point(150,120)
$cancelButton.Size = New-Object System.Drawing.Size(75,23)
$cancelButton.Text = 'Cancel'
$cancelButton.DialogResult = [System.Windows.Forms.DialogResult]::Cancel
$form.CancelButton = $cancelButton
$form.Controls.Add($cancelButton)

$label = New-Object System.Windows.Forms.Label
$label.Location = New-Object System.Drawing.Point(10,20)
$label.Size = New-Object System.Drawing.Size(280,20)
$label.Text = 'Please select a computer:'
$form.Controls.Add($label)

$listBox = New-Object System.Windows.Forms.ListBox
```

```

$listBox.Location = New-Object System.Drawing.Point(10,40)
$listBox.Size = New-Object System.Drawing.Size(260,20)
$listBox.Height = 80

[void] $listBox.Items.Add('atl-dc-001')
[void] $listBox.Items.Add('atl-dc-002')
[void] $listBox.Items.Add('atl-dc-003')
[void] $listBox.Items.Add('atl-dc-004')
[void] $listBox.Items.Add('atl-dc-005')
[void] $listBox.Items.Add('atl-dc-006')
[void] $listBox.Items.Add('atl-dc-007')

$form.Controls.Add($listBox)

$form.Topmost = $true

$result = $form.ShowDialog()

if ($result -eq [System.Windows.Forms.DialogResult]::OK)
{
    $x = $listBox.SelectedItem
    $x
}

```

The script begins by loading two .NET Framework classes: **System.Drawing** and **System.Windows.Forms**. You then start a new instance of the .NET Framework class **System.Windows.Forms.Form**. That provides a blank form or window to which you can start adding controls.

PowerShell

```

Add-Type -AssemblyName System.Windows.Forms
Add-Type -AssemblyName System.Drawing

```

After you create an instance of the **Form** class, assign values to three properties of this class.

- **Text**. This becomes the title of the window.
- **Size**. This is the size of the form, in pixels. The preceding script creates a form that's 300 pixels wide by 200 pixels tall.
- **StartPosition**. This optional property is set to **CenterScreen** in the preceding script. If you don't add this property, Windows selects a location when the form is opened. By setting the **StartPosition** to **CenterScreen**, you're automatically displaying the form in the middle of the screen each time it loads.

PowerShell

```
$form.Text = 'Select a Computer'  
$form.Size = New-Object System.Drawing.Size(300,200)  
$form.StartPosition = 'CenterScreen'
```

Next, create an **OK** button for your form. Specify the size and behavior of the **OK** button. In this example, the button position is 120 pixels from the form's top edge, and 75 pixels from the left edge. The button height is 23 pixels, while the button length is 75 pixels. The script uses predefined Windows Forms types to determine the button behaviors.

PowerShell

```
$okButton = New-Object System.Windows.Forms.Button  
$okButton.Location = New-Object System.Drawing.Point(75,120)  
$okButton.Size = New-Object System.Drawing.Size(75,23)  
$okButton.Text = 'OK'  
$okButton.DialogResult = [System.Windows.Forms.DialogResult]::OK  
$form.AcceptButton = $okButton  
$form.Controls.Add($okButton)
```

Similarly, you create a **Cancel** button. The **Cancel** button is 120 pixels from the top, but 150 pixels from the left edge of the window.

PowerShell

```
$cancelButton = New-Object System.Windows.Forms.Button  
$cancelButton.Location = New-Object System.Drawing.Point(150,120)  
$cancelButton.Size = New-Object System.Drawing.Size(75,23)  
$cancelButton.Text = 'Cancel'  
$cancelButton.DialogResult = [System.Windows.Forms.DialogResult]::Cancel  
$form.CancelButton = $cancelButton  
$form.Controls.Add($cancelButton)
```

Next, provide label text on your window that describes the information you want users to provide. In this case, you want users to select a computer.

PowerShell

```
$label = New-Object System.Windows.Forms.Label  
$label.Location = New-Object System.Drawing.Point(10,20)  
$label.Size = New-Object System.Drawing.Size(280,20)  
$label.Text = 'Please select a computer:'  
$form.Controls.Add($label)
```

Add the control (in this case, a list box) that lets users provide the information you've described in your label text. There are many other controls you can apply besides list boxes; for more controls, see [System.Windows.Forms Namespace](#).

PowerShell

```
$listBox = New-Object System.Windows.Forms.ListBox  
$listBox.Location = New-Object System.Drawing.Point(10,40)  
$listBox.Size = New-Object System.Drawing.Size(260,20)  
$listBox.Height = 80
```

In the next section, you specify the values you want the list box to display to users.

ⓘ Note

The list box created by this script allows only one selection. To create a list box control that allows multiple selections, specify a value for the **SelectionMode** property, similarly to the following: `$listBox.SelectionMode = 'MultiExtended'`. For more information, see [Multiple-selection List Boxes](#).

PowerShell

```
[void] $listBox.Items.Add('atl-dc-001')  
[void] $listBox.Items.Add('atl-dc-002')  
[void] $listBox.Items.Add('atl-dc-003')  
[void] $listBox.Items.Add('atl-dc-004')  
[void] $listBox.Items.Add('atl-dc-005')  
[void] $listBox.Items.Add('atl-dc-006')  
[void] $listBox.Items.Add('atl-dc-007')
```

Add the list box control to your form, and instruct Windows to open the form atop other windows and dialog boxes when it's opened.

PowerShell

```
$form.Controls.Add($listBox)  
$form.Topmost = $true
```

Add the following line of code to display the form in Windows.

PowerShell

```
$result = $form.ShowDialog()
```

Finally, the code inside the `if` block instructs Windows what to do with the form after users select an option from the list box, and then click the **OK** button or press the **Enter** key.

PowerShell

```
if ($result -eq [System.Windows.Forms.DialogResult]::OK) {  
    $x = $listBox.SelectedItem  
    $x  
}
```

Using Experimental Features in PowerShell

Article • 01/23/2025

The Experimental Features support in PowerShell provides a mechanism for experimental features to coexist with existing stable features in PowerShell or PowerShell modules.

An experimental feature is one where the design isn't finalized. The feature is available for users to test and provide feedback. Once an experimental feature is finalized, the design changes become breaking changes.

✖ Caution

Experimental features aren't intended to be used in production since the changes are allowed to be breaking. Experimental features aren't officially supported. However, we appreciate any feedback and bug reports. You can file issues in the [GitHub source repository](#).

For more information about enabling or disabling these features, see [about_Experimental_Features](#).

Experimental feature lifecycle

The `Get-ExperimentalFeature` cmdlet returns all experimental features available to PowerShell. Experimental features can come from modules or the PowerShell engine. Module-based experimental features are only available after you import the module. In the following example, the `PSDesiredStateConfiguration` isn't loaded, so the `PSDesiredStateConfiguration.InvokeDscResource` feature isn't available.

PowerShell	Output								
<pre>Get-ExperimentalFeature</pre>									
	<table><thead><tr><th>Name</th><th>Enabled</th><th>Source</th><th>Description</th></tr></thead><tbody><tr><td>PSCommandNotFoundSuggestion</td><td>False</td><td>PSEngine</td><td>Recommend potential commands based on fuzzy searc...</td></tr></tbody></table>	Name	Enabled	Source	Description	PSCommandNotFoundSuggestion	False	PSEngine	Recommend potential commands based on fuzzy searc...
Name	Enabled	Source	Description						
PSCommandNotFoundSuggestion	False	PSEngine	Recommend potential commands based on fuzzy searc...						

PSCommandWithArgs	False	PSEngine Enable ``-CommandWithArgs`` parameter for pwsh
PSFeedbackProvider	True	PSEngine Replace the hard-coded suggestion framework with ...
PSLoadAssemblyFromNativeCode	False	PSEngine Expose an API to allow assembly loading from native...
PSModuleAutoLoadSkipOfflineFiles	True	PSEngine Module discovery will skip over files that are ma...
PSSerializeJSONLongEnumAsNumber	True	PSEngine Serialize enums based on long or ulong as an nume...
PSSubsystemPluginModel	True	PSEngine A plugin model for registering and un-registering...

Use the [Enable-ExperimentalFeature](#) and [Disable-ExperimentalFeature](#) cmdlets to enable or disable a feature. You must start a new PowerShell session for this change to be in effect. Run the following command to enable the `PSCommandNotFoundSuggestion` feature:

PowerShell

```
Enable-ExperimentalFeature PSCommandNotFoundSuggestion
```

Output

WARNING: Enabling and disabling experimental features do not take effect until next start of PowerShell.

When an experimental feature becomes *mainstream*, it's no longer available as an experimental feature because the functionality is now part of the PowerShell engine or module. For example, the `PSAnsiRenderingFileInfo` feature became mainstream in PowerShell 7.3. You get the functionality of the feature automatically.

Note

Some features have configuration requirements, such as preference variables, that must be set to get the desired results from the feature.

When an experimental feature is *discontinued*, that feature is no longer available in the PowerShell. For example, the `PSNativePSPPathResolution` feature was discontinued in PowerShell 7.3.

Available features

This article describes the experimental features that are available and how to use the feature.

Legend

- The  icon indicates that the experimental feature is available in the version of PowerShell
- The  icon indicates the version of PowerShell where the experimental feature became mainstream
- The  icon indicates the version of PowerShell where the experimental feature was removed

[Expand table](#)

Name	7.4	7.5	7.6 (preview)
PSCommandNotFoundSuggestion			
PSDesiredStateConfiguration.InvokeDscResource			
PSSubsystemPluginModel			
PSLoadAssemblyFromNativeCode			
PSFeedbackProvider			
PSModuleAutoLoadSkipOfflineFiles			
PSCommandWithArgs			
PSNativeWindowsTildeExpansion			
PSRedirectToVariable			
PSSerializeJSONLongEnumAsNumber			

PSCommandNotFoundSuggestion

Note

This feature became mainstream in PowerShell 7.5-preview.5.

Recommends potential commands based on fuzzy matching search after a [CommandNotFoundException](#).

```
PS> get
```

Output

```
get: The term 'get' isn't recognized as the name of a cmdlet, function,
script file,
or operable program. Check the spelling of the name, or if a path was
included, verify
that the path is correct and try again.
```

```
Suggestion [4,General]: The most similar commands are: set, del, ft, gal,
gbp, gc, gci,
gcm, gdr, gcs.
```

PSCommandWithArgs

ⓘ Note

This feature became mainstream in PowerShell 7.5-preview.5.

This feature enables the `-CommandWithArgs` parameter for `pwsh`. This parameter allows you to execute a PowerShell command with arguments. Unlike `-Command`, this parameter populates the `$args` built-in variable that can be used by the command.

The first string is the command and subsequent strings delimited by whitespace are the arguments.

For example:

PowerShell

```
pwsh -CommandWithArgs '$args | % { "arg: $_" }' arg1 arg2
```

This example produces the following output:

Output

```
arg: arg1
arg: arg2
```

This feature was added in PowerShell 7.4-preview.2.

PSDesiredStateConfiguration.InvokeDscResource

Enables compilation to MOF on non-Windows systems and enables the use of `Invoke-DscResource` without an LCM.

Beginning with PowerShell 7.2, the **PSDesiredStateConfiguration** module was removed and this feature is disabled by default. To enable this feature you must install the **PSDesiredStateConfiguration** v2.0.5 module from the PowerShell Gallery and enable the feature.

DSC v3 doesn't have this experimental feature. DSC v3 only supports `Invoke-DscResource` and doesn't use or support MOF compilation. For more information, see [PowerShell Desired State Configuration v3](#).

PSFeedbackProvider

When you enable this feature, PowerShell uses a new feedback provider to give you feedback when a command can't be found. The feedback provider is extensible, and can be implemented by third-party modules. The feedback provider can be used by other subsystems, such as the predictor subsystem, to provide predictive IntelliSense results.

This feature includes two built-in feedback providers:

- **GeneralCommandErrorFeedback** serves the same suggestion functionality existing today
- **UnixCommandNotFound**, available on Linux, provides feedback similar to bash.

The **UnixCommandNotFound** serves as both a feedback provider and a predictor. The suggestion from command-not-found command is used both for providing the feedback when command can't be found in an interactive run, and for providing predictive IntelliSense results for the next command line.

This feature was added in PowerShell 7.4-preview.3.

PSLoadAssemblyFromNativeCode

Exposes an API to allow assembly loading from native code.

PSModuleAutoLoadSkipOfflineFiles

Note

This feature became mainstream in PowerShell 7.5-preview.5.

With this feature enabled, if a user's **PSModulePath** contains a folder from a cloud provider, such as OneDrive, PowerShell no longer triggers the download of all files contained within that folder. Any file marked as not downloaded are skipped. Users who use cloud providers to sync their modules between machines should mark the module folder as **Pinned** or the equivalent status for providers other than OneDrive. Marking the module folder as **Pinned** ensures that the files are always kept on disk.

This feature was added in PowerShell 7.4-preview.1.

PSRedirectToVariable

ⓘ Note

This experimental feature was added in PowerShell 7.5-preview.4.

When enabled, this feature adds support for redirecting to the Variable: drive. This feature allows you to redirect data to a variable using the `Variable:name` syntax. PowerShell inspects the target of the redirection and if it uses the Variable provider it calls `Set-Variable` rather than `Out-File`.

The following example shows how to redirect the output of a command to a Variable:

PowerShell

```
. {
    "Output 1"
    Write-Warning "Warning, Warning!"
    "Output 2"
} 3> Variable:warnings
$warnings
```

Output

```
Output 1
Output 2
WARNING: Warning, Warning!
```

PSSubsystemPluginModel

This feature enables the subsystem plugin model in PowerShell. The feature makes it possible to separate components of `System.Management.Automation.dll` into individual subsystems that reside in their own assembly. This separation reduces the disk footprint of the core PowerShell engine and allows these components to become optional features for a minimal PowerShell installation.

Currently, only the **CommandPredictor** subsystem is supported. This subsystem is used along with the `PSReadLine` module to provide custom prediction plugins. In future, **Job**, **CommandCompleter**, **Remoting** and other components could be separated into subsystem assemblies outside of `System.Management.Automation.dll`.

The experimental feature includes a new cmdlet, [Get-PSSubsystem](#). This cmdlet is only available when the feature is enabled. This cmdlet returns information about the subsystems that are available on the system.

PSNativeWindowsTildeExpansion

When this feature is enabled, PowerShell expands unquoted tilde (~) to the user's current home folder before invoking native commands. The following examples show how the feature works.

With the feature disabled, the tilde is passed to the native command as a literal string.

```
PowerShell  
PS> cmd.exe /c echo ~  
~
```

With the feature enabled, PowerShell expands the tilde before it's passed to the native command.

```
PowerShell  
PS> cmd.exe /c echo ~  
C:\Users\username
```

This feature only applies to Windows. On non-Windows platforms, tilde expansion is handled natively.

This feature was added in PowerShell 7.5-preview.2.

PSSerializeJSONLongEnumAsNumber

This feature enables the cmdlet [ConvertTo-Json](#) to serialize any enum values based on `Int64/long` or `UInt64/ulong` as a numeric value rather than the string representation of that enum value. This aligns the behavior of enum serialization with other enum base types where the cmdlet serializes enums as their numeric value. Use the `EnumsAsStrings` parameter to serialize as the string representation.

For example:

PowerShell

```
# PSSerializeJSONLongEnumAsNumber disabled
@{
    Key =
[System.Management.Automation.Tracing.PowerShellTraceKeywords]::Cmdlets
} | ConvertTo-Json
# { "Key": "Cmdlets" }

# PSSerializeJSONLongEnumAsNumber enabled
@{
    Key =
[System.Management.Automation.Tracing.PowerShellTraceKeywords]::Cmdlets
} | ConvertTo-Json
# { "Key": 32 }

# -EnumsAsStrings to revert back to the old behaviour
@{
    Key =
[System.Management.Automation.Tracing.PowerShellTraceKeywords]::Cmdlets
} | ConvertTo-Json -EnumsAsStrings
# { "Key": "Cmdlets" }
```

Using aliases

Article • 07/23/2024

An alias is an alternate name or shorthand name for a cmdlet or for a command element, such as a function, script, file, or executable file. You can run the command using the alias instead of the executable name.

Managing command aliases

PowerShell provides cmdlets for managing command aliases. The following command shows the cmdlets that manage aliases.

PowerShell

```
Get-Command -Noun Alias
```

Output

CommandType	Name	Version	Source
Cmdlet	Export-Alias	7.0.0.0	Microsoft.PowerShell.Utility
Cmdlet	Get-Alias	7.0.0.0	Microsoft.PowerShell.Utility
Cmdlet	Import-Alias	7.0.0.0	Microsoft.PowerShell.Utility
Cmdlet	New-Alias	7.0.0.0	Microsoft.PowerShell.Utility
Cmdlet	Remove-Alias	7.0.0.0	Microsoft.PowerShell.Utility
Cmdlet	Set-Alias	7.0.0.0	Microsoft.PowerShell.Utility

For more information, see [about_Aliases](#).

Use the [Get-Alias](#) cmdlet to list the aliases available in your environment. To list the aliases for a single cmdlet, use the **Definition** parameter and specify the executable name.

PowerShell

```
Get-Alias -Definition Get-ChildItem
```

Output

CommandType	Name
Alias	dir -> Get-ChildItem
Alias	gci -> Get-ChildItem
Alias	ls -> Get-ChildItem

To get the definition of a single alias, use the `Name` parameter.

PowerShell

```
Get-Alias -Name gci
```

Output

CommandType	Name
Alias	gci -> Get-ChildItem

To create an alias, use the `Set-Alias` command. You can create aliases for cmdlets, functions, scripts, and native executables files.

PowerShell

```
Set-Alias -Name np -Value Notepad.exe
Set-Alias -Name cmpo -Value Compare-Object
```

Compatibility aliases in Windows

PowerShell has several aliases that allow **Unix** and `cmd.exe` users to use familiar commands in Windows. The following table show common commands, the related PowerShell cmdlet, and the PowerShell alias:

[] Expand table

Windows Command Shell	Unix command	PowerShell cmdlet	PowerShell alias
<code>cd</code> , <code>chdir</code>	<code>cd</code>	<code>Set-Location</code>	<code>sl</code> , <code>cd</code> , <code>chdir</code>
<code>cls</code>	<code>clear</code>	<code>Clear-Host</code>	<code>cls</code> <code>clear</code>
<code>copy</code>	<code>cp</code>	<code>Copy-Item</code>	<code>cpi</code> , <code>cp</code> , <code>copy</code>
<code>del</code> , <code>erase</code> , <code>rd</code> , <code>rmdir</code>	<code>rm</code>	<code>Remove-Item</code>	<code>ri</code> , <code>del</code> , <code>erase</code> , <code>rd</code> , <code>rm</code> , <code>rmdir</code>
<code>dir</code>	<code>ls</code>	<code>Get-ChildItem</code>	<code>gci</code> , <code>dir</code> , <code>ls</code>
<code>echo</code>	<code>echo</code>	<code>Write-Output</code>	<code>write</code> <code>echo</code>
<code>md</code>	<code>mkdir</code>	<code>New-Item</code>	<code>ni</code>
<code>move</code>	<code>mv</code>	<code>Move-Item</code>	<code>mi</code> , <code>move</code> , <code>mi</code>

Windows Command Shell	Unix command	PowerShell cmdlet	PowerShell alias
popd	popd	Pop-Location	popd
	pwd	Get-Location	gl, pwd
pushd	pushd	Push-Location	pushd
ren	mv	Rename-Item	rni, ren
type	cat	Get-Content	gc, cat, type

! Note

The aliases in this table are Windows-specific. Some aliases aren't available on other platforms. This is to allow the native command to work in a PowerShell session. For example, `ls` isn't defined as a PowerShell alias on macOS or Linux so that the native command is run instead of `Get-ChildItem`.

Creating alternate names for commands with parameters

You can assign an alias to a cmdlet, script, function, or executable file. Unlike some Unix shells, you cannot assign an alias to a command with parameters. For example, you can assign an alias to the `Get-EventLog` cmdlet, but you cannot assign an alias to the `Get-EventLog -LogName System` command. You must create a function that contains the command with parameters.

For more information, see [about_Aliases](#).

Parameter aliases and shorthand names

PowerShell also provides ways to create shorthand names for parameters. Parameter aliases are defined using the `Alias` attribute when you declare the parameter. These can't be defined using the `*-Alias` cmdlets.

For more information, see the [Alias attribute](#) documentation.

In addition to parameter aliases, PowerShell lets you specify the parameter name using the fewest characters needed to uniquely identify the parameter. For example, the `Get-ChildItem` cmdlet has the `Recurse` and `ReadOnly` parameters. To uniquely identify the `Recurse` parameter

you only need to provide `-Rec`. If you combine that with the command alias, `Get-ChildItem -Recurse` can be shortened to `dir -Rec`.

Don't use aliases in scripts

Aliases are a convenience feature to be used interactively in the shell. You should always use the full command and parameter names in your scripts.

- Aliases can be deleted or redefined in a profile script
- Any aliases you define may not be available to the user of your scripts
- Aliases make your code harder to read and maintain

PowerShell learning resources

Article • 09/20/2022

Additional resources for learning about PowerShell.

Learn modules

Microsoft Learn is a free, online training platform that provides interactive learning for Microsoft products and more. Our goal is to help you become proficient on our technologies and learn more skills with fun, guided, hands-on, interactive content that's specific to your role and goals.

PowerShell Glossary

Article • 04/10/2024

This article lists common terms used to talk about PowerShell.

B

binary module

A PowerShell module whose root module is a binary (`.dll`) file. A binary module may or may not include a module manifest.

C

CommonParameter

A parameter that's added to all cmdlets, advanced functions, and workflows by the PowerShell engine.

D

dot source

In PowerShell, to start a command by typing a dot and a space before the command. Commands that are dot sourced run in the current scope instead of in a new scope. Any variables, aliases, functions, or drives that command creates are created in the current scope and are available to users when the command is completed.

dynamic module

A module that exists only in memory. The `New-Module` and `Import-PSSession` cmdlets create dynamic modules.

dynamic parameter

A parameter that's added to a PowerShell cmdlet, function, or script under certain conditions. Cmdlets, functions, providers, and scripts can add dynamic parameters.

F

format file

A PowerShell XML file that has the `.format.ps1xml` extension and that defines how PowerShell displays an object based on its .NET Framework type.

G

global session state

The session state that contains the data that's accessible to the user of a PowerShell session.

H

Host

The interface that the PowerShell engine uses to communicate with the user. For example, the host specifies how prompts are handled between PowerShell and the user.

host application

A program that loads the PowerShell engine into its process and uses it to perform operations.

I

input processing method

A method that a cmdlet can use to process the records it receives as input. The input processing methods include the `BeginProcessing` method, the `ProcessRecord` method, the `EndProcessing` method, and the `StopProcessing` method.

M

manifest module

A PowerShell module that has a manifest and whose `RootModule` key is empty.

member-access enumeration

A PowerShell convenience feature to automatically enumerate items in a collection when using the member-access operator (`.`).

module

A self-contained reusable unit that allows you to partition, organize, and abstract your PowerShell code. A module can contain cmdlets, providers, functions, variables, and other types of resources that can be imported as a single unit.

module manifest

A PowerShell data file (`.psd1`) that describes the contents of a module and that controls how a module is processed.

module session state

The session state that contains the public and private data of a PowerShell module. The private data in this session state isn't available to the user of a PowerShell session.

N

non-terminating error

An error that doesn't stop PowerShell from continuing to process the command. See also, [terminating error](#).

noun

The word that follows the hyphen in a PowerShell cmdlet name. The noun describes the resources upon which the cmdlet acts.

P

parameter set

A group of parameters that can be used in the same command to perform a specific action.

pipe

In PowerShell, to send the results of the preceding command as input to the next command in the pipeline.

pipeline

A series of commands connected by pipeline operators (`|`). Each pipeline operator sends the results of the preceding command as input to the next command.

PowerShell cmdlet

A single command that participates in the pipeline semantics of PowerShell. This includes binary (C#) cmdlets, advanced script functions, CDXML, and Workflows.

PowerShell command

The elements in a pipeline that cause an action to be carried out. PowerShell commands are either typed at the keyboard or invoked programmatically.

PowerShell data file

A text file that has the `.psd1` file extension. PowerShell uses data files for various purposes such as storing module manifest data and storing translated strings for script internationalization.

PowerShell drive

A virtual drive that provides direct access to a data store. It can be defined by a PowerShell provider or created at the command line. Drives created at the command line are session-specific drives and are lost when the session is closed.

provider

A Microsoft .NET Framework-based program that makes the data in a specialized data store available in PowerShell so that you can view and manage it.

PSSession

A type of PowerShell session that's created, managed, and closed by the user.

R

root module

The module specified in the **RootModule** key in a module manifest.

runspace

In PowerShell, the operating environment in which each command in a pipeline is executed.

S

scalar value

In PowerShell, a scalar value is any value type that is not enumerable. This includes the .NET primitive types, such as booleans and numbers, and other value types such as **String**, **DateTime** and **Guid**.

For a list of .NET primitive types, see the *Remarks* section of [System.Type.IsPrimitive Property](#).

script block

In the PowerShell programming language, a collection of statements or expressions that can be used as a single unit. A script block can accept arguments and return values.

script file

A file that has the `.ps1` extension and contains a script written in the PowerShell language.

script module

A PowerShell module whose root module is a script module (`.psm1`) file. A script module may include a module manifest. The script defines the members that the script module exports.

shell

The command interpreter that's used to pass commands to the operating system.

switch parameter

A parameter that doesn't take an argument. The value of a switch parameter defaults to `$false`. When a switch parameter is used, its value becomes `$true`.

T

terminating error

An error that stops PowerShell from processing the command. See also, [non-terminating error](#).

transaction

An atomic unit of work. The work in a transaction must be completed as a whole. If any part of the transaction fails, the entire transaction fails.

type file

A PowerShell XML file that has the `.types.ps1xml` extension and that extends the properties of Microsoft .NET Framework types in PowerShell.

V

verb

The word that precedes the hyphen in a PowerShell cmdlet name. The verb describes the action that the cmdlet performs.

W

Windows PowerShell ISE

The Integrated Scripting Environment (ISE) - A Windows PowerShell host application that enables you to run commands and to write, test, and debug scripts in a friendly, syntax-colored, Unicode-compliant environment.

Windows PowerShell snap-in

A resource that defines a set of cmdlets, providers, and Microsoft .NET Framework types that can be added to the Windows PowerShell environment. PowerShell snap-ins have been replaced by modules.

Windows PowerShell Workflow

A workflow is a sequence of programmed, connected steps that perform long-running tasks or require the coordination of multiple steps across multiple devices or managed nodes. Windows PowerShell Workflow lets IT pros and developers author sequences of multi-device management activities, or single tasks within a workflow, as workflows. Windows PowerShell Workflow lets you adapt and run both PowerShell scripts and XAML files as workflows. Windows PowerShell Workflow is built on the Windows Workflow Foundation, which has been deprecated.

What's New in PowerShell 7.6

Article • 04/09/2025

PowerShell 7.6-preview.4 includes the following features, updates, and breaking changes. PowerShell 7.6 is built on .NET 9.0.101 GA release.

For a complete list of changes, see the [CHANGELOG](#) in the GitHub repository.

Updated modules

PowerShell 7.6-preview.4 includes the following updated modules:

- `Microsoft.PowerShell.PSResourceGet` v1.1.0
- `PSReadLine` v2.3.6
- `Microsoft.PowerShell.ThreadJob` v2.2.0
- `ThreadJob` v2.1.0

The `ThreadJob` was renamed to `Microsoft.PowerShell.ThreadJob` module. There is no difference in the functionality of the module. To ensure backward compatibility for scripts that use the old name, the `ThreadJob` v2.1.0 module is a proxy module that points to the `Microsoft.PowerShell.ThreadJob` v2.2.0.

Breaking Changes

- Fix `WildcardPattern.Escape` to escape lone backticks correctly ([#25211](#)) (Thanks @ArmaanMcleod!)
- Convert `-ChildPath` parameter to `string[]` for `Join-Path` cmdlet ([#24677](#)) (Thanks @ArmaanMcleod!)
- Remove trailing space from event source name ([#24192](#)) (Thanks @MartinGC94!)

Tab completion improvements

- Update Named and Statement block type inference to not consider `AssignmentStatements` and Increment/decrement operators as part of their output ([#21137](#)) (Thanks @MartinGC94!)
- Add `-PropertyType` argument completer for `New-ItemProperty` ([#21117](#)) (Thanks @ArmaanMcleod!)
- Add completion single/double quote support for `-Noun` parameter for `Get-Command` ([#24977](#)) (Thanks @ArmaanMcleod!)

- Add completion single/double quote support for `-PSEdition` parameter for `Get-Module` (#24971) (Thanks @ArmaanMcleod!)
- Convert `InvalidCommandNameCharacters` in `AnalysisCache` to `SearchValues<char>` for more efficient char searching (#24880) (Thanks @ArmaanMcleod!)
- Convert `s_charactersRequiringQuotes` in `Completion Completers` to `SearchValues<char>` for more efficient char searching (#24879) (Thanks @ArmaanMcleod!)
- Update `IndexOfAny()` calls with invalid path/filename to `SearchValues<char>` for more efficient char searching ([#24896][24896]) (Thanks @ArmaanMcleod!)
- Replace `char[]` array in `CompletionRequiresQuotes` with cached `SearchValues<char>` (#24907) (Thanks @ArmaanMcleod!)
- Add quote handling in `Verb`, `StrictModeVersion`, `Scope` and `PropertyType` Argument Completers with single helper method (#24839) (Thanks @ArmaanMcleod!)
- Fix share completion with provider and spaces (#19440) (Thanks @MartinGC94!)
- Improve variable type inference (#19830) (Thanks @MartinGC94!)
- Add tooltips for hashtable key completions (#17864) (Thanks @MartinGC94!)
- Fix type inference of parameters in classic functions (#25172) (Thanks @MartinGC94!)
- Improve assignment type inference (#21143) (Thanks @MartinGC94!)
- Exclude `OutVariable` assignments within the same `CommandAst` when inferring variables (#25224) (Thanks @MartinGC94!)
- Fix parameter completion when script requirements fail (#17687) (Thanks @MartinGC94!)
- Improve the completion for attribute arguments (#25129) (Thanks @MartinGC94!)
- Fix completion that relies on pseudobinding in script blocks (#25122) (Thanks @MartinGC94!)
- Don't complete duplicate command names (#21113) (Thanks @MartinGC94!)
- Add completion for variables assigned by command redirection (#25104) (Thanks @MartinGC94!)
- Fix `TypeName.GetReflectionType()` to work when the `TypeName` instance represents a generic type definition within a `GenericTypeDefinition` (#24985)
- Update variable/property assignment completion so it can fallback to type inference (#21134) (Thanks @MartinGC94!)
- Handle type inference for redirected commands (#21131) (Thanks @MartinGC94!)
- Use `Get-Help` approach to find `about_*.help.txt` files with correct locale for completions (#24194) (Thanks @MartinGC94!)
- Fix completion of variables assigned inside Do loops (#25076) (Thanks @MartinGC94!)
- Fix completion of provider paths when a path returns itself instead of its children (#24755) (Thanks @MartinGC94!)
- Enable completion of scoped variables without specifying scope (#20340) (Thanks @MartinGC94!)

- Fix issue with incomplete results when completing paths with wildcards in non-filesystem providers ([#24757](#)) (Thanks @MartinGC94!)

Cmdlet improvements

- Add `-ExcludeModule` parameter to `Get-Command` ([#18955](#)) (Thanks @MartinGC94!)
- Return correct `FileName` property for `Get-Item` when listing alternate data streams ([#18019](#)) (Thanks @kilasuit!)
- Fix `Get-ItemProperty` to report non-terminating error for cast exception ([#21115](#)) (Thanks @ArmaanMcleod!)
- Fix a bug in how q handles XmlNode object ([#24669](#)) (Thanks @brendandburns!)
- Error when `New-Item -Force` is passed an invalid directory name ([#24936](#)) (Thanks @kborowinski!)
- Allow `Start-Transcript` to use `$Transcript` which is a `PSObject` wrapped string to specify the transcript path ([#24963](#)) (Thanks @kborowinski!)
- Improve `Start-Process -Wait` polling efficiency ([#24711](#)) (Thanks @jborean93!)
- Add completion of modules by their shortname ([#20330](#)) (Thanks @MartinGC94!)

Engine improvements

- Added the AIShell module to telemetry collection list ([#24747](#))
- Added helper in `EnumSingleTypeConverter` to get enum names as array ([#17785](#)) (Thanks @fflaten!)
- Update `DnsNameList` for `X509Certificate2` to use `X509SubjectAlternativeNameExtension.EnumerateDnsNames()` Method ([#24714](#)) (Thanks @ArmaanMcleod!)
- Stringify `ErrorRecord` with empty exception message to empty string ([#24949](#)) (Thanks @MatejKafka!)
- Add `PipelineStopToken` to `Cmdlet` which will be signaled when the pipeline is stopping ([#24620](#)) (Thanks @jborean93!)
- Fallback to AppLocker after `W1dpCanExecuteFile` ([#24912](#))
- Move .NET method invocation logging to after the needed type conversion is done for method arguments ([#25022](#))
- Fix infinite loop in variable type inference ([#25206](#)) (Thanks @MartinGC94!)
- Remove the old fuzzy suggestion and fix the local script file name suggestion ([#25177](#))
- Make `SystemPolicy` public APIs visible but non-op on Unix platforms so that they can be included in `PowerShellStandard.Library` ([#25051](#))
- Set standard handles explicitly when starting a process with `-NoNewWindow` ([#25061](#))
- Fix tooltip for variable expansion and include desc ([#25112](#)) (Thanks @jborean93!)

- Allow empty prefix string in 'Import-Module -Prefix' to override default prefix in manifest (#20409) (Thanks @MartinGC94!)
- Use script filepath when completing relative paths for using statements (#20017) (Thanks @MartinGC94!)
- Allow DSC parsing through OS architecture translation layers (#24852) (Thanks @bdeb1337!)

Experimental features

The following experimental features are included in PowerShell 7.6-preview.3:

- `PSNativeWindowsTildeExpansion` - Add tilde expansion for Windows-native executables
- `PSRedirectToVariable` - Allow redirecting to a variable
- `PSSerializeJSONLongEnumAsNumber` - `ConvertTo-Json` now treats large enums as numbers

What's New in PowerShell 7.5

Article • 04/25/2025

PowerShell 7.5.1 includes the following features, updates, and breaking changes. PowerShell 7.5 is built on .NET 9.0.203 release.

For a complete list of changes, see the [CHANGELOG](#) in the GitHub repository. For more information about .NET 9, see [What's new in .NET 9][07].

Breaking Changes

- Fix `-OlderThan` and `-NewerThan` parameters for `Test-Path` when using `PathType` and date range ([#20942](#)) (Thanks @ArmaanMcleod!)
 - Previously `-OlderThan` would be ignored if specified together
- Change `New-FileCatalog -CatalogVersion` default to 2 ([#20428](#)) (Thanks @ThomasNieto!)
- Block getting help from network locations in restricted remoting sessions ([#20593](#))
- The Windows installer now remembers installation options used and uses them to initialize options for the next installation ([#20420](#)) (Thanks @reduckted!)
- `ConvertTo-Json` now serializes `BigInteger` as a number ([#21000](#)) (Thanks @jborean93!)
- .NET 9 removed the `BinaryFormatter` implementation causing a regression in the `Out-GridView` cmdlet. The search feature of `Out-GridView` doesn't work in PowerShell 7.5. This problem is tracked in [Issue #24749](#).

Updated modules

PowerShell 7.5.0 includes the following updated modules:

- `Microsoft.PowerShell.PSResourceGet` v1.1.0
- `PSReadLine` v2.3.6

Tab completion improvements

Many thanks to @ArmaanMcleod and others for all their work to improve tab completion.

- Fall back to type inference when hashtable key-value cannot be retrieved from safe expression ([#21184](#)) (Thanks @MartinGC94!)
- Fix the regression when doing type inference for `$_` ([#21223](#)) (Thanks @MartinGC94!)
- Expand `~` to `$HOME` on Windows with tab completion ([#21529](#))

- Don't complete when declaring parameter name and class member (#21182 ↗) (Thanks @MartinGC94!)
- Prevent fallback to file completion when tab completing type names (#20084 ↗) (Thanks @MartinGC94)
- Add argument completer to `-Version` for `Set-StrictMode` (#20554 ↗) (Thanks @ArmaanMcleod!)
- Add `-Verb` argument completer for `Get-Verb` / `Get-Command` and refactor `Get-Verb` (#20286 ↗) (Thanks @ArmaanMcleod)
- Add `-Verb` argument completer for `Start-Process` (#20415 ↗) (Thanks @ArmaanMcleod)
- Add `-Scope` argument completer for `*-Variable`, `*-Alias` & `*-PSDrive` commands (#20451 ↗) (Thanks @ArmaanMcleod)
- Add `-Module` completion for `Save-Help`/`Update-Help` commands (#20678 ↗) (Thanks @ArmaanMcleod)

New cmdlets

- Add `ConvertTo-CliXml` and `ConvertFrom-CliXml` cmdlets (#21063 ↗) (Thanks @ArmaanMcleod!)

Web cmdlets improvements

- Fix to allow `-PassThru` and `-Outfile` work together (#24086 ↗)
- Add `OutFile` property in `WebResponseObject` (#24047 ↗)
- Show filename in `Invoke-WebRequest -OutFile -Verbose` (#24041 ↗)
- Fix WebCmdlets when `-Body` is specified but `ContentType` is not (#23952 ↗) (Thanks @CarloToso!)
- Fix `Invoke-WebRequest` to report correct size when `-Resume` is specified (#20207 ↗) (Thanks @LNKLEO!)
- Fix Web Cmdlets to allow `WinForm` apps to work correctly (#20606 ↗)

Other cmdlet improvements

- Enable `-NoRestart` to work with `Register-PSSessionConfiguration` (#23891 ↗)
- Add `IgnoreComments` and `AllowTrailingCommas` options to `Test-Json` cmdlet (#23817 ↗) (Thanks @ArmaanMcleod!)
- Get-Help may report parameters with `ValueFromRemainingArguments` attribute as pipeline-able (#23871 ↗)

- Change type of `LineNumber` to `ulong` in `Select-String` (#24075) (Thanks @Snowman-25!)
- `Get-Process`: Remove admin requirement for `-IncludeUserName` (#21302) (Thanks @jborean93!)
- Fix `Test-Path -IsValid` to check for invalid path and filename characters (#21358)
- Add `RecommendedAction` to `ConciseView` of the error reporting (#20826) (Thanks @JustinGrote!)
- Added progress bar for `Remove-Item` cmdlet (#20778) (Thanks @ArmaanMcleod!)
- Fix `Test-Connection` due to .NET 8 changes (#20369)
- Fix `Get-Service` non-terminating error message to include category (#20276)
- Add `-Empty` and `-InputObject` parameters to `New-Guid` (#20014) (Thanks @CarloToso!)
- Add the alias `r` to the parameter `-Recurse` for the `Get-ChildItem` command (#20100) (Thanks @kilasuit!)
- Add `LP` to `LiteralPath` aliases for functions still missing it (#20820)
- Add implicit localization fallback to `Import-LocalizedData` (#19896) (Thanks @chrisdent-de!)
- Add `Aliases` to the properties shown up when formatting the help content of the parameter returned by `Get-Help` (#20994)
- Add `HelpUri` to `Remove-Service` (#20476)
- Fix completion crash for the SCCM provider (#20815, #20919, #20915) (Thanks @MartinGC94!)
- Fix regression in `Get-Content` when `-Tail 0` and `-Wait` are used together (#20734) (Thanks @CarloToso!)
- Fix `Start-Process -PassThru` to make sure the `ExitCode` property is accessible for the returned `Process` object (#20749) (Thanks @CodeCyclone!)
- Fix `Group-Object` to use current culture for its output (#20608)
- Fix `Group-Object` output using interpolated strings (#20745) (Thanks @mawosoft!)
- Fix rendering of `DisplayRoot` for network `PSDrive` (#20793)
- Fix `Copy-Item` progress to only show completed when all files are copied (#20517)
- Fix UNC path completion regression (#20419) (Thanks @MartinGC94!)
- Report error if invalid `-ExecutionPolicy` is passed to `pwsh` (#20460)
- Add `WinGetCommandNotFound` and `CompletionPredictor` modules to track usage (#21040)
- Add `DateKind` parameter to `ConvertFrom-Json` (#20925) (Thanks @jborean93!)
- Add `DirectoryInfo` to the `OutputType` for `New-Item` (#21126) (Thanks @MartinGC94!)
- Fix `Get-Error` serialization of array values (#21085) (Thanks @jborean93!)
- Fix `Test-ModuleManifest` so it can use a UNC path (#24115)

- Fix `Get-TypeData` to write to the pipeline immediately instead of collecting data first (#24236) (Thanks @MartinGC94)
- Add `-Force` parameter to `Resolve-Path` and `Convert-Path` cmdlets to support wildcard hidden files #20981 (Thanks @ArmaanMcleod!)

Engine improvements

- Fallback to AppLocker after `WldpCanExecuteFile` (#25305)
- Explicitly start and stop ANSI Error Color (#24065) (Thanks @JustinGrote!)
- Improve .NET overload definition of generic methods (#21326) (Thanks @jborean93!)
- Optimize the `+=` operation for a collection when it's an object array (#23901) (Thanks @jborean93!)
- Add telemetry to check for specific tags when importing a module (#20371)
- Add `PSAdapter` and `ConsoleGuiTools` to module load telemetry allowlist (#20641)
- Add WinGet module to track usage (#21040)
- Ensure the filename is not null when logging WDAC ETW events (#20910) (Thanks @jborean93!)
- Fix four regressions introduced by the WDAC logging feature (#20913)
- Leave the input, output, and error handles unset when they are not redirected (#20853)
- Fix implicit remoting proxy cmdlets to act on common parameters (#20367)
- Include the module version in error messages when module is not found (#20144) (Thanks @ArmaanMcleod!)
- Fix `unixmode` to handle `setuid` and `sticky` when file is not an executable (#20366)
- Fix using assembly to use `Path.Combine` when constructing assembly paths (#21169)
- Validate the value for using namespace during semantic checks to prevent declaring invalid namespaces (#21162)
- Handle global tool specially when prepending `$PSHOME` to PATH (#24228)

Experimental features

The following experimental features were converted to mainstream features in PowerShell 7.5-rc.1:

- `PSCommandNotFoundSuggestion`
- `PSCommandWithArgs`
- `PSModuleAutoLoadSkipOfflineFiles`

The following experimental features are included in PowerShell 7.5-rc.1:

- `PSRedirectToVariable` - Allow redirecting to a variable (#20381)

- [PSNativeWindowsTildeExpansion](#) - Add tilde expansion for Windows-native executables (#20402) (Thanks @domsleee!)
- [PSSerializeJSONLongEnumAsNumber](#) - `ConvertTo-Json` now treats large enums as numbers (#20999) (Thanks @jborean93!)

Performance improvements

PowerShell 7.5-rc.1 included [PR#23901](#) from @jborean93 that improves the performance of the `+ =` operation for an array of objects.

The following example measures the performance for different methods of adding elements to an array.

PowerShell

```
$tests = @{
    'Direct Assignment' = {
        param($count)

        $result = foreach($i in 1..$count) {
            $i
        }
    }
    'List<T>.Add(T)' = {
        param($count)

        $result = [Collections.Generic.List[int]]::new()
        foreach($i in 1..$count) {
            $result.Add($i)
        }
    }
    'Array+= Operator' = {
        param($count)

        $result = @()
        foreach($i in 1..$count) {
            $result += $i
        }
    }
}

5kb, 10kb | ForEach-Object {
    $groupResult = foreach($test in $tests.GetEnumerator()) {
        $ms = (Measure-Command { & $test.Value -Count $_ }).TotalMilliseconds

        [pscustomobject]@{
            CollectionSize      = $_
            Test                = $test.Key
            TotalMilliseconds = [Math]::Round($ms, 2)
        }
    }
}
```

```

[GC]::Collect()
[GC]::WaitForPendingFinalizers()
}

$groupResult = $groupResult | Sort-Object TotalMilliseconds
$groupResult | Select-Object *, @{
    Name      = 'RelativeSpeed'
    Expression = {
        $relativeSpeed = $_.TotalMilliseconds /
$groupResult[0].TotalMilliseconds
        $speed = [Math]::Round($relativeSpeed, 2).ToString() + 'x'
        if ($speed -eq '1x') { $speed } else { $speed + ' slower' }
    }
} | Format-Table -AutoSize
}

```

When you run the script in PowerShell 7.4.6, you see that using the `+EQ` operator is the slowest method.

Output

CollectionSize Test	TotalMilliseconds	RelativeSpeed
5120 Direct Assignment	4.17	1x
5120 List<T>.Add(T)	90.79	21.77x slower
5120 Array+= Operator	342.58	82.15x slower
CollectionSize Test	TotalMilliseconds	RelativeSpeed
10240 Direct Assignment	0.64	1x
10240 List<T>.Add(T)	184.10	287.66x slower
10240 Array+= Operator	1668.13	2606.45x slower

When you run the script in PowerShell 7.5-rc.1, you see that using the `+EQ` operator is much faster than PowerShell 7.4.6. Now, it's also faster than using the `List<T>.Add(T)` method.

Output

CollectionSize Test	TotalMilliseconds	RelativeSpeed
5120 Direct Assignment	4.71	1x
5120 Array+= Operator	40.42	8.58x slower
5120 List<T>.Add(T)	92.17	19.57x slower
CollectionSize Test	TotalMilliseconds	RelativeSpeed
10240 Direct Assignment	1.76	1x

10240 Array+= Operator	104.73 59.51x slower
10240 List<T>.Add(T)	173.00 98.3x slower

What's New in PowerShell 7.4

Article • 05/13/2025

PowerShell 7.4.10 includes the following features, updates, and breaking changes. PowerShell 7.4.10 is built on .NET 8.0.408.

For a complete list of changes, see the [CHANGELOG](#) in the GitHub repository.

Breaking changes

- Nano server docker images aren't available for this release
- Added the **ProgressAction** parameter to the Common Parameters
- Update some PowerShell APIs to throw **ArgumentException** instead of **ArgumentNullException** when the argument is an empty string ([#19215](#)) (Thanks @xtqqczze!)
- Remove code related to `#Requires -PSSnapin` ([#19320](#))
- `Test-Json` now uses JsonSchema.NET instead of Newtonsoft.Json.Schema.
 - With this change, `Test-Json` no longer supports the older Draft 4 schemas. ([#18141](#)) (Thanks @gregsdennis!). For more information about JSON schemas, see [JSON Schema](#) documentation. This also breaks `Test-Json` for JSON and JSONC files with comments.
 - `ConvertFrom-Json` support still uses Newtonsoft.Json.Schema so it can convert JSON files with comments.
- Output from `Test-Connection` now includes more detailed information about TCP connection tests
- .NET introduced changes that affected `Test-Connection`. The cmdlet now returns an error about the need to use `sudo` on Linux platforms when using a custom buffer size ([#20369](#))
- Experimental feature **PSNativeCommandPreserveBytePipe** is now mainstream. PowerShell now preserves the byte-stream data when redirecting the **stdout** stream of a native command to a file or when piping byte-stream data to the **stdin** stream of a native command.
- Change how relative paths in `Resolve-Path` are handled when using the **RelativebasePath** parameter ([#19755](#)) (Thanks @MartinGC94!)
- Remove unused PSv2 code - removes TabExpansion function ([#18337](#))

Installer updates

The Windows MSI package now provides an option to disable PowerShell telemetry during installation. For more information, see [Install the msi package from the command line](#).

Updated versions of PSResourceGet and PSReadLine

PowerShell 7.4 includes `Microsoft.PowerShell.PSResourceGet` v1.0.1. This module is installed side-by-side with `PowerShellGet` v2.2.5 and `PackageManagement` v1.4.8.1. For more information, see the documentation for [Microsoft.PowerShell.PSResourceGet](#).

PowerShell 7.4 now includes `PSReadLine` v2.3.4. For more information, see the documentation for [PSReadLine](#).

Tab completion improvements

Many thanks to [@MartinGC94](#) and others for all their work to improve tab completion.

- Fix issue when completing the first command in a script with an empty array expression ([#18355](#))
- Fix positional argument completion ([#17796](#))
- Prioritize the default parameter set when completing positional arguments ([#18755](#))
- Improve pseudo binding for dynamic parameters ([#18030](#))
- Improve type inference of hashtable keys ([#17907](#))
- Fix type inference error for empty return statements ([#18351](#))
- Improve type inference for Get-Random ([#18972](#))
- Fix type inference for all scope variables ([#18758](#))
- Improve enumeration of inferred types in pipeline ([#17799](#))
- Add completion for values in comparisons when comparing Enums ([#17654](#))
- Add property assignment completion for enums ([#19178](#))
- Fix completion for PSCustomObject variable properties ([#18682](#))
- Fix member completion in attribute argument ([#17902](#))
- Exclude redundant parameter aliases from completion results ([#19382](#))
- Fix class member completion for classes with base types ([#19179](#))
- Add completion for the `using` keyword ([#16514](#))
- Fix TabExpansion2 variable leak when completing variables ([#18763](#))
- Enable completion of variables across ScriptBlock scopes ([#19819](#))
- Fix completion of the foreach statement variable ([#19814](#))
- Fix variable type inference precedence ([#18691](#))
- Fix member completion for PowerShell Enum class ([#19740](#))
- Fix parsing for array literals in index expressions in method calls ([#19224](#))

- Improve path completion ([#19489 ↗](#))
- Fix an indexing out of bound error in `CompleteInput` for empty script input ([#19501 ↗](#))
- Improve variable completion performance ([#19595 ↗](#))
- Improve Hashtable key completion for type constrained variable assignments, nested Hashtables and more ([#17660 ↗](#))
- Infer external application output as strings ([#19193 ↗](#))
- Update parameter completion for enums to exclude values not allowed by `ValidateRange` attributes ([#17750 ↗](#)) (Thanks @fflaten!).
- Fix dynamic parameter completion ([#19510 ↗](#))
- Add completion for variables assigned by the `data` statement ([#19831 ↗](#))
- Fix expanding tilde (~) on Windows systems to `$HOME` to prevent breaking use cases with native commands ([#21529 ↗](#))

Web cmdlet improvements

Many thanks to [@CarloToso](#) and others for all the work on improving web cmdlets.

- Fix decompression in web cmdlets to include Brotli ([#17955 ↗](#)) (Thanks @iSazonov!)
- Webcmdlets add 308 to redirect codes and small cleanup ([#18536 ↗](#))
- Complete the progress bar rendering in `Invoke-WebRequest` when downloading is complete or cancelled ([#18130 ↗](#))
- Web cmdlets get **Retry-After** interval from response headers if the status code is 429 ([#18717 ↗](#))
- Web cmdlets set default charset encoding to UTF8 ([#18219 ↗](#))
- Preserve `WebSession.MaximumRedirection` from changes ([#19190 ↗](#))
- WebCmdlets parse XML declaration to get encoding value, if present. ([#18748 ↗](#))
- Fix using `xml -Body` in webcmdlets without an encoding ([#19281 ↗](#))
- Adjust PUT method behavior to POST one for default content type in WebCmdlets ([#19152 ↗](#))
- Take into account `ContentType` from Headers in WebCmdlets ([#19227 ↗](#))
- Allow to preserve the original HTTP method by adding `-PreserveHttpMethodOnRedirect` to Web cmdlets ([#18894 ↗](#))
- Webcmdlets display an error on https to http redirect ([#18595 ↗](#))
- Add **AllowInsecureRedirect** switch to Web cmdlets ([#18546 ↗](#))
- Improve verbose message in web cmdlets when content length is unknown ([#19252 ↗](#))
- Build the relative URI for links from the response in `Invoke-WebRequest` ([#19092 ↗](#))
- Fix redirection for `-CustomMethod POST` in WebCmdlets ([#19111 ↗](#))
- Dispose previous response in Webcmdlets ([#19117 ↗](#))
- Improve `Invoke-WebRequest` xml and json errors format ([#18837 ↗](#))

- Add `ValidateNotNullOrEmpty` to `OutFile` and `InFile` parameters of WebCmdlets (#19044 ↗)
- `HttpKnownHeaderNames` update headers list (#18947 ↗)
- `Invoke-RestMethod -FollowRelLink` fix links containing commas (#18829 ↗)
- Fix bug with managing redirection and `KeepAuthorization` in Web cmdlets (#18902 ↗)
- Add `StatusCode` to `HttpResponseException` (#18842 ↗)
- Support HTTP persistent connections in Web Cmdlets (#19249 ↗) (Thanks @stevenebutler!)
- Small cleanup `Invoke-RestMethod` (#19490 ↗)
- Improve the verbose message of WebCmdlets to show correct HTTP version (#19616 ↗)
- Add `FileNameStar` to `MultipartFileContent` in WebCmdlets (#19467 ↗)
- Fix HTTP status from 409 to 429 for WebCmdlets to get retry interval from `Retry-After` header. (#19622 ↗) (Thanks @mkht!)
- Change `-TimeoutSec` to `-ConnectionTimeoutSeconds` and add `-OperationTimeoutSeconds` to web cmdlets (#19558 ↗) (Thanks @stevenebutler!) Other cmdlets
- Support Ctrl+c when connection hangs while reading data in WebCmdlets (#19330 ↗) (Thanks @stevenebutler!)
- Support Unix domain socket in WebCmdlets (#19343 ↗)

Other cmdlet improvements

- `Test-Connection` now returns error about the need to use `sudo` on Linux platforms when using a custom buffer size (#20369 ↗)
- Add output types to Format commands (#18746 ↗) (Thanks @MartinGC94!)
- Add output type attributes for `Get-WinEvent` (#17948 ↗) (Thanks @MartinGC94!)
- Add `Path` and `LiteralPath` parameters to `Test-Json` cmdlet (#19042 ↗) (Thanks @ArmaanMcleod!)
- Add `NoHeader` parameter to `ConvertTo-Csv` and `Export-Csv` cmdlets (#19108 ↗) (Thanks @ArmaanMcleod!)
- Add `Confirm` and `WhatIf` parameters to `Stop-Transcript` (#18731 ↗) (Thanks @JohnLBevan!)
- Add `FuzzyMinimumDistance` parameter to `Get-Command` (#18261 ↗)
- Make `Encoding` parameter able to take `ANSI` encoding in PowerShell (#19298 ↗) (Thanks @CarloToso!)
- Add progress to `Copy-Item` (#18735 ↗)
- `Update-Help` now reports an error when using implicit culture on non-US systems. (#17780 ↗) (Thanks @dkaszews!)
- Don't require activity when creating a completed progress record (#18474 ↗) (Thanks @MartinGC94!)

- Disallow negative values for `Get-Content` cmdlet parameters `-Head` and `-Tail` (#19715 ↴) (Thanks @CarloToso!)
- Make `Update-Help` throw proper error when current culture isn't associated with a language (#19765 ↴) (Thanks @josea!)
- Allow combining of `-Skip` and `-SkipLast` parameters in `Select-Object` cmdlet. (#18849 ↴) (Thanks @ArmaanMcleod!)
- Add `Get-SecureRandom` cmdlet (#19587 ↴)
- `Set-Clipboard -AsOSC52` for remote usage (#18222 ↴) (Thanks @dkaszews!)
- Speed up `Resolve-Path` relative path resolution (#19171 ↴) (Thanks @MartinGC94!)
- Added the switch parameter `-CaseInsensitive` to `Select-Object` and `Get-Unique` cmdlets (#19683 ↴) (Thanks @ArmaanMcleod!)
- `Restart-Computer` and `Stop-Computer` should fail with error when not running via sudo on Unix (#19824 ↴)

Engine improvements

Updates to `$PSSStyle`

- Adds `Dim` and `DimOff` properties (#18653 ↴)
- Added static methods to the `PSSStyle` class that map foreground and background `ConsoleColor` values to ANSI escape sequences (#17938 ↴)
- Table headers for calculated fields are formatted in italics by default
- Add support of respecting `$PSSStyle.OutputRendering` on the remote host (#19601 ↴)
- Updated telemetry data to include use of `CrescendoBuilt` modules (#20371 ↴)

Other Engine updates

- Fallback to AppLocker after `WldpCanExecuteFile` (#25229 ↴)
- Make PowerShell class not affiliate with Runspace when declaring the `NoRunspaceAffinity` attribute (#18138 ↴)
- Add the `ValidateNotNullOrWhiteSpace` attribute (#17191 ↴) (Thanks @wmentha!)
- Add `sqlcmd` to the list for legacy argument passing (#18559 ↴)
- Add the function `cd~` (#18308 ↴) (Thanks @GigaScratch!)
- Fix array type parsing in generic types (#19205 ↴) (Thanks @MartinGC94!)
- Fix wildcard globbing in root of device paths (#19442 ↴) (Thanks @MartinGC94!)
- Add a public API for getting locations of `PSModulePath` elements (#19422 ↴)
- Fix incorrect string to type conversion (#19560 ↴) (Thanks @MartinGC94!)
- Fix slow execution when many breakpoints are used (#14953 ↴) (Thanks @nohwnd!)
- Remove code related to `#Requires -PSSnapin` (#19320 ↴)

Experimental Features

PowerShell 7.4 introduces the following experimental features:

- [PSFeedbackProvider](#) - Replaces the hard-coded suggestion framework with an extensible feedback provider.
 - This feature also adds the **FeedbackName**, **FeedbackText**, and **FeedbackAction** properties to `$PSStyle.Formatting` that allow you to change the formatting of feedback messages.
- [PSModuleAutoLoadSkipOfflineFiles](#) - Module discovery now skips over files that are marked by cloud providers as not fully on disk.
- [PSCmdWithArgs](#) - Add support for passing arguments to commands as a single string

The following experimental features became mainstream:

- [PSConstrainedAuditLogging](#)
- [PSCustomTableHeaderLabelDecoration](#)
- [PSNativeCommandErrorActionPreference](#)
- [PSNativeCommandPreserveBytePipe](#)
- [PSWindowsNativeCommandArgPassing](#)

PowerShell 7.4 changed the following experimental features:

- [PSCmdNotFoundSuggestion](#) - This feature now uses an extensible feedback provider rather than hard-coded suggestions ([#18726 ↗](#))

For more information about the Experimental Features, see [Using Experimental Features](#).

What's New in PowerShell 7.3

Article • 01/23/2025

PowerShell 7.3 is the next stable release, built on .NET 7.0.

PowerShell 7.3 includes the following features, updates, and breaking changes.

Breaking Changes and Improvements

- In this release, Windows APIs were updated or removed for compliance, which means that PowerShell 7.3 doesn't run on Windows 7. While Windows 7 is no longer supported, previous builds could run on Windows 7.
- PowerShell Direct for Hyper-V is only supported on Windows 10, version 1809 and higher.
- `Test-Connection` is broken due to an intentional [breaking change](#) in .NET 7. It's tracked by [#17018](#)
- Add `clean` block to script block as a peer to `begin`, `process`, and `end` to allow easy resource cleanup ([#15177](#))
- Change default for `$PSStyle.OutputRendering` to `Host`
- Make `Out-String` and `Out-File` keep string input unchanged ([#17455](#))
- Move the type data definition of `System.Security.AccessControl.ObjectSecurity` to the `Microsoft.PowerShell.Security` module ([#16355](#)) (Thanks @iSazonov!)
 - Before this change, a user doesn't need to explicitly import the `Microsoft.PowerShell.Security` module to use the code properties defined for an instance of `System.Security.AccessControl.ObjectSecurity`.
 - After this change, a user needs to explicitly import `Microsoft.PowerShell.Security` module in order to use those code properties and code methods.

Tab completion improvements

- PowerShell 7.3 includes PSReadLine 2.2.6, which enables Predictive IntelliSense by default. For more information, see [about_PSReadLine](#).
- Fix tab completion within the script block specified for the `ValidateScriptAttribute`. ([#14550](#)) (Thanks @MartinGC94!)
- Added tab completion for loop labels after `break`/`continue` ([#16438](#)) (Thanks @MartinGC94!)
- Improve Hashtable completion in multiple scenarios ([#16498](#)) (Thanks @MartinGC94!)

- Parameter splatting
- **Arguments** parameter for `Invoke-CimMethod`
- **FilterHashtable** parameter for `Get-WinEvent`
- **Property** parameter for the CIM cmdlets
- Removes duplicates from member completion scenarios
- Support forward slashes in network share (UNC path) completion (#17111 ↴) (Thanks @sba923!)
- Improve member autocompletion (#16504 ↴) (Thanks @MartinGC94!)
- Prioritize ValidateSet completions over Enums for parameters (#15257 ↴) (Thanks @MartinGC94!)
- Add type inference support for generic methods with type parameters (#16951 ↴) (Thanks @MartinGC94!)
- Improve type inference and completions (#16963 ↴) (Thanks @MartinGC94!)
 - Allows methods to be shown in completion results for `ForEach-Object -MemberName`
 - Prevents completion on expressions that return void like `([void]("")`)
 - Allows non-default Class constructors to show up when class completion is based on the AST
- Improve type inference for `$_` (#17716 ↴) (Thanks @MartinGC94!)
- Fix type inference for **ICollection** (#17752 ↴) (Thanks @MartinGC94!)
- Prevent braces from being removed when completing variables (#17751 ↴) (Thanks @MartinGC94!)
- Add completion for index expressions for dictionaries (#17619 ↴) (Thanks @MartinGC94!)
- Fix type completion for attribute tokens (#17484 ↴) (Thanks @MartinGC94!)
- Improve dynamic parameter tab completion (#17661 ↴) (Thanks @MartinGC94!)
- Avoid binding positional parameters when completing parameter in front of value (#17693 ↴) (Thanks @MartinGC94!)

Improved error handling

- Set `$?` correctly for command expression with redirections (#16046 ↴)
- Fix a casting error when using `$PSNativeCommandUseErrorActionPreference` (#15993 ↴)
- Make the native command error handling optionally honor `ErrorActionPreference` (#15897 ↴)
- Specify the executable path as `TargetObject` for non-zero exit code ErrorRecord (#16108 ↴) (Thanks @rkeithhill!)

Session and remoting improvements

- Add `-Options` to the PSRP over SSH commands to allow passing OpenSSH options directly ([#12802](#)) (Thanks @BrannenGH!)
- Add `-ConfigurationFile` parameter to `pwsh` to allow starting a new process with the session configuration defined in a `.pssc` file ([#17447](#))
- Add support for using `New-PSSessionConfigurationFile` on non-Windows platforms ([#17447](#))

Updated cmdlets

- Add `-HttpVersion` parameter to web cmdlets ([#15853](#)) (Thanks @hayhay27!)
- Add support to web cmdlets for open-ended input tags ([#16193](#)) (Thanks @farmerau!)
- Fix `ConvertTo-Json -Depth` to allow 100 at maximum ([#16197](#)) (Thanks @KevRitchie!)
- Improve variable handling when calling `Invoke-Command` with the `$Using:` expression ([#16113](#)) (Thanks @dwtaber!)
- Add `-StrictMode` to `Invoke-Command` to allow specifying strict mode when invoking command locally ([#16545](#)) (Thanks @Thomas-Yu!)
- Add `clean` block to script block as a peer to `begin`, `process`, and `end` to allow easy resource cleanup ([#15177](#))
- Add `-Amended` switch to `Get-CimClass` cmdlet ([#17477](#)) (Thanks @iSazonov)
- Changed `ConvertFrom-Json -AsHashtable` to use ordered hashtable ([#17405](#))
- Removed ANSI escape sequences in strings before sending to `Out-GridView` ([#17664](#))
- Added the `Milliseconds` parameter to `New-TimeSpan` ([#17621](#)) (Thanks @NoMoreFood!)
- Show optional parameters when displaying method definitions and overloads ([#13799](#)) (Thanks @eugenescmlv!)
- Allow commands to still be executed even if the current working directory no longer exists ([#17579](#))
- Add support for HTTPS with `Set-AuthenticodeSignature -TimeStampServer` ([#16134](#)) (Thanks @Ryan-Hutchison-USAF!)
- Render decimal numbers in a table using current culture ([#17650](#))
- Add type accelerator ordered for `OrderedDictionary` ([#17804](#)) (Thanks @fflaten!)
- Add `find.exe` to legacy argument binding behavior for Windows ([#17715](#))
- Add `-NoProfileLoadTime` switch to `pwsh` ([#17535](#)) (Thanks @rkeithhill!)

For a complete list of changes, see the [Change Log](#) in the GitHub repository.

Experimental Features

In PowerShell 7.3, following experimental features became mainstream:

- `PSAnsiRenderingFileInfo` - This feature adds the `$PSStyle.FileInfo` member and enables coloring of specific file types.
- `PSCleanBlock` - Adds `clean` block to script block as a peer to `begin`, `process`, and `end` to allow easy resource cleanup.
- `PSAMSIMethodInvocationLogging` - Extends the data sent to AMSI for inspection to include all invocations of .NET method members.
- `PSNativeCommandArgumentPassing` - PowerShell now uses the `ArgumentList` property of the `StartProcessInfo` object rather than the old mechanism of reconstructing a string when invoking a native executable.

PowerShell 7.3.1 adds `sqlcmd.exe` to the list of native commands in Windows that use the `Legacy` style of argument passing.

- `PSExec` - Adds the new `Switch-Process` cmdlet (alias `exec`) to provide `exec` compatibility for non-Windows systems.

PowerShell 7.3.1 changed the `exec` alias to a function that wraps `Switch-Process`. The function allows you to pass parameters to the native command that might have erroneously bound to the `WithCommand` parameter.

PowerShell 7.3 introduces the following experimental features:

- `PSNativeCommandErrorActionPreference` - Adds the `$PSNativeCommandUseErrorActionPreference` variable to enable errors produced by native commands to be PowerShell errors.

PowerShell 7.3 removed the following experimental features:

- `PSNativePSPPathResolution` experimental feature is no longer supported.
- `PSStrictModeAssignment` experimental feature is no longer supported.

For more information about the Experimental Features, see [Using Experimental Features](#).

What's New in PowerShell 7.2

Article • 01/23/2025

PowerShell 7.2 is the next Long Term Servicing (LTS) release is built on .NET 6.0.

PowerShell 7.2 includes the following features, updates, and breaking changes.

- New universal installer packages for most supported Linux distributions
- Microsoft Update support on Windows
- 2 new experimental features
 - Improved native command argument passing support
 - ANSI FileInfo color support
- Improved Tab Completions
- PSReadLine 2.1 with Predictive IntelliSense
- 7 experimental features promoted to mainstream and 1 removed
- Separating DSC from PowerShell 7 to enable future improvements
- Several breaking changes to improve usability

For a complete list of changes, see the [Change Log ↗](#) in the GitHub repository.

Installation updates

Check the installation instructions for your preferred operating system:

- [Windows](#)
- [macOS](#)
- [Linux](#)

Additionally, PowerShell 7.2 supports ARM64 versions of Windows and macOS and ARM32 and ARM64 versions of Debian and Ubuntu.

For up-to-date information about supported operating systems and support lifecycle, see the [PowerShell Support Lifecycle](#).

New universal install packages for Linux distributions

Previously, we created separate installer packages for each supported version of CentOS, RHEL, Debian, and Ubuntu. The universal installer package combines eight different packages into one, making installation on Linux simpler. The universal package installs the necessary dependencies for the target distribution and creates the platform-specific changes to make PowerShell work.

Microsoft Update support for Windows

PowerShell 7.2 add support for Microsoft Update. When you enable this feature, you'll get the latest PowerShell 7 updates in your traditional Windows Update (WU) management flow, whether that's with Windows Update for Business, WSUS, SCCM, or the interactive WU dialog in Settings.

The PowerShell 7.2 MSI package includes following command-line options:

- `USE_MU` - This property has two possible values:
 - `1` (default) - Opts into updating through Microsoft Update or WSUS
 - `0` - don't opt into updating through Microsoft Update or WSUS
- `ENABLE_MU`
 - `1` (default) - Opts into using Microsoft Update the Automatic Updates or Windows Update
 - `0` - don't opt into using Microsoft Update the Automatic Updates or Windows Update

Experimental Features

The following experimental features are now mainstream features in this release:

- `Microsoft.PowerShell.Utility.PSImportPSDataFileSkipLimitCheck` - see [Import-PowerShellDataFile](#)
- `Microsoft.PowerShell.Utility.PSManageBreakpointsInRunspace`
- `PSAnsiRendering` - see [about_ANSI_Terminals](#)
- `PSAnsiProgress` - see [about_ANSI_Terminals](#)
- `PSCultureInvariantReplaceOperator`
- `PSNotApplyErrorActionToStderr`
- `PSUnixFileStat`

The following experimental feature was added in this release:

- [PSNativeCommandArgumentPassing](#) - When this experimental feature is enabled PowerShell uses the `ArgumentList` property of the `StartProcessInfo` object rather than our current mechanism of reconstructing a string when invoking a native executable. This feature adds a new automatic variable `$PSNativeCommandArgumentPassing` that allows you to select the behavior at runtime.
- [PSAnsiRenderingFileInfo](#) - Allow ANSI color customization of file information.

- `PSLoadAssemblyFromNativeCode` - Exposes an API to allow assembly loading from native code.

For more information about the Experimental Features, see [Using Experimental Features](#).

Improved Tab Completions

PowerShell 7.2 includes several improvements to Tab Completion. These changes include bugfixes and improve usability.

- Fix tab completion for unlocalized about* topics (#15265) (Thanks @MartinGC94)
- Fix splatting being treated as positional parameter in completions (#14623) (Thanks @MartinGC94)
- Add completions for comment-based help keywords (#15337) (Thanks @MartinGC94)
- Add completion for Requires statements (#14596) (Thanks @MartinGC94)
- Added tab completion for View parameter of Format-* cmdlets (#14513) (Thanks @iSazonov)

PSReadLine 2.1 Predictive IntelliSense

PSReadLine 2.1 introduced `CommandPrediction` APIs that establish a framework for providing predictions for command-line completion. The API enables users to discover, edit, and execute full commands based on matching predictions from the user's history.

Predictive IntelliSense is disabled by default. To enable predictions, run the following command:

```
PowerShell  
Set-PSReadLineOption -PredictionSource History
```

Separating DSC from PowerShell 7 to enable future improvements

The PSDesiredStateConfiguration module was removed from the PowerShell 7.2 package and is now published to the PowerShell Gallery. This allows the PSDesiredStateConfiguration module to be developed independently of PowerShell and users can mix and match versions of PowerShell and PSDesiredStateConfiguration for

their environment. To install PSDesiredStateConfiguration 2.0.5 from the PowerShell Gallery:

```
PowerShell
```

```
Install-Module -Name PSDesiredStateConfiguration -Repository PSGallery -  
MaximumVersion 2.99
```

ⓘ Important

Be sure to include the parameter MaximumVersion or you could install version 3 (or higher) of PSDesireStateConfiguration that contains significant differences.

Engine updates

- Add `LoadAssemblyFromNativeMemory` function to load assemblies in memory from a native PowerShell host by awakecoding · Pull Request #14652

Breaking Changes and Improvements

- The PSDesiredStateConfiguration was removed from the PowerShell 7.2 package
- Make PowerShell Linux deb and RPM packages universal (#15109)
- Experimental feature `PSNativeCommandArgumentPassing`: Use ArgumentList for native executable invocation (#14692)
- Ensure `-PipelineVariable` is set for all output from script cmdlets (#12766)
- Emit warning if `ConvertToJson` exceeds `-Depth` value (#13692)
- Remove alias D of `-Directory` switch CL-General #15171
- Improve detection of mutable value types (#12495)
- Restrict `New-Object` in `NoLanguage` mode under lock down (#14140)
- Enforce AppLocker Deny configuration before Execution Policy Bypass configuration (#15035)
- Change `FileSystemInfo.Target` from a `CodeProperty` to an `AliasProperty` that points to `FileSystemInfo.LinkTarget` (#16165)

Migrating from Windows PowerShell 5.1 to PowerShell 7

Article • 04/02/2024

Designed for cloud, on-premises, and hybrid environments, PowerShell 7 is packed with enhancements and [new features](#).

- Installs and runs side-by-side with Windows PowerShell
- Improved compatibility with existing Windows PowerShell modules
- New language features, like ternary operators and `ForEach-Object -Parallel`
- Improved performance
- SSH-based remoting
- Cross-platform interoperability
- Support for Docker containers

PowerShell 7 works side-by-side with Windows PowerShell letting you easily test and compare between editions before deployment. Migration is simple, quick, and safe.

PowerShell 7 is supported on the following Windows operating systems:

- Windows 10, and 11
- Windows Server 2016, 2019, and 2022

PowerShell 7 also runs on macOS and several Linux distributions. For a list of supported operating systems and information about the support lifecycle, see the [PowerShell Support Lifecycle](#).

Installing PowerShell 7

For flexibility and to support the needs of IT, DevOps engineers, and developers, there are several options available to install PowerShell 7. In most cases, the installation options can be reduced to the following methods:

- Deploy PowerShell using the [MSI package](#)
- Deploy PowerShell using the [ZIP package](#)

Note

The MSI package can be deployed and updated with management products such as [Microsoft Configuration Manager](#). Download the packages from [GitHub Release page](#).

Deploying the MSI package requires Administrator permission. The ZIP package can be deployed by any user. The ZIP package is the easiest way to install PowerShell 7 for testing, before committing to a full installation.

You may also install PowerShell 7 via the Windows Store or [winget](#). For more information about both of these methods, see the detailed instructions in [Installing PowerShell on Windows](#).

Using PowerShell 7 side-by-side with Windows PowerShell 5.1

PowerShell 7 is designed to coexist with Windows PowerShell 5.1. The following features ensure that your investment in PowerShell is protected and your migration to PowerShell 7 is simple.

- Separate installation path and executable name
- Separate PSModulePath
- Separate profiles for each version
- Improved module compatibility
- New remoting endpoints
- Group policy support
- Separate Event logs

Differences in .NET versions

PowerShell 7.4 is built on .NET 8.0. Windows PowerShell 5.1 is built on .NET Framework 4.x. The differences between the .NET versions might affect the behavior of your scripts, especially if you are calling .NET method directly. For more information, [Differences between Windows PowerShell 5.1 and PowerShell 7.x](#).

Separate installation path and executable name

PowerShell 7 installs to a new directory, enabling side-by-side execution with Windows PowerShell 5.1.

Install locations by version:

- Windows PowerShell 5.1: `$Env:windir\System32\WindowsPowerShell\v1.0`
- PowerShell 6.x: `$Env:ProgramFiles\PowerShell\6`
- PowerShell 7: `$Env:ProgramFiles\PowerShell\7`

The new location is added to your PATH allowing you to run both Windows PowerShell 5.1 and PowerShell 7. If you're migrating from PowerShell 6.x to PowerShell 7, PowerShell 6 is removed and the PATH replaced.

In Windows PowerShell, the PowerShell executable is named `powershell.exe`. In version 6 and above, the executable is named `pwsh.exe`. The new name makes it easy to support side-by-side execution of both versions.

Separate PSModulePath

By default, Windows PowerShell and PowerShell 7 store modules in different locations.

PowerShell 7 combines those locations in the `$Env:PSModulePath` environment variable. When importing a module by name, PowerShell checks the location specified by `$Env:PSModulePath`. This allows PowerShell 7 to load both Core and Desktop modules.

 Expand table

Install Scope	Windows PowerShell 5.1	PowerShell 7.0
PowerShell modules	<code>\$Env:windir\system32\WindowsPowerShell\v1.0\Modules</code>	<code>\$Env:ProgramFiles\PowerShell\7\Modules</code>
User installed AllUsers scope	<code>\$Env:ProgramFiles\WindowsPowerShell\Modules</code>	<code>\$Env:ProgramFiles\PowerShell\Modules</code>
User installed CurrentUser scope	<code>\$HOME\Documents\WindowsPowerShell\Modules</code>	<code>\$HOME\Documents\PowerShell\Modules</code>

The following examples show the default values of `$Env:PSModulePath` for each version.

- For Windows PowerShell 5.1:

```
PowerShell  
$Env:PSModulePath -split ';'
```

```
Output  
C:\Users<user>\Documents\WindowsPowerShell\Modules  
C:\Program Files\WindowsPowerShell\Modules  
C:\WINDOWS\System32\WindowsPowerShell\v1.0\Modules
```

- For PowerShell 7:

```
PowerShell
```

```
$Env:PSModulePath -split ';'
```

Output

```
C:\Users\<user>\Documents\PowerShell\Modules
C:\Program Files\PowerShell\Modules
C:\Program Files\PowerShell\7\Modules
C:\Program Files\WindowsPowerShell\Modules
C:\WINDOWS\System32\WindowsPowerShell\v1.0\Modules
```

Notice that PowerShell 7 includes the Windows PowerShell paths and the PowerShell 7 paths to provide autoloading of modules.

① Note

Additional paths may exist if you have changed the PSModulePath environment variable or installed custom modules or applications.

For more information, see [about_PSMODULEPATH](#).

For more information about Modules, see [about_Modules](#).

Separate profiles

A PowerShell profile is a script that executes when PowerShell starts. This script customizes your environment by adding commands, aliases, functions, variables, modules, and PowerShell drives. The profile script makes these customizations available in every session without having to manually recreate them.

The path to the location of the profile has changed in PowerShell 7.

- In Windows PowerShell 5.1, the location of the profile is `$HOME\Documents\WindowsPowerShell`.
- In PowerShell 7, the location of the profile is `$HOME\Documents\PowerShell`.

The profile filenames have also changed:

PowerShell

```
$PROFILE | Select-Object *Host* | Format-List
```

Output

```
AllUsersAllHosts      : C:\Program Files\PowerShell\7\profile.ps1
AllUsersCurrentHost   : C:\Program
Files\PowerShell\7\Microsoft.PowerShell_profile.ps1
```

```
CurrentUserAllHosts      : C:\Users\<user>\Documents\PowerShell\profile.ps1
CurrentUserCurrentHost : C:\Users\
<user>\Documents\PowerShell\Microsoft.PowerShell_profile.ps1
```

For more information [about_Profiles](#).

PowerShell 7 compatibility with Windows PowerShell 5.1 modules

Most of the modules you use in Windows PowerShell 5.1 already work with PowerShell 7, including Azure PowerShell and Active Directory. We're continuing to work with other teams to add native PowerShell 7 support for more modules including Microsoft Graph, Office 365, and others. For the current list of supported modules, see [PowerShell 7 module compatibility](#).

Note

On Windows, we've also added a **UseWindowsPowerShell** switch to `Import-Module` to ease the transition to PowerShell 7 for those using incompatible modules. For more information on this functionality, see [about_Windows_PowerShell_Compatibility](#).

PowerShell Remoting

PowerShell remoting lets you run any PowerShell command on one or more remote computers. You can establish persistent connections, start interactive sessions, and run scripts on remote computers.

WS-Management remoting

Windows PowerShell 5.1 and below use the WS-Management (WSMAN) protocol for connection negotiation and data transport. Windows Remote Management (WinRM) uses the WSMAN protocol. If WinRM has been enabled, PowerShell 7 uses the existing Windows PowerShell 5.1 endpoint named `Microsoft.PowerShell` for remoting connections. To update PowerShell 7 to include its own endpoint, run the `Enable-PSRemoting` cmdlet. For information about connecting to specific endpoints, see [WS-Management Remoting in PowerShell](#)

To use Windows PowerShell remoting, the remote computer must be configured for remote management. For more information, including instructions, see [About Remote Requirements](#).

For more information about working with remoting, see [About Remote](#)

SSH-based remoting

SSH-based remoting was added in PowerShell 6.x to support other operating systems that can't use Windows native components like WinRM. SSH remoting creates a PowerShell host process on the target computer as an SSH subsystem. For details and examples on setting up SSH-based remoting on Windows or Linux, see: [PowerShell remoting over SSH](#).

① Note

The PowerShell Gallery (PSGallery) contains a module and cmdlet that automatically configures SSH-based remoting. Install the `Microsoft.PowerShell.RemotingTools` module from the [PSGallery](#) and run the `Enable-SSH` cmdlet.

The `New-PSSession`, `Enter-PSSession`, and `Invoke-Command` cmdlets have new parameter sets to support SSH connections.

PowerShell

```
[ -HostName <string> ] [ -UserName <string> ] [ -KeyFilePath <string> ]
```

To create a remote session, specify the target computer with the **HostName** parameter and provide the user name with **UserName**. When running the cmdlets interactively, you're prompted for a password.

PowerShell

```
Enter-PSSession -HostName <Computer> -UserName <Username>
```

Alternatively, when using the **HostName** parameter, provide the username information followed by the at sign (@), followed by the computer name.

PowerShell

```
Enter-PSSession -HostName <Username>@<Computer>
```

You may set up SSH key authentication using a private key file with the **KeyFilePath** parameter. For more information, see [OpenSSH Key Management](#).

Group Policy supported

PowerShell includes Group Policy settings to help you define consistent option values for servers in an enterprise environment. These settings include:

- Console session configuration: Sets a configuration endpoint in which PowerShell is run.
- Turn on Module Logging: Sets the `LogPipelineExecutionDetails` property of modules.

- Turn on PowerShell Script Block Logging: Enables detailed logging of all PowerShell scripts.
- Turn on Script Execution: Sets the PowerShell execution policy.
- Turn on PowerShell Transcription: enables capturing of input and output of PowerShell commands into text-based transcripts.
- Set the default source path for Update-Help: Sets the source for Updatable Help to a directory, not the Internet.

For more information, see [about_Group_Policy_Settings](#).

PowerShell 7 includes Group Policy templates and an installation script in `$PSHOME`.

Group Policy tools use administrative template files (`.admx`, `.adml`) to populate policy settings in the user interface. This allows administrators to manage registry-based policy settings. The `InstallPSCorePolicyDefinitions.ps1` script installs PowerShell Administrative Templates on the local machine.

PowerShell

```
Get-ChildItem -Path $PSHOME -Filter *Core*Policy*
```

Output

Directory: C:\Program Files\PowerShell\7

Mode	LastWriteTime	Length	Name
----	-----	-----	-----
-a---	2/27/2020 12:38 AM	15861	
	InstallPSCorePolicyDefinitions.ps1		
-a---	2/27/2020 12:28 AM	9675	
	PowerShellCoreExecutionPolicy.adml		
-a---	2/27/2020 12:28 AM	6201	
	PowerShellCoreExecutionPolicy.admx		

Separate Event Logs

Windows PowerShell and PowerShell 7 log events to separate event logs. Use the following command to get a list of the PowerShell logs.

PowerShell

```
Get-WinEvent -ListLog *PowerShell*
```

For more information, see [about_Logging_Windows](#).

Improved editing experience with Visual Studio Code

Visual Studio Code (VSCode)  with the [PowerShell Extension](#)  is the supported scripting environment for PowerShell 7. The Windows PowerShell Integrated Scripting Environment (ISE) only supports Windows PowerShell.

The updated PowerShell extension includes:

- New ISE compatibility mode
- PSReadLine in the Integrated Console, including syntax highlighting, multi-line editing, and back search
- Stability and performance improvements
- New CodeLens integration
- Improved path autocomplete

To make the transition to Visual Studio Code easier, use the **Enable ISE Mode** function available in the **Command Palette**. This function switches VSCode into an ISE-style layout. The ISE-style layout gives you all the new features and capabilities of PowerShell in a familiar user experience.

To switch to the new ISE layout, press `Ctrl + Shift + P` to open the **Command Palette**, type `PowerShell` and select **PowerShell: Enable ISE Mode**.

To set the layout to the original layout, open the **Command Palette**, select **PowerShell: Disable ISE Mode (restore to defaults)**.

For details about customizing the VSCode layout to ISE, see [How to Replicate the ISE Experience in Visual Studio Code](#)

Note

There are no plans to update the ISE with new features. In the latest versions of Windows 10 or Windows Server 2019 and higher, the ISE is now a user-uninstallable feature. There are no plans to permanently remove the ISE. The PowerShell Team and its partners are focused on improving the scripting experience in the PowerShell extension for Visual Studio Code.

Next Steps

Armed with the knowledge to effectively migrate, [install PowerShell 7](#) now!

Differences between Windows PowerShell 5.1 and PowerShell 7.x

Article • 04/02/2024

Windows PowerShell 5.1 is built on top of the .NET Framework v4.5. With the release of PowerShell 6.0, PowerShell became an open source project built on .NET Core 2.0. Moving from the .NET Framework to .NET Core allowed PowerShell to become a cross-platform solution. PowerShell runs on Windows, macOS, and Linux.

There are few differences in the PowerShell language between Windows PowerShell and PowerShell. The most notable differences are in the availability and behavior of PowerShell cmdlets between Windows and non-Windows platforms and the changes that stem from the differences between the .NET Framework and .NET Core.

This article summarizes the significant differences and breaking changes between Windows PowerShell and the current version of PowerShell. This summary does not include new features or cmdlets that have been added. Nor does this article discuss what changed between versions. The goal of this article is to present the current state of PowerShell and how that is different from Windows PowerShell. For a detailed discussion of changes between versions and the addition of new features, see the [What's New](#) articles for each version.

- [What's new in PowerShell 7.5](#)
- [What's new in PowerShell 7.4](#)
- [What's new in PowerShell 7.3](#)
- [What's new in PowerShell 7.2](#)
- [What's new in PowerShell 7.1](#)
- [What's new in PowerShell 7.0](#)
- [What's new in PowerShell 6.x](#)

.NET Framework vs .NET Core

PowerShell on Linux and macOS uses .NET core, which is a subset of the full .NET Framework on Microsoft Windows. This is significant because PowerShell provides direct access to the underlying framework types and methods. As a result, scripts that run on Windows may not run on non-Windows platforms because of the differences in the frameworks. For more information about changes in .NET Core, see [Breaking changes for migration from .NET Framework to .NET Core](#).

Each new release of PowerShell is built on a newer version of .NET. There can be breaking changes in .NET that affect PowerShell.

- PowerShell 7.5 - Built on .NET 9.0
- PowerShell 7.4 - Built on .NET 8.0
- PowerShell 7.3 - Built on .NET 7.0
- PowerShell 7.2 (LTS-current) - Built on .NET 6.0 (LTS-current)
- PowerShell 7.1 - Built on .NET 5.0
- PowerShell 7.0 (LTS) - Built on .NET Core 3.1 (LTS)
- PowerShell 6.2 - Built on .NET Core 2.1
- PowerShell 6.1 - Built on .NET Core 2.1
- PowerShell 6.0 - Built on .NET Core 2.0

With the advent of [.NET Standard 2.0](#), PowerShell can load many traditional Windows PowerShell modules without modification. Additionally, PowerShell 7 includes a Windows PowerShell Compatibility feature that allows you to use Windows PowerShell modules that still require the full framework.

For more information see:

- [about_Windows_PowerShell_Compatibility](#)
- [PowerShell 7 module compatibility](#)

Be aware of .NET method changes

While .NET method changes are not specific to PowerShell, they can affect your scripts, especially if you are calling .NET methods directly. Also, there might be new overloads for constructors. This can have an impact on how you create objects using `New-Object` or the `[type]::new()` method.

For example, .NET added overloads to the `[System.String]::Split()` method that aren't available in .NET Framework 4.5. The following list shows the overloads for the `Split()` method available in Windows PowerShell 5.1:

```
PowerShell
PS> "" .Split
OverloadDefinitions
-----
string[] Split(Params char[] separator)
string[] Split(char[] separator, int count)
string[] Split(char[] separator, System.StringSplitOptions options)
string[] Split(char[] separator, int count, System.StringSplitOptions options)
```

```
string[] Split(string[] separator, System.StringSplitOptions options)
string[] Split(string[] separator, int count, System.StringSplitOptions
options)
```

The following list shows the overloads for the `Split()` method available in PowerShell 7:

```
PowerShell

"".Split

OverloadDefinitions
-----
string[] Split(char separator, System.StringSplitOptions options)
string[] Split(char separator, int count, System.StringSplitOptions options)
string[] Split(Params char[] separator)
string[] Split(char[] separator, int count)
string[] Split(char[] separator, System.StringSplitOptions options)
string[] Split(char[] separator, int count, System.StringSplitOptions
options)
string[] Split(string separator, System.StringSplitOptions options)
string[] Split(string separator, int count, System.StringSplitOptions
options)
string[] Split(string[] separator, System.StringSplitOptions options)
string[] Split(string[] separator, int count, System.StringSplitOptions
options)
```

In Windows PowerShell 5.1, you could pass a character array (`char[]`) to the `Split()` method as a `string`. The method splits the target string at any occurrence of a character in the array. The following command splits the target string in Windows PowerShell 5.1, but not in PowerShell 7:

```
PowerShell

# PowerShell 7 example
"1111p2222q3333".Split('pq')
```

Output

```
1111p2222q3333
```

To bind to the correct overload, you must typecast the string to a character array:

```
PowerShell

# PowerShell 7 example
"1111p2222q3333".Split([char[]]'pq')
```

Output

```
1111  
2222  
3333
```

Modules no longer shipped with PowerShell

For various compatibility reasons, the following modules are no longer included in PowerShell.

- ISE
- Microsoft.PowerShell.LocalAccounts
- Microsoft.PowerShell.ODataUtils
- Microsoft.PowerShell.Operation.Validation
- PSScheduledJob
- PSWorkflow
- PSWorkflowUtility

PowerShell Workflow

[PowerShell Workflow](#) is a feature in Windows PowerShell that builds on top of [Windows Workflow Foundation \(WF\)](#) that enables the creation of robust runbooks for long-running or parallelized tasks.

Due to the lack of support for Windows Workflow Foundation in .NET Core, we removed PowerShell Workflow from PowerShell.

In the future, we would like to enable native parallelism/concurrency in the PowerShell language without the need for PowerShell Workflow.

If there is a need to use checkpoints to resume a script after the OS restarts, we recommend using Task Scheduler to run a script on OS startup, but the script would need to maintain its own state (like persisting it to a file).

Cmdlets removed from PowerShell

For the modules that are included in PowerShell, the following cmdlets were removed from PowerShell for various compatibility reasons or the use of unsupported APIs.

CimCmdlets

- `Export-BinaryMiLog`

Microsoft.PowerShell.Core

- `Add-PSSnapin`
- `Export-Console`
- `Get-PSSnapin`
- `Remove-PSSnapin`
- `Resume-Job`
- `Suspend-Job`

Microsoft.PowerShell.Diagnostics

- `Export-Counter`
- `Import-Counter`

Microsoft.PowerShell.Management

- `Add-Computer`
- `Checkpoint-Computer`
- `Clear-EventLog`
- `Complete-Transaction`
- `Disable-ComputerRestore`
- `Enable-ComputerRestore`
- `Get-ComputerRestorePoint`
- `Get-ControlPanelItem`
- `Get-EventLog`
- `Get-Transaction`
- `Get-WmiObject`
- `Invoke-WmiMethod`
- `Limit-EventLog`
- `New-EventLog`
- `New-WebServiceProxy`
- `Register-WmiEvent`
- `Remove-Computer`
- `Remove-EventLog`
- `Remove-WmiObject`
- `Reset-ComputerMachinePassword`
- `Restore-Computer`
- `Set-WmiInstance`

- `Show-ControlPanelItem`
- `Show-EventLog`
- `Start-Transaction`
- `Test-ComputerSecureChannel`
- `Undo-Transaction`
- `Use-Transaction`
- `Write-EventLog`

Microsoft.PowerShell.Utility

- `Convert-String`
- `ConvertFrom-String`

PSDesiredStateConfiguration

- `Disable-DscDebug`
- `Enable-DscDebug`
- `Get-DscConfiguration`
- `Get-DscConfigurationStatus`
- `Get-DscLocalConfigurationManager`
- `Publish-DscConfiguration`
- `Remove-DscConfigurationDocument`
- `Restore-DscConfiguration`
- `Set-DscLocalConfigurationManager`
- `Start-DscConfiguration`
- `Stop-DscConfiguration`
- `Test-DscConfiguration`
- `Update-DscConfiguration`

WMI v1 cmdlets

The following WMI v1 cmdlets were removed from PowerShell:

- `Register-WmiEvent`
- `Set-WmiInstance`
- `Invoke-WmiMethod`
- `Get-WmiObject`
- `Remove-WmiObject`

The CimCmdlets module (aka WMI v2) cmdlets perform the same function and provide new functionality and a redesigned syntax.

New-WebServiceProxy cmdlet removed

.NET Core does not support the Windows Communication Framework, which provide services for using the SOAP protocol. This cmdlet was removed because it requires SOAP.

*-Transaction cmdlets removed

These cmdlets had very limited usage. The decision was made to discontinue support for them.

- `Complete-Transaction`
- `Get-Transaction`
- `Start-Transaction`
- `Undo-Transaction`
- `Use-Transaction`

*-EventLog cmdlets

Due to the use of unsupported APIs, the `*-EventLog` cmdlets have been removed from PowerShell. `Get-WinEvent` and `New-WinEvent` are available to get and create events on Windows.

Cmdlets that use the Windows Presentation Framework (WPF)

.NET Core 3.1 added support for WPF, so the release of PowerShell 7.0 restored the following Windows-specific features:

- The `Show-Command` cmdlet
- The `Out-GridView` cmdlet
- The `ShowWindow` parameter of `Get-Help`

PowerShell Desired State Configuration (DSC) changes

`Invoke-DscResource` was restored as an experimental feature in PowerShell 7.0.

Beginning with PowerShell 7.2, the PSDesiredStateConfiguration module has been removed from PowerShell and has been published to the PowerShell Gallery. For more information, see the [announcement](#) in the PowerShell Team blog.

PowerShell executable changes

Renamed `powershell.exe` to `pwsh.exe`

The binary name for PowerShell has been changed from `powershell(.exe)` to `pwsh(.exe)`. This change provides a deterministic way for users to run PowerShell on machines and support side-by-side installations of Windows PowerShell and PowerShell.

Additional changes to `pwsh(.exe)` from `powershell.exe`:

- Changed the first positional parameter from `-Command` to `-File`. This change fixes the usage of `#!` (aka as a shebang) in PowerShell scripts that are being executed from non-PowerShell shells on non-Windows platforms. It also means that you can run commands like `pwsh foo.ps1` or `pwsh fooScript` without specifying `-File`. However, this change requires that you explicitly specify `-c` or `-Command` when trying to run commands like `pwsh.exe -Command Get-Command`.
- `pwsh` accepts the `-i` (or `-Interactive`) switch to indicate an interactive shell. This allows PowerShell to be used as a default shell on Unix platforms.
- Removed parameters `-ImportSystemModules` and `-PSConsoleFile` from `pwsh.exe`.
- Changed `pwsh -Version` and built-in help for `pwsh.exe` to align with other native tools.
- Invalid argument error messages for `-File` and `-Command` and exit codes consistent with Unix standards
- Added `-WindowStyle` parameter on Windows. Similarly, package-based installations updates on non-Windows platforms are in-place updates.

The shortened name is also consistent with naming of shells on non-Windows platforms.

Support running a PowerShell script with bool parameter

Previously, using `pwsh.exe` to execute a PowerShell script using `-File` provided no way to pass `$true/$false` as parameter values. Support for `$true/$false` as parsed values to parameters was added. Switch values are also supported.

Improved backwards compatibility with Windows PowerShell

For Windows, a new switch parameter `UseWindowsPowerShell` is added to `Import-Module`. This switch creates a proxy module in PowerShell 7 that uses a local Windows PowerShell process to implicitly run any cmdlets contained in that module. For more information, see [Import-Module](#).

For more information on which Microsoft modules work with PowerShell 7.0, see the [Module Compatibility Table](#).

Microsoft Update support for Windows

PowerShell 7.2 added support for Microsoft Update. When you enable this feature, you'll get the latest PowerShell 7 updates in your traditional Windows Update (WU) management flow, whether that's with Windows Update for Business, WSUS, SCCM, or the interactive WU dialog in Settings.

The PowerShell 7.2 MSI package includes following command-line options:

- `USE_MU` - This property has two possible values:
 - `1` (default) - Opts into updating through Microsoft Update or WSUS
 - `0` - Do not opt into updating through Microsoft Update or WSUS
- `ENABLE_MU`
 - `1` (default) - Opts into using Microsoft Update the Automatic Updates or Windows Update
 - `0` - Do not opt into using Microsoft Update the Automatic Updates or Windows Update

Engine changes

Support PowerShell as a default Unix shell

On Unix, it is a convention for shells to accept `-i` for an interactive shell and many tools expect this behavior (`script` for example, and when setting PowerShell as the default shell) and calls the shell with the `-i` switch. This change is breaking in that `-i` previously could be used as short hand to match `-InputFormat`, which now needs to be `-in`.

Custom snap-ins

[PowerShell snap-ins](#) are a predecessor to PowerShell modules that do not have widespread adoption in the PowerShell community.

Due to the complexity of supporting snap-ins and their lack of usage in the community, we no longer support custom snap-ins in PowerShell.

Experimental feature flags

PowerShell 6.2 enabled support for [Experimental Features](#). This allows PowerShell developers to deliver new features and get feedback before the design is complete. This way we avoid making breaking changes as the design evolves.

Use `Get-ExperimentalFeature` to get a list of available experimental features. You can enable or disable these features with `Enable-ExperimentalFeature` and `Disable-ExperimentalFeature`.

Load assembly from module base path before trying to load from the GAC

Previously, when a binary module has the module assembly in GAC, we loaded the assembly from GAC before trying to load it from module base path.

Skip null-element check for collections with a value-type element type

For the `Mandatory` parameter and `ValidateNotNull` and `ValidateNotNullOrEmpty` attributes, skip the null-element check if the collection's element type is value type.

Preserve `$?` for ParenExpression, SubExpression and ArrayExpression

This PR alters the way we compile subpipelines `(...)`, subexpressions `$(...)` and array expressions `@()` so that `$?` is not automatically `true`. Instead the value of `$?` depends on the result of the pipeline or statements executed.

Fix `$?` to not be `$false` when native command writes to `stderr`

`$?` is not set to `$false` when native command writes to `stderr`. It is common for native commands to write to `stderr` without intending to indicate a failure. `$?` is set to `$false` only when the native command has a non-zero exit code.

Make `$ErrorActionPreference` not affect `stderr` output of native commands

It is common for native commands to write to `stderr` without intending to indicate a failure. With this change, `stderr` output is still captured in `ErrorRecord` objects, but the runtime no longer applies `$ErrorActionPreference` if the `ErrorRecord` comes from a native command.

Change `$OutputEncoding` to use `UTF-8 NoBOM` encoding rather than ASCII

The previous encoding, ASCII (7-bit), would result in incorrect alteration of the output in some cases. Making `UTF-8 NoBOM` the default preserves Unicode output with an encoding supported by most tools and operating systems.

Unify cmdlets with parameter `-Encoding` to be of type `System.Text.Encoding`

The `-Encoding` value `Byte` has been removed from the `FileSystem` provider cmdlets. A new parameter, `-AsByteStream`, is now used to specify that a byte stream is required as input or that the output is a stream of bytes.

Change `New-ModuleManifest` encoding to `UTF8NoBOM` on non-Windows platforms

Previously, `New-ModuleManifest` creates `psd1` manifests in UTF-16 with BOM, creating a problem for Linux tools. This breaking change changes the encoding of `New-ModuleManifest` to be UTF (no BOM) in non-Windows platforms.

Remove `AllScope` from most default aliases

To speed up scope creation, `AllScope` was removed from most default aliases. `AllScope` was left for a few frequently used aliases where the lookup was faster.

`-Verbose` and `-Debug` no longer overrides `$ErrorActionPreference`

Previously, if `-Verbose` or `-Debug` were specified, it overrode the behavior of `$ErrorActionPreference`. With this change, `-Verbose` and `-Debug` no longer affect the behavior of `$ErrorActionPreference`.

Also, the `-Debug` parameter sets `$DebugPreference` to **Continue** instead of **Inquire**.

Make `$PSCulture` consistently reflect in-session culture changes

In Windows PowerShell, the current culture value is cached, which can allow the value to get out of sync with the culture is change after session-startup. This caching behavior is fixed in PowerShell core.

Allow explicitly specified named parameter to supersede the same one from hashtable splatting

With this change, the named parameters from splatting are moved to the end of the parameter list so that they are bound after all explicitly specified named parameters are bound. Parameter binding for simple functions doesn't throw an error when a specified named parameter cannot be found. Unknown named parameters are bound to the `$args` parameter of the simple function. Moving splatting to the end of the argument list changes the order the parameters appears in `$args`.

For example:

```
PowerShell

function SimpleTest {
    param(
        $Name,
        $Path
    )
    "Name: $Name; Path: $Path; Args: $args"
}
```

In the previous behavior, **MyPath** is not bound to `-Path` because it's the third argument in the argument list. ## So it ends up being stuffed into '\$args' along with `Blah = "World"`

```
PowerShell

PS> $hash = @{ Name = "Hello"; Blah = "World" }
PS> SimpleTest @hash "MyPath"
```

```
Name: Hello; Path: ; Args: -Blah: World MyPath
```

With this change, the arguments from `@hash` are moved to the end of the argument list. **MyPath** becomes the first argument in the list, so it is bound to `-Path`.

PowerShell

```
PS> SimpleTest @hash "MyPath"
Name: Hello; Path: MyPath; Args: -Blah: World
```

Language changes

Null-coalescing operator `??`

The null-coalescing operator `??` returns the value of its left-hand operand if it isn't null. Otherwise, it evaluates the right-hand operand and returns its result. The `??` operator doesn't evaluate its right-hand operand if the left-hand operand evaluates to non-null.

PowerShell

```
$x = $null
$x ?? 100
```

Output

```
100
```

In the following example, the right-hand operand won't be evaluated.

PowerShell

```
[string] $todaysDate = '1/10/2020'
$todaysDate ?? (Get-Date).ToString()
```

Output

```
1/10/2020
```

Null-coalescing assignment operator `??=`

The null-coalescing assignment operator `??=` assigns the value of its right-hand operand to its left-hand operand only if the left-hand operand evaluates to null. The `??` operator doesn't evaluate its right-hand operand if the left-hand operand evaluates to non-null.

PowerShell

```
$x = $null  
$x ??= 100  
$x
```

Output

```
100
```

In the following example, the right-hand operand won't be evaluated.

PowerShell

```
[string] $todaysDate = '1/10/2020'  
$todaysDate ??= (Get-Date).ToShortDateString()
```

Output

```
1/10/2020
```

Null-conditional operators

ⓘ Note

This feature was moved from experimental to mainstream in PowerShell 7.1.

A null-conditional operator applies a member access, `?.`, or element access, `?[]`, operation to its operand only if that operand evaluates to non-null; otherwise, it returns null.

Since PowerShell allows `?` to be part of the variable name, formal specification of the variable name is required for using these operators. So it is required to use `{}` around the variable names like `${a}` or when `?` is part of the variable name `${a?}`.

In the following example, the value of `PropName` is returned.

PowerShell

```
$a = @{ PropName = 100 }
${a}?.PropName
```

Output

```
100
```

The following example will return null, without trying to access the member name **PropName**.

PowerShell

```
$a = $null
${a}?.PropName
```

Similarly, the value of the element will be returned.

PowerShell

```
$a = 1..10
${a}?[0]
```

Output

```
1
```

And when the operand is null, the element isn't accessed and null is returned.

PowerShell

```
$a = $null
${a}?[0]
```

ⓘ Note

The variable name syntax of `${<name>}` should not be confused with the `$()` subexpression operator. For more information, see Variable name section of [about_Variables](#).

Added & operator for job control

Putting & at the end of a pipeline causes the pipeline to be run as a PowerShell job. When a pipeline is backgrounded, a job object is returned. Once the pipeline is running as a job, all of the standard `*-Job` cmdlets can be used to manage the job. Variables (ignoring process-specific variables) used in the pipeline are automatically copied to the job so `Copy-Item $foo $bar &` just works. The job is also run in the current directory instead of the user's home directory.

New methods/properties on `PSCustomObject`

We've added new methods and properties to `PSCustomObject`. `PSCustomObject` now includes a `Count / Length` property like other objects.

PowerShell

```
$PSCustomObject = [pscUSTOMOBJECT]@{foo = 1}  
$PSCustomObject.Length
```

Output

```
1
```

PowerShell

```
$PSCustomObject.Count
```

Output

```
1
```

This work also includes `ForEach` and `Where` methods that allow you to operate and filter on `PSCustomObject` items:

PowerShell

```
$PSCustomObject.ForEach({$_.foo + 1})
```

Output

PowerShell

```
$PSCustomObject.Where({$_.foo -gt 0})
```

Output

```
foo
---
1
```

Conversions from PSMethod to Delegate

You can convert a `PSMethod` into a delegate. This allows you to do things like passing `PSMethod [M]::DoubleStrLen` as a delegate value into `[M]::AggregateString`:

PowerShell

```
class M {
    static [int] DoubleStrLen([string] $value) { return 2 * $value.Length }

    static [long] AggregateString([string[]] $values, [Func[string, int]] $selector) {
        [long] $res = 0
        foreach($s in $values){
            $res += $selector.Invoke($s)
        }
        return $res
    }
}

[M]::AggregateString((gci).Name, [M]::DoubleStrLen)
```

String comparison behavior changed in PowerShell 7.1

PowerShell 7.1 is built on .NET 5.0, which introduced the following breaking change:

- [Behavior changes when comparing strings on .NET 5+](#)

As of .NET 5.0, culture invariant string comparisons ignore non-printing control characters.

For example, the following two strings are considered to be identical:

PowerShell

```
# Escape sequence ``a`` is Ctrl-G or [char]7
'Food' -eq "Foo`ad"
```

Output

```
True
```

New cmdlets

New Get-Uptime cmdlet

The [Get-Uptime](#) cmdlet returns the time elapsed since the last boot of the operating system. The cmdlet was introduced in PowerShell 6.0.

New Remove-Alias cmdlet

The [Remove-Alias](#) cmdlet removes an alias from the current PowerShell session. The cmdlet was introduced in PowerShell 6.0.

New cmdlet Remove-Service

The [Remove-Service](#) cmdlet removes a Windows service in the registry and in the service database. The [Remove-Service](#) cmdlet was introduced in PowerShell 6.0.

New Markdown cmdlets

Markdown is a standard for creating readable plaintext documents with basic formatting that can be rendered into HTML.

The following cmdlets were added in PowerShell 6.1:

- [ConvertFrom-Markdown](#) - Convert the contents of a string or a file to a `MarkdownInfo` object.
- [Get-MarkdownOption](#) - Returns the current colors and styles used for rendering Markdown content in the console.
- [Set-MarkdownOption](#) - Sets the colors and styles used for rendering Markdown content in the console.
- [Show-Markdown](#) - Displays Markdown content in the console or as HTML

New Test-Json cmdlet

The [Test-Json](#) cmdlet tests whether a string is a valid JavaScript Object Notation (JSON) document and can optionally verify that JSON document against a provided schema.

This cmdlet was introduced in PowerShell 6.1

New cmdlets to support Experimental Features

The following cmdlets were added in PowerShell 6.2 to support Experimental Features.

- [Disable-ExperimentalFeature](#)
- [Enable-ExperimentalFeature](#)
- [Get-ExperimentalFeature](#)

New Join-String cmdlet

The [Join-String](#) cmdlet combines objects from the pipeline into a single string. This cmdlet was added in PowerShell 6.2.

New view ConciseView and cmdlet Get-Error

PowerShell 7.0 enhances the display of error messages to improve the readability of interactive and script errors with a new default view, **ConciseView**. The views are user-selectable through the preference variable `$ErrorView`.

With **ConciseView**, if an error is not from a script or parser error, then it's a single line error message:

```
PowerShell
Get-ChildItem -Path C:\NotReal
Output
Get-ChildItem: Cannot find path 'C:\NotReal' because it does not exist
```

If the error occurs during script execution or is a parsing error, PowerShell returns a multiline error message that contains the error, a pointer, and an error message showing where the error is in that line. If the terminal doesn't support ANSI color escape sequences (VT100), then colors are not displayed.

The default view in PowerShell 7 is **ConciseView**. The previous default view was **NormalView** and you can select this by setting the preference variable `$ErrorView`.

```
PowerShell
```

```
$ErrorView = 'NormalView' # Sets the error view to NormalView  
$ErrorView = 'ConciseView' # Sets the error view to ConciseView
```

ⓘ Note

A new property **ErrorAccentColor** is added to `$Host.PrivateData` to support changing the accent color of the error message.

The new `Get-Error` cmdlet provides a complete detailed view of the fully qualified error when desired. By default the cmdlet displays the full details, including inner exceptions, of the last error that occurred.

The `Get-Error` cmdlet supports input from the pipeline using the built-in variable `$Error`. `Get-Error` displays all piped errors.

```
PowerShell
```

```
$Error | Get-Error
```

The `Get-Error` cmdlet supports the **Newest** parameter, allowing you to specify how many errors from the current session you wish displayed.

```
PowerShell
```

```
Get-Error -Newest 3 # Displays the 1st three errors that occurred in the session
```

For more information, see [Get-Error](#).

Cmdlet changes

Parallel execution added to `ForEach-Object`

Beginning in PowerShell 7.0, the `ForEach-Object` cmdlet, which iterates items in a collection, now has built-in parallelism with the new **Parallel** parameter.

By default, parallel script blocks use the current working directory of the caller that started the parallel tasks.

This example retrieves 50,000 log entries from 5 system logs on a local Windows machine:

```
PowerShell

$logNames = 'Security','Application','System','Windows
PowerShell','Microsoft-Windows-Store/Operational'

$logEntries = $logNames | ForEach-Object -Parallel {
    Get-WinEvent -LogName $_ -MaxEvents 10000
} -ThrottleLimit 5

$logEntries.Count

50000
```

The **Parallel** parameter specifies the script block that is run in parallel for each input log name.

The new **ThrottleLimit** parameter limits the number of script blocks running in parallel at a given time. The default is 5.

Use the `$_` variable to represent the current input object in the script block. Use the `Using:` scope modifier to pass variable references to the running script block.

For more information, see [ForEach-Object](#).

Check `system32` for compatible built-in modules on Windows

In the Windows 10 1809 update and Windows Server 2019, we updated a number of built-in PowerShell modules to mark them as compatible with PowerShell.

When PowerShell starts up, it automatically includes `$windir\System32` as part of the `PSModulePath` environment variable. However, it only exposes modules to `Get-Module` and `Import-Module` if its `CompatiblePSEdition` is marked as compatible with `Core`.

You can override this behavior to show all modules using the `-SkipEditionCheck` switch parameter. We've also added a `PSEdition` property to the table output.

-1p alias for all `-LiteralPath` parameters

We created a standard parameter alias `-1p` for all the built-in PowerShell cmdlets that have a `-LiteralPath` parameter.

Fix `Get-Item -LiteralPath a*b` if `a*b` doesn't actually exist to return error

Previously, `-LiteralPath` given a wildcard would treat it the same as `-Path` and if the wildcard found no files, it would silently exit. Correct behavior should be that `-LiteralPath` is literal so if the file doesn't exist, it should error. Change is to treat wildcards used with `-Literal` as literal.

Set working directory to current directory in `Start-Job`

The `Start-Job` cmdlet now uses the current directory as the working directory for the new job.

Remove `-Protocol` from `*-Computer` cmdlets

Due to issues with RPC remoting in CoreFX (particularly on non-Windows platforms) and ensuring a consistent remoting experience in PowerShell, the `-Protocol` parameter was removed from the `*-Computer` cmdlets. DCOM is no longer supported for remoting.

The following cmdlets only support WSMAN remoting:

- `Rename-Computer`
- `Restart-Computer`
- `Stop-Computer`

Remove `-ComputerName` from `*-Service` cmdlets

In order to encourage the consistent use of PSRP, the `-ComputerName` parameter was removed from `*-Service` cmdlets.

Fix `Get-Content -Delimiter` to not include the delimiter in the returned lines

Previously, the output while using `Get-Content -Delimiter` was inconsistent and inconvenient as it required further processing of the data to remove the delimiter. This change removes the delimiter in returned lines.

Changes to `Format-Hex`

The `-Raw` parameter is now a "no-op" (in that it does nothing). Going forward all output is displayed with a true representation of numbers that includes all of the bytes for its type. This is what the `-Raw` parameter was doing prior to this change.

Typo fix in `Get-ComputerInfo` property name

`BiosSerialNumber` was misspelled as `BiosSeralNumber` and has been changed to the correct spelling.

Add `Get-StringHash` and `Get-FileHash` cmdlets

This change is that some hash algorithms are not supported by CoreFX, therefore they are no longer available:

- `MACTripleDES`
- `RIPEMD160`

Add validation on `Get-*` cmdlets where passing `$null` returns all objects instead of error

Passing `$null` to any of the following now throws an error:

- `Get-Credential -UserName`
- `Get-Event -SourceIdentifier`
- `Get-EventSubscriber -SourceIdentifier`
- `Get-Help -Name`
- `Get-PSBreakpoint -Script`
- `Get-PSPowerShellProvider -PSProvider`
- `Get-PSSessionConfiguration -Name`
- `Get-Runspace -Name`
- `Get-RunspaceDebug -RunspaceName`
- `Get-Service -Name`
- `Get-TraceSource -Name`
- `Get-Variable -Name`

Add support for the W3C Extended Log File Format in `Import-Csv`

Previously, the `Import-Csv` cmdlet cannot be used to directly import the log files in W3C extended log format and additional action would be required. With this change, W3C extended log format is supported.

`Import-Csv` applies `pstypenames` upon import when type information is present in the CSV

Previously, objects exported using `Export-Csv` with `TypeInformation` imported with `ConvertFrom-Csv` were not retaining the type information. This change adds the type information to `pstypenames` member if available from the CSV file.

-NoTypeInformation is the default on `Export-Csv`

Previously, the `Export-Csv` cmdlet would output a comment as the first line containing the type name of the object. The change excludes the type information by default because it's not understood by most CSV tools. This change was made to address customer feedback.

Use `-IncludeTypeInformation` to retain the previous behavior.

Allow `*` to be used in registry path for `Remove-Item`

Previously, `-LiteralPath` given a wildcard would treat it the same as `-Path` and if the wildcard found no files, it would silently exit. Correct behavior should be that `-LiteralPath` is literal so if the file doesn't exist, it should error. Change is to treat wildcards used with `-Literal` as literal.

Group-Object now sorts the groups

As part of the performance improvement, `Group-Object` now returns a sorted listing of the groups. Although you should not rely on the order, you could be broken by this change if you wanted the first group. We decided that this performance improvement was worth the change since the impact of being dependent on previous behavior is low.

Standard deviation in `Measure-Object`

The output from `Measure-Object` now includes a `StandardDeviation` property.

```
Get-Process | Measure-Object -Property CPU -AllStats
```

Output

```
Count          : 308
Average       : 31.3720576298701
Sum           : 9662.59375
Maximum       : 4416.046875
Minimum       :
StandardDeviation : 264.389544720926
Property      : CPU
```

Get-PfxCertificate -Password

`Get-PfxCertificate` now has the `Password` parameter, which takes a `SecureString`. This allows you to use it non-interactively:

PowerShell

```
$certFile = '\\server\share\pwd-protected.pfx'
$certPass = Read-Host -AsSecureString -Prompt 'Enter the password for
certificate: '

$certThumbPrint = (Get-PfxCertificate -FilePath $certFile -Password
$certPass ).ThumbPrint
```

Removal of the `more` function

In the past, PowerShell shipped a function on Windows called `more` that wrapped `more.com`. That function has now been removed.

Also, the `help` function changed to use `more.com` on Windows, or the system's default pager specified by `$Env:PAGER` on non-Windows platforms.

`cd DriveName:` now returns users to the current working directory in that drive

Previously, using `Set-Location` or `cd` to return to a PSDrive sent users to the default location for that drive. Users are now sent to the last known current working directory for that session.

`cd -` returns to previous directory

PowerShell

```
C:\Windows\System32> cd C:\  
C:\> cd -  
C:\Windows\System32>
```

Or on Linux:

ShellSession

```
PS /etc> cd /usr/bin  
PS /usr/bin> cd -  
PS /etc>
```

Also, `cd` and `cd --` change to `$HOME`.

`Update-Help` as non-admin

By popular demand, `Update-Help` no longer needs to be run as an administrator.

`Update-Help` now defaults to saving help to a user-scoped folder.

`Where-Object -Not`

With the addition of `-Not` parameter to `Where-Object`, can filter an object at the pipeline for the non-existence of a property, or a null/empty property value.

For example, this command returns all services that don't have any dependent services defined:

PowerShell

```
Get-Service | Where-Object -Not DependentServices
```

Changes to Web Cmdlets

The underlying .NET API of the Web Cmdlets has been changed to `System.Net.Http.HttpClient`. This change provides many benefits. However, this change along with a lack of interoperability with Internet Explorer have resulted in several breaking changes within `Invoke-WebRequest` and `Invoke-RestMethod`.

- `Invoke-WebRequest` now supports basic HTML Parsing only. `Invoke-WebRequest` always returns a `BasicHtmlWebResponseObject` object. The `ParsedHtml` and `Forms` properties have been removed.
- `BasicHtmlWebResponseObject.Headers` values are now `String[]` instead of `String`.
- `BasicHtmlWebResponseObject.BaseResponse` is now a `System.Net.Http.HttpResponseMessage` object.
- The `Response` property on Web Cmdlet exceptions is now a `System.Net.Http.HttpResponseMessage` object.
- Strict RFC header parsing is now default for the `-Headers` and `-UserAgent` parameter. This can be bypassed with `-SkipHeaderValidation`.
- `file://` and `ftp://` URI schemes are no longer supported.
- `System.Net.ServicePointManager` settings are no longer honored.
- There is currently no certificate based authentication available on macOS.
- Use of `-Credential` over an `http://` URI will result in an error. Use an `https://` URI or supply the `-AllowUnencryptedAuthentication` parameter to suppress the error.
- `-MaximumRedirection` now produces a terminating error when redirection attempts exceed the provided limit instead of returning the results of the last redirection.
- In PowerShell 6.2, a change was made to default to UTF-8 encoding for JSON responses. When a charset is not supplied for a JSON response, the default encoding should be UTF-8 per RFC 8259.
- Default encoding set to UTF-8 for `application-json` responses
- Added `-SkipHeaderValidation` parameter to allow `Content-Type` headers that aren't standards-compliant
- Added `-Form` parameter to support simplified `multipart/form-data` support
- Compliant, case-insensitive handling of relation keys
- Added `-Resume` parameter for web cmdlets

Invoke-RestMethod returns useful info when no data is returned

When an API returns just `null`, `Invoke-RestMethod` was serializing this as the string `"null"` instead of `$null`. This change fixes the logic in `Invoke-RestMethod` to properly serialize a valid single value JSON `null` literal as `$null`.

Web Cmdlets warn when `-Credential` is sent over unencrypted connections

When using HTTP, content including passwords are sent as clear-text. This change is to not allow this by default and return an error if credentials are being passed insecurely. Users can bypass this by using the `-AllowUnencryptedAuthentication` switch.

Make `-OutFile` parameter in web cmdlets to work like `-LiteralPath`

Beginning in PowerShell 7.1, the `OutFile` parameter of the web cmdlets works like `LiteralPath` and does not process wildcards.

API changes

Remove `AddTypeCommandBase` class

The `AddTypeCommandBase` class was removed from `Add-Type` to improve performance. This class is only used by the `Add-Type` cmdlet and should not impact users.

Removed `VisualBasic` as a supported language in `Add-Type`

In the past, you could compile Visual Basic code using the `Add-Type` cmdlet. Visual Basic was rarely used with `Add-Type`. We removed this feature to reduce the size of PowerShell.

Removed `RunspaceConfiguration` support

Previously, when creating a PowerShell runspace programmatically using the API, you could use the legacy `RunspaceConfiguration` or the newer `InitialSessionState` classes. This change removed support for `RunspaceConfiguration` and only supports `InitialSessionState`.

`CommandInvocationIntrinsics.InvokeScript` bind arguments to `$input` instead of `$args`

An incorrect position of a parameter resulted in the args passed as input instead of as args.

Remove `ClrVersion` and `BuildVersion` properties from `$PSVersionTable`

The `ClrVersion` property of `$PSVersionTable` is not useful with CoreCLR. End users should not be using that value to determine compatibility.

The `BuildVersion` property was tied to the Windows build version, which is not available on non-Windows platforms. Use the `GitCommitId` property to retrieve the exact build version of PowerShell.

Implement Unicode escape parsing

`\u####` or `\u{####}` is converted to the corresponding Unicode character. To output a literal `\u`, escape the backtick: `\`u`.

Parameter binding problem with `ValueFromRemainingArguments` in PS functions

`ValueFromRemainingArguments` now returns the values as an array instead of a single value which itself is an array.

Cleaned up uses of `CommandTypes.Workflow` and `WorkflowInfoCleaned`

Clean up code related to the uses of `CommandTypes.Workflow` and `WorkflowInfo` in `System.Management.Automation`.

These minor breaking changes mainly affect help provider code.

- Change the public constructors of `WorkflowInfo` to internal. We don't support workflow anymore, so it makes sense to not allow people to create `Workflow` instances.
- Remove the type `System.Management.Automation.DebugSource` since it's only used for workflow debugging.
- Remove the overload of `SetParent` from the abstract class `Debugger` that is only used for workflow debugging.
- Remove the same overload of `SetParent` from the derived class `RemotingJobDebugger`.

Do not wrap return result in `PSObject` when converting a `ScriptBlock` to a delegate

When a `ScriptBlock` is converted to a delegate type to be used in C# context, wrapping the result in a `PSObject` brings unneeded troubles:

- When the value is converted to the delegate return type, the `PSObject` essentially gets unwrapped. So the `PSObject` is unneeded.
- When the delegate return type is `object`, it gets wrapped in a `PSObject` making it hard to work with in C# code.

After this change, the returned object is the underlying object.

Remoting Support

PowerShell Remoting (PSRP) using WinRM on Unix platforms requires NTLM/Negotiate or Basic Auth over HTTPS. PSRP on macOS only supports Basic Auth over HTTPS. Kerberos-based authentication is not supported for non-Windows platforms.

PowerShell also supports PowerShell Remoting (PSRP) over SSH on all platforms (Windows, macOS, and Linux). For more information, see [SSH remoting in PowerShell](#).

PowerShell Direct for Containers tries to use `pwsh` first

[PowerShell Direct](#) is a feature of PowerShell and Hyper-V that allows you to connect to a Hyper-V VM or Container without network connectivity or other remote management services.

In the past, PowerShell Direct connected using the built-in Windows PowerShell instance on the Container. Now, PowerShell Direct first attempts to connect using any available `pwsh.exe` on the `PATH` environment variable. If `pwsh.exe` isn't available, PowerShell Direct falls back to use `powershell.exe`.

`Enable-PSRemoting` now creates separate remoting endpoints for preview versions

`Enable-PSRemoting` now creates two remoting session configurations:

- One for the major version of PowerShell. For example, `PowerShell.6`. This endpoint that can be relied upon across minor version updates as the "system-wide" PowerShell 6 session configuration

- One version-specific session configuration, for example: `PowerShell.6.1.0`

This behavior is useful if you want to have multiple PowerShell 6 versions installed and accessible on the same machine.

Additionally, preview versions of PowerShell now get their own remoting session configurations after running the `Enable-PSRemoting` cmdlet:

```
PowerShell  
C:\WINDOWS\system32> Enable-PSRemoting
```

Your output may be different if you haven't set up WinRM before.

```
Output  
WinRM is already set up to receive requests on this computer.  
WinRM is already set up for remote management on this computer.
```

Then you can see separate PowerShell session configurations for the preview and stable builds of PowerShell 6, and for each specific version.

```
PowerShell  
Get-PSSessionConfiguration  
  
Output  
Name : PowerShell.6.2-preview.1  
PSVersion : 6.2  
StartupScript :  
RunAsUser :  
Permission : NT AUTHORITY\INTERACTIVE AccessAllowed,  
BUILTIN\Administrators AccessAllowed, BUILTIN\Remote Management Users  
AccessAllowed  
  
Name : PowerShell.6-preview  
PSVersion : 6.2  
StartupScript :  
RunAsUser :  
Permission : NT AUTHORITY\INTERACTIVE AccessAllowed,  
BUILTIN\Administrators AccessAllowed, BUILTIN\Remote Management Users  
AccessAllowed  
  
Name : powershell.6  
PSVersion : 6.1  
StartupScript :  
RunAsUser :
```

```
Permission      : NT AUTHORITY\INTERACTIVE AccessAllowed,  
BUILTIN\Administrators AccessAllowed, BUILTIN\Remote Management Users  
AccessAllowed  
  
Name          : powershell.6.1.0  
PSVersion     : 6.1  
StartupScript :  
RunAsUser     :  
Permission    : NT AUTHORITY\INTERACTIVE AccessAllowed,  
BUILTIN\Administrators AccessAllowed, BUILTIN\Remote Management Users  
AccessAllowed
```

`user@host:port` syntax supported for SSH

SSH clients typically support a connection string in the format `user@host:port`. With the addition of SSH as a protocol for PowerShell Remoting, we've added support for this format of connection string:

```
Enter-PSSession -HostName fooUser@ssh.contoso.com:2222
```

Telemetry can only be disabled with an environment variable

PowerShell sends basic telemetry data to Microsoft when it is launched. The data includes the OS name, OS version, and PowerShell version. This data allows us to better understand the environments where PowerShell is used and enables us to prioritize new features and fixes.

To opt-out of this telemetry, set the environment variable `POWERSHELL_TELEMETRY_OPTOUT` to `true`, `yes`, or `1`. We no longer support deletion of the file

```
DELETE_ME_TO_DISABLE_CONSOLEHOST_TELEMETRY
```

 to disable telemetry.

PowerShell differences on non-Windows platforms

Article • 07/18/2024

PowerShell strives to provide feature parity across all supported platforms. However, some features behave differently or aren't available due to differences in .NET Core and platform-specific differences. Other changes were made to improve the interoperability of PowerShell on non-Windows platforms.

.NET Framework vs .NET Core

PowerShell on Linux and macOS uses .NET Core, a subset of the full .NET Framework on Microsoft Windows. As a result, scripts that run on Windows might not run on non-Windows platforms because of the differences in the frameworks.

For more information about changes in .NET Core, see [Breaking changes for migration from .NET Framework to .NET Core](#).

General Unix interoperability changes

- Added support for native command globbing on Unix platforms. This means you can use wildcards with native commands like `ls *.txt`.
- The `more` functionality respects the Linux `$PAGER` and defaults to `less`.
- Trailing backslash is automatically escaped when dealing with native command arguments.
- Fixed ConsoleHost to honor `NoEcho` on Unix platforms.
- Don't add `PATHEXT` environment variable on Unix.
- A `powershell` man-page is included in the package.

Execution policy

PowerShell ignores execution policies when running on non-Windows platforms. `Get-ExecutionPolicy` returns **Unrestricted** on Linux and macOS. `Set-ExecutionPolicy` does nothing on Linux and macOS.

Case-sensitivity in PowerShell

Historically, PowerShell has been uniformly case-insensitive, with few exceptions. On Unix-like operating systems, the file system is predominantly case-sensitive, and PowerShell adheres to the standard of the file system.

- You must use the correct case when a filename is specified in PowerShell.
- If a script tries to load a module and the module name isn't cased correctly, then the module load fails. This behavior might cause a problem with existing scripts if the name referenced by the module doesn't match the proper case of the actual filename.
- While names in the filesystem are case-sensitive, tab-completion of filenames isn't case-sensitive. Tab-completion cycles through the list of names using case-insensitive matching.
- `Get-Help` supports case-insensitive pattern matching on Unix platforms.
- `Import-Module` is case insensitive when used with a filename to determine the module name.

Filesystem support for Linux and macOS

- Paths given to cmdlets are now slash-agnostic (both `/` and `\` work as directory separators)
- XDG Base Directory Specification is now respected and used by default:
 - The Linux/macOS profile path is located at `~/.config/powershell/profile.ps1`
 - The history save path is located at
`~/.local/share/powershell/PSReadLine/ConsoleHost_history.txt`
 - The user module path is located at `~/.local/share/powershell/Modules`
- Support for file and folder names containing the colon character on Unix.
- Support for script names or full paths that have commas.
- Detect when the `LiteralPath` parameter is used to suppress wildcard expansion for navigation cmdlets.
- Updated `Get-ChildItem` to work more like the *nix `ls -R` and the Windows `DIR /S` native commands. `Get-ChildItem` now returns the symbolic links encountered during a recursive search and doesn't search the directories that those links target.

.PS1 File Extensions

PowerShell scripts must end in `.ps1` for the interpreter to understand how to load and run them in the current process. Running scripts in the current process is the expected usual behavior for PowerShell. You can add the `#!` magic number to a script that doesn't have a `.ps1` extension, but this causes the script to be run in a new PowerShell

instance, preventing the script from working correctly when interchanging objects. This behavior might be desirable when executing a PowerShell script from Bash or another shell.

Convenience aliases removed

PowerShell provides a set of aliases on Windows that map to Linux command names for user convenience. On Linux and macOS, the "convenience aliases" for the basic commands `ls`, `cp`, `mv`, `rm`, `cat`, `man`, `mount`, and `ps` were removed to allow the native executable to run without specifying a path.

Logging

On macOS, PowerShell uses the native `os_log` APIs to log to Apple's [unified logging system](#). On Linux, PowerShell uses [Syslog](#), a ubiquitous logging solution.

Job Control

There's no Unix-style job-control support in PowerShell on Linux or macOS. The `fg` and `bg` commands aren't available. However, you can use [PowerShell jobs](#) that work on all platforms.

Putting `&` at the end of a pipeline causes the pipeline to be run as a PowerShell job. When a pipeline is backgrounded, a job object is returned. Once the pipeline is running as a job, all `*-Job` cmdlets can be used to manage the job. Variables (ignoring process-specific variables) used in the pipeline are automatically copied to the job so `Copy-Item $foo $bar &` just works. The job runs in the current directory instead of the user's home directory.

Remoting Support

PowerShell Remoting (PSRP) using WinRM on Unix platforms requires NTLM/Negotiate or Basic Auth over HTTPS. PSRP on macOS only supports Basic Auth over HTTPS. Kerberos-based authentication isn't supported.

PowerShell supports PowerShell Remoting (PSRP) over SSH on all platforms (Windows, Linux, and macOS). For more information, see [SSH remoting in PowerShell](#).

Just-Enough-Administration (JEA) Support

PowerShell on Linux or macOS doesn't allow you to create constrained administration (JEA) remoting endpoints.

`sudo`, `exec`, and PowerShell

Because PowerShell runs most commands in memory (like Python or Ruby), you can't use `sudo` directly with PowerShell built-ins. You can run `pwsh` from `sudo`. If it's necessary to run a PowerShell cmdlet from within PowerShell with `sudo`, for example, `sudo Set-Date 8/18/2016`, then you would use `sudo pwsh Set-Date 8/18/2016`.

Modules included on non-Windows platforms

For non-Windows platforms, PowerShell includes the following modules:

- Microsoft.PowerShell.Archive
- Microsoft.PowerShell.Core
- Microsoft.PowerShell.Host
- Microsoft.PowerShell.Management
- Microsoft.PowerShell.Security
- Microsoft.PowerShell.Utility
- PackageManagement
- PowerShellGet
- PSReadLine
- ThreadJob

A large number of the commands (cmdlets) commonly available in PowerShell aren't available on Linux or macOS. Often, these commands don't apply to these platforms. For example, commands for Windows-specific features like the registry or services aren't available. Other commands, like `Set-ExecutionPolicy`, are present but not functional.

For a comprehensive list of modules and cmdlets and the platforms they support, see [Release history of modules and cmdlets](#).

Modules no longer shipped with PowerShell

For various compatibility reasons, the following modules are no longer included in PowerShell.

- ISE
- Microsoft.PowerShell.LocalAccounts
- Microsoft.PowerShell.ODataUtils

- Microsoft.PowerShell.Operation.Validation
- PSScheduledJob
- PSWorkflow
- PSWorkflowUtility

The following Windows-specific modules aren't included in PowerShell for Linux or macOS.

- CimCmdlets
- Microsoft.PowerShell.Diagnostics
- Microsoft.WSMan.Management
- PSDiagnostics

Cmdlets not available on non-Windows platforms

Some cmdlets were removed from PowerShell. Others aren't available or might work differently on non-Windows platforms. For a comprehensive list of cmdlets removed from PowerShell, see [Cmdlets removed from PowerShell](#).

Microsoft.PowerShell.Core

The following cmdlets aren't available on Linux or macOS:

- `Disable-PSRemoting`
- `Enable-PSRemoting`
- `Connect-PSSession`
- `Disconnect-PSSession`
- `Receive-PSSession`
- `Get-PSSessionCapability`
- `Disable-PSSessionConfiguration`
- `Enable-PSSessionConfiguration`
- `Get-PSSessionConfiguration`
- `Register-PSSessionConfiguration`
- `Set-PSSessionConfiguration`
- `Unregister-PSSessionConfiguration`
- `Test-PSSessionConfigurationFile`

The `ShowWindow` parameter of `Get-Help` isn't available for non-Windows platforms. PowerShell 7.3 added the `Switch-Process` cmdlet and the `exec` function for Linux and

macOS. These commands aren't available on Windows.

Microsoft.PowerShell.Security cmdlets

The following cmdlets aren't available on Linux or macOS:

- `Get-Acl`
- `Set-Acl`
- `Get-AuthenticodeSignature`
- `Set-AuthenticodeSignature`
- `New-FileCatalog`
- `Test-FileCatalog`

These cmdlets are only available beginning in PowerShell 7.1.

- `Get-CmsMessage`
- `Protect-CmsMessage`
- `Unprotect-CmsMessage`

Microsoft.PowerShell.Management cmdlets

The following cmdlets aren't available on Linux and macOS:

- `Rename-Computer`
- `Get-ComputerInfo`
- `Get-HotFix`
- `Clear-RecycleBin`
- `Get-Service`
- `New-Service`
- `Remove-Service`
- `Restart-Service`
- `Resume-Service`
- `Set-Service`
- `Start-Service`
- `Stop-Service`
- `Suspend-Service`
- `Set-TimeZone`

The following cmdlets are available with limitations:

- `Get-Clipboard` - available in PowerShell 7.0+

- `Set-Clipboard` - available in PowerShell 7.0+
- `Restart-Computer` - available for Linux and macOS in PowerShell 7.1+
- `Stop-Computer` - available for Linux and macOS in PowerShell 7.1+

Microsoft.PowerShell.Utility cmdlets

The following cmdlets aren't available on Linux and macOS:

- `Convert-String`
- `ConvertFrom-String`
- `ConvertFrom-SddlString`
- `Out-GridView`
- `Out-Printer`
- `Show-Command`

Aliases not available on Linux or macOS

The following table lists the aliases available for Windows that aren't available on non-Windows platforms. These aliases aren't available because the alias conflicts with a native command on those platforms.

[] Expand table

Alias	Cmdlet
<code>ac</code>	<code>Add-Content</code>
<code>cat</code>	<code>Get-Content</code>
<code>clear</code>	<code>Clear-Host</code>
<code>compare</code>	<code>Compare-Object</code>
<code>cp</code>	<code>Copy-Item</code>
<code>cpp</code>	<code>Copy-ItemProperty</code>
<code>diff</code>	<code>Compare-Object</code>
<code>kill</code>	<code>Stop-Process</code>
<code>ls</code>	<code>Get-ChildItem</code>
<code>man</code>	<code>help</code>

Alias	Cmdlet
mount	New-PSDrive
mv	Move-Item
ps	Get-Process
rm	Remove-Item
rmdir	Remove-Item
sleep	Start-Sleep
sort	Sort-Object
start	Start-Process
tee	Tee-Object
write	Write-Output

The table doesn't include aliases unavailable for cmdlets that don't exist on non-Windows platforms.

PowerShell Desired State Configuration (DSC)

Beginning with PowerShell 7.2, the `PSDesiredStateConfiguration` module was removed from PowerShell and is published in the PowerShell Gallery. For more information, see the [announcement](#) on the PowerShell Team blog. For more information about using DSC on Linux, see [Get started with DSC for Linux](#). DSC v1.1 and v2.x aren't supported on macOS. DSC v3 is supported on Windows, Linux, and macOS, but it's still in early development.

Release history of modules and cmdlets

Article • 01/17/2025

This article lists the modules and cmdlets that are included in various versions of PowerShell. This is a summary of information found in the release notes. More detailed information can be found in the release notes:

- [What's new in PowerShell 7.5](#)
- [What's new in PowerShell 7.4](#)
- [What's new in PowerShell 7.3](#)
- [What's new in PowerShell 7.2](#)
- [What's new in PowerShell 7.1](#)
- [What's new in PowerShell 7.0](#)

This is a work in progress. Please help us keep this information fresh.

PowerShell 7 module compatibility

Article • 06/28/2023

This article contains a partial list of PowerShell modules published by Microsoft.

The PowerShell team is working with the various feature teams that create PowerShell modules to help them produce modules that work in PowerShell 7. These modules are not owned by the PowerShell team.

The following modules are known to support PowerShell 7.

Azure PowerShell

The Az PowerShell module is a set of cmdlets for managing Azure resources directly from PowerShell. PowerShell 7.0.6 LTS or higher is the recommended version of PowerShell for use with the Azure Az PowerShell module on all platforms.

For more information, see [Introducing the Azure Az PowerShell module](#).

MSGraph PowerShell SDK

The Microsoft Graph SDKs are designed to simplify building high-quality, efficient, and resilient applications that access Microsoft Graph. PowerShell 7 and later is the recommended PowerShell version for use with the Microsoft Graph PowerShell SDK.

For more information, see [Install the Microsoft Graph PowerShell SDK](#).

Windows management modules

The Windows management modules provide management and support for various Windows features and services. Most of these modules have been updated to work natively with PowerShell 7, or tested for compatibility with PowerShell 7.

These modules are installed in different ways depending on the Edition of Windows, and how the module is packaged for that Edition.

For more information about installation and compatibility, see [PowerShell 7 module compatibility](#) in the Windows documentation.

Exchange Online Management 2.0

The Exchange Online PowerShell V2 module (EXO V2) connects to all Exchange-related PowerShell environments in Microsoft 365: Exchange Online PowerShell, Security & Compliance PowerShell, and standalone Exchange Online Protection (EOP) PowerShell.

EXO v2.0.4 or later is supported in PowerShell 7.0.3 or later.

For more information, see [About the Exchange Online PowerShell V2 module](#).

PowerShell modules for SQL Server

There are two SQL Server PowerShell modules:

- **SqlServer:** This module includes new cmdlets to support the latest SQL features, including updated versions of the cmdlets in SQLPS.
- **SQLPS:** The SQLPS is the module used by SQL Agent to run agent jobs in agent job steps using the PowerShell subsystem.

The SqlServer modules require PowerShell version 5.0 or greater.

For more information, see [Install the SQL Server PowerShell module](#).

Finding the status of other modules

You can find a complete list of modules using the [PowerShell Module Browser](#). Using the Module Browser, you can find documentation for other PowerShell modules to determine their PowerShell version requirements.

Collaborate with us on GitHub

The source for this content can be found on GitHub, where you can also create and review issues and pull requests. For more information, see [our contributor guide](#).

PowerShell feedback

PowerShell is an open source project. Select a link to provide feedback:

The Windows PowerShell ISE

Article • 03/27/2025

The Windows PowerShell Integrated Scripting Environment (ISE) is a host application for Windows PowerShell. In the ISE, you can run commands and write, test, and debug scripts in a single Windows-based graphic user interface. The ISE provides multiline editing, tab completion, syntax coloring, selective execution, context-sensitive help, and support for right-to-left languages. Menu items and keyboard shortcuts are mapped to many of the same tasks that you would do in the Windows PowerShell console. For example, when you debug a script in the ISE, you can right-click on a line of code in the edit pane to set a breakpoint.

Support

The ISE was first introduced with Windows PowerShell V2 and was re-designed with PowerShell V3. The ISE is supported in all supported versions of Windows PowerShell up to and including Windows PowerShell V5.1.

Note

The PowerShell ISE is no longer in active feature development. As a shipping component of Windows, it continues to be officially supported for security and high-priority servicing fixes. We currently have no plans to remove the ISE from Windows.

There is no support for the ISE in PowerShell v6 and beyond. Users looking for replacement for the ISE should use [Visual Studio Code](#) with the [PowerShell Extension](#).

Key Features

Key features in Windows PowerShell ISE include:

- Multiline editing: To insert a blank line under the current line in the Command pane, press **SHIFT + ENTER**.
- Selective execution: To run part of a script, select the text you want to run, and then click the **Run Script** button. Or, press **F5**.
- Context-sensitive help: Type **Invoke-Item**, and then press **F1**. The Help file opens to the article for the **Invoke-Item** cmdlet.

The Windows PowerShell ISE lets you customize some aspects of its appearance. It also has its own Windows PowerShell profile script.

To start the Windows PowerShell ISE

Click **Start**, select **Windows PowerShell**, and then click **Windows PowerShell ISE**.

Alternately, you can type `powershell_ise.exe` in any command shell or in the Run box.

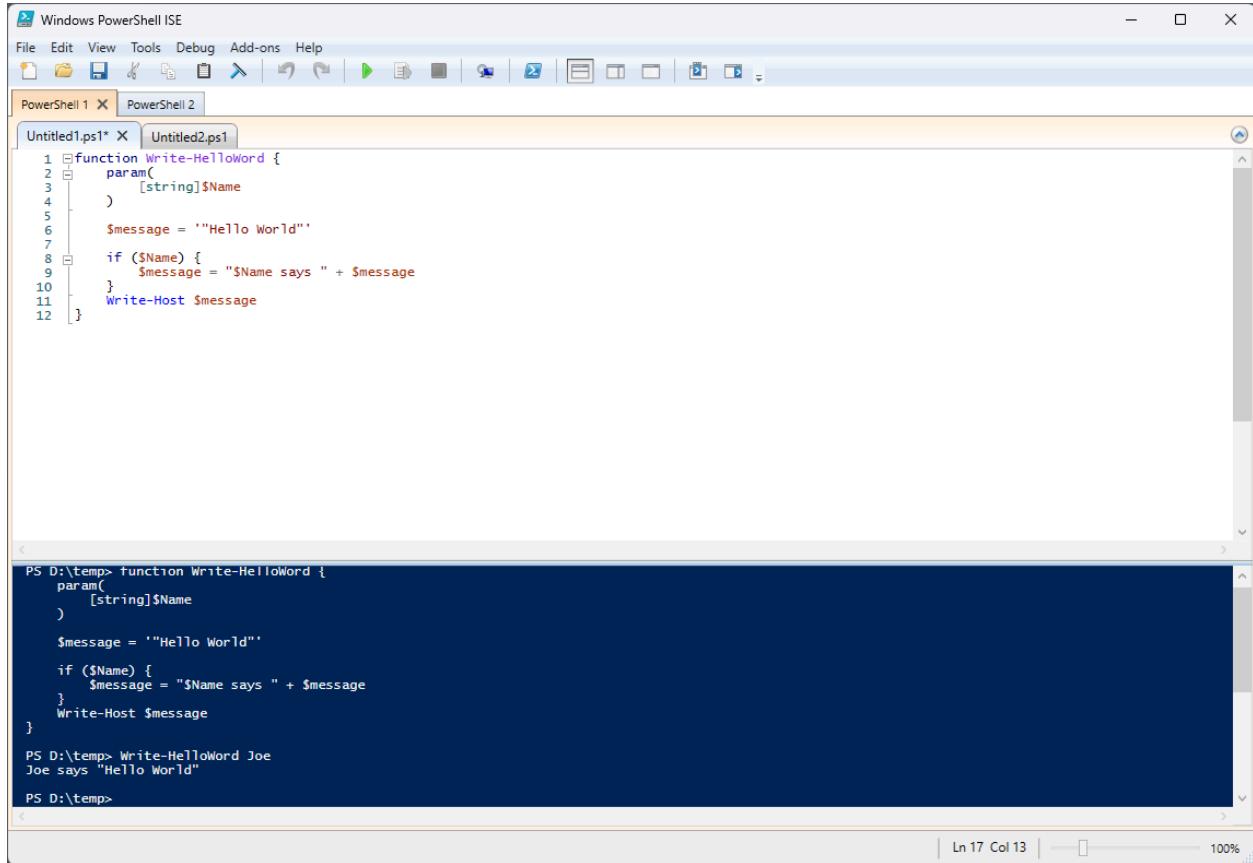

To get Help in the Windows PowerShell ISE

On the **Help** menu, click **Windows PowerShell Help**. Or, press `F1`. The file that opens describes Windows PowerShell ISE and Windows PowerShell, including all the help available from the `Get-Help` cmdlet.

Exploring the Windows PowerShell ISE

Article • 03/27/2025

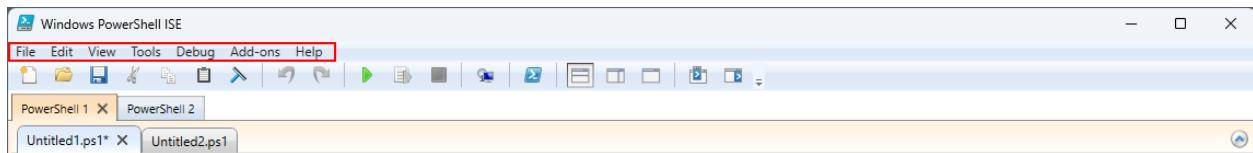

You can use the Windows PowerShell Integrated Scripting Environment (ISE) to create, run, and debug commands and scripts.

The Windows PowerShell ISE consists of the menu bar, Windows PowerShell tabs, the toolbar, script tabs, a Script Pane, a Console Pane, a status bar, a text-size slider and context-sensitive Help.

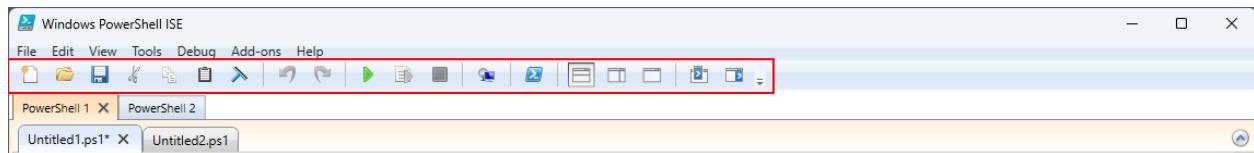

Menu Bar

The menu bar contains the **File**, **Edit**, **View**, **Tools**, **Debug**, **Add-ons**, and **Help** menus.

The buttons on the menus allow you to perform tasks related to writing and running scripts and running commands in the Windows PowerShell ISE. Additionally, an [add-on tool](#) may be placed on the menu bar by running scripts that use the [The ISE Object Model Hierarchy](#).

Toolbar

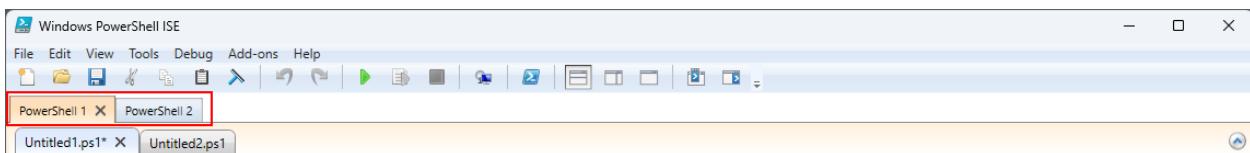

The following buttons are located on the toolbar.

[\[+\] Expand table](#)

Button	Function
New	Opens a new script.
Open	Opens an existing script or file.
Save	Saves a script or file.
Cut	Cuts the selected text and copies it to the clipboard.
Copy	Copies the selected text to the clipboard.
Paste	Pastes the contents of the clipboard at the cursor location.
Clear Console Pane	Clears all content in the Console Pane.
Undo	Reverses the action that was just performed.
Redo	Performs the action that was just undone.
Run Script	Runs a script.
Run Selection	Runs a selected portion of a script.
Stop Operation	Stops a script that's running.
New Remote PowerShell Tab	Creates a new PowerShell Tab that establishes a session on a remote computer. A dialog box appears and prompts you to enter details required to establish the remote connection.
Start powershell.exe	Opens a PowerShell Console.
Show Script Pane Top	Moves the Script Pane to the top in the display.
Show Script Pane Right	Moves the Script Pane to the right in the display.
Show Script Pane	Maximizes the Script Pane.

Button	Function
Maximized	
Show Command Window	Shows the Commands Pane for installed Modules, as a separate Window.
Show Command Add-on	Shows the Commands Pane for installed Modules, as a sidebar Add-on.

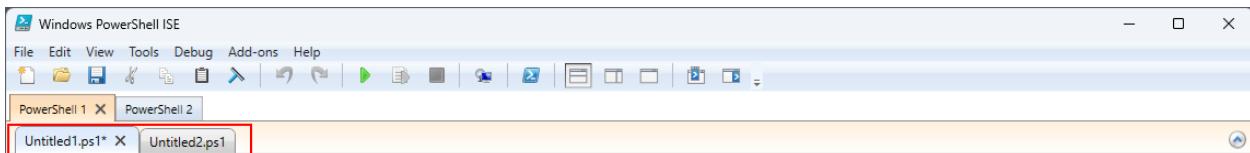

Windows PowerShell Tabs

A Windows PowerShell tab is the environment in which a Windows PowerShell script runs. You can open new Windows PowerShell tabs in the Windows PowerShell ISE to create separate environments on your local computer or on remote computers. You may have a maximum of eight PowerShell tabs simultaneously open.

For more information, see [How to Create a PowerShell Tab in Windows PowerShell ISE](#).

Script Tab

Displays the name of the script you are editing. You can click a script tab to select the script you want to edit.

When you point to the script tab, the fully qualified path to the script file appears in a tooltip.

Script Pane

Allows you to create and run scripts. You can open, edit and run existing scripts in the Script Pane. For more information, see [How to Write and Run Scripts in the Windows PowerShell ISE](#).

Console Pane

Displays the results of the commands and scripts you have run. You can run commands in the Console pane. You can also copy and clear the contents in the Console Pane.

For more information, see the following articles:

- [How to Use the Console Pane in the Windows PowerShell ISE](#)
- [How to Debug Scripts in Windows PowerShell ISE](#)
- [How to Use Tab Completion in the Script Pane and Console Pane](#)

Status Bar

Allows you to see whether the commands and scripts that you run are complete. The status bar is at the bottom of the window. Selected portions of error messages are displayed on the status bar.

Text-Size Slider

Increases or decreases the size of the text on the screen.

Help

Help for Windows PowerShell ISE is available on Microsoft Learn. You can open the Help by clicking **Windows PowerShell ISE Help** on the **Help** menu or by pressing the **F1** key anywhere except when the cursor is on a cmdlet name in either the Script Pane or the Console Pane. From the **Help** menu you can also run the `Update-Help` cmdlet, and display the Command Window, which assists you in constructing commands by showing you all the parameters for a cmdlet and enabling you to fill in the parameters in an easy-to-use form.

How to Create a PowerShell Tab in Windows PowerShell ISE

Article • 03/27/2025

Tabs in the Windows PowerShell Integrated Scripting Environment (ISE) allow you to simultaneously create and use several execution environments within the same application. Each PowerShell tab corresponds to a separate execution environment or session.

ⓘ Note

Variables, functions, and aliases that you create in one tab don't carry over to another. They are different Windows PowerShell sessions.

Use the following steps to open or close a tab in Windows PowerShell. To rename a tab, set the [DisplayName](#) property on the Windows PowerShell Tab scripting object.

To create and use a new PowerShell Tab

On the **File** menu, click **New PowerShell Tab**. The new PowerShell tab always opens as the active window. PowerShell tabs are incrementally numbered in the order that they're opened. Each tab is associated with its own Windows PowerShell console window. You can have up to 32 PowerShell tabs with their own session open at a time (this is limited to 8 on Windows PowerShell ISE 2.0.)

Note that clicking the **New** or **Open** icons on the toolbar doesn't create a new tab with a separate session. Instead, those buttons open a new or existing script file on the currently active tab with a session. You can have multiple script files open with each tab and session. The script tabs for a session only appear below the session tabs when the associated session is active.

To make a PowerShell tab active, click the tab. To select from all PowerShell tabs that are open, on the **View** menu, click the PowerShell tab you want to use.

To create and use a new Remote PowerShell tab

On the **File** menu, click **New Remote PowerShell Tab** to establish a session on a remote computer. A dialog box appears and prompts you to enter details required to establish the remote connection. The remote tab functions just like a local PowerShell tab, but the commands and scripts are run on the remote computer.

To close a PowerShell Tab

To close a tab, you can use any of the following techniques:

- Click the tab that you want to close.
- On the **File** menu, click **Close PowerShell Tab**, or click the Close button (X) on an active tab to close the tab.

If you have unsaved files open in the PowerShell tab that you are closing, you are prompted to save or discard them. For more information about how to save a script, see [How to Save a Script](#).

How to Debug Scripts in Windows PowerShell ISE

Article • 03/27/2025

This article describes how to debug scripts on a local computer by using the Windows PowerShell Integrated Scripting Environment (ISE) visual debugging features.

How to manage breakpoints

A breakpoint is a designated spot in a script where you would like operation to pause so that you can examine the current state of the variables and the environment in which your script is running. Once your script is paused by a breakpoint, you can run commands in the Console Pane to examine the state of your script. You can output variables or run other commands. You can even modify the value of any variables that are visible to the context of the currently running script. After you have examined what you want to see, you can resume operation of the script.

You can set three types of breakpoints in the Windows PowerShell debugging environment:

1. **Line breakpoint.** The script pauses when the designated line is reached during the operation of the script
2. **Variable breakpoint.** The script pauses whenever the designated variable's value changes.
3. **Command breakpoint.** The script pauses whenever the designated command is about to be run during the operation of the script. It can include parameters to further filter the breakpoint to only the operation you want. The command can also be a function you created.

Of these, in the Windows PowerShell ISE debugging environment, only line breakpoints can be set by using the menu or the keyboard shortcuts. The other two types of breakpoints can be set, but they are set from the Console Pane by using the [Set-PSBreakpoint](#) cmdlet. This section describes how you can perform debugging tasks in Windows PowerShell ISE by using the menus where available, and perform a wider range of commands from the Console Pane by using scripting.

To set a breakpoint

A breakpoint can be set in a script only after it has been saved. Right-click the line where you want to set a line breakpoint, and then click **Toggle Breakpoint**. Or, click the line where you want to set a line breakpoint, and press **F9** or, on the **Debug** menu, click **Toggle Breakpoint**.

The following script is an example of how you can set a variable breakpoint from the Console Pane by using the [Set-PSBreakpoint](#) cmdlet.

PowerShell

```
# This command sets a breakpoint on the Server variable in the Sample.ps1
# script.
Set-PSBreakpoint -Script sample.ps1 -Variable Server
```

List all breakpoints

Displays all breakpoints in the current Windows PowerShell session.

On the **Debug** menu, click **List Breakpoints**. The following script is an example of how you can list all breakpoints from the Console Pane by using the [Get-PSBreakpoint](#) cmdlet.

PowerShell

```
# This command lists all breakpoints in the current session.
Get-PSBreakpoint
```

Remove a breakpoint

Removing a breakpoint deletes it.

If you think you might want to use it again later, consider [Disable a Breakpoint](#) instead. Right-click the line where you want to remove a breakpoint, and then click **ToggleBreakpoint**. Or, click the line where you want to remove a breakpoint, and on the **Debug** menu, click **Toggle Breakpoint**. The following script is an example of how to remove a breakpoint with a specified ID from the Console Pane by using the [Remove-PSBreakpoint](#) cmdlet.

PowerShell

```
# This command deletes the breakpoint with breakpoint ID 2.
Remove-PSBreakpoint -Id 2
```

Remove All Breakpoints

To remove all breakpoints defined in the current session, on the **Debug** menu, click **Remove All Breakpoints**.

The following script is an example of how to remove all breakpoints from the Console Pane by using the [Remove-PSBreakpoint](#) cmdlet.

PowerShell

```
# This command deletes all of the breakpoints in the current session.  
Get-PSBreakpoint | Remove-PSBreakpoint
```

Disable a Breakpoint

Disabling a breakpoint doesn't remove it. It turns it off until it's enabled. To disable a specific line breakpoint, right-click the line where you want to disable a breakpoint, and then click **Disable Breakpoint**.

Or, click the line where you want to disable a breakpoint, and press **F9** or, on the **Debug** menu, click **Disable Breakpoint**. The following script is an example of how you can remove a breakpoint with a specified ID from the Console Pane using the [Disable-PSBreakpoint](#) cmdlet.

PowerShell

```
# This command disables the breakpoint with breakpoint ID 0.  
Disable-PSBreakpoint -Id 0
```

Disable All Breakpoints

Disabling a breakpoint doesn't remove it; it turns it off until it's enabled. To disable all breakpoints in the current session, on the **Debug** menu, click **Disable all Breakpoints**. The following script is an example of how you can disable all breakpoints from the Console Pane by using the [Disable-PSBreakpoint](#) cmdlet.

PowerShell

```
# This command disables all breakpoints in the current session.  
# You can abbreviate this command as: "gbp | dbp".  
Get-PSBreakpoint | Disable-PSBreakpoint
```

Enable a Breakpoint

To enable a specific breakpoint, right-click the line where you want to enable a breakpoint, and then click **Enable Breakpoint**. Or, click the line where you want to enable a breakpoint, and then press **F9** or, on the **Debug** menu, click **Enable Breakpoint**. The following script is an example of how you can enable specific breakpoints from the Console Pane by using the [Enable-PSBreakpoint](#) cmdlet.

PowerShell

```
# This command enables breakpoints with breakpoint IDs 0, 1, and 5.  
Enable-PSBreakpoint -Id 0, 1, 5
```

Enable All Breakpoints

To enable all breakpoints defined in the current session, on the **Debug** menu, click **Enable all Breakpoints**. The following script is an example of how you can enable all breakpoints from the Console Pane by using the [Enable-PSBreakpoint](#) cmdlet.

PowerShell

```
# This command enables all breakpoints in the current session.  
# You can abbreviate the command by using their aliases: "gbp | ebp".  
Get-PSBreakpoint | Enable-PSBreakpoint
```

How to manage a debugging session

Before you start debugging, you must set one or more breakpoints. You can't set a breakpoint unless the script that you want to debug is saved. For directions on how to set a breakpoint, see [How to manage breakpoints](#) or [Set-PSBreakpoint](#). After you start debugging, you can't edit a script until you stop debugging. A script that has one or more breakpoints set is automatically saved before it's run.

To start debugging

Press **F5** or, on the toolbar, click the **Run Script** icon, or on the **Debug** menu click **Run/Continue**. The script runs until it encounters the first breakpoint. It pauses operation there and highlights the line on which it paused.

To continue debugging

Press **F5** or, on the toolbar, click the **Run Script** icon, or on the **Debug** menu, click **Run/Continue** or, in the **Console Pane**, type **C** and then press **ENTER**. This causes the script to continue running to the next breakpoint or to the end of the script if no further breakpoints are encountered.

To view the call stack

The call stack displays the current run location in the script. If the script is running in a function that was called by a different function, then that's represented in the display by additional rows in the output. The bottom-most row displays the original script and the line in it in which a function was called. The next line up shows that function and the line in it in which another function might have been called. The top-most row shows the current context of the current line on which the breakpoint is set.

While paused, to see the current call stack, press **CTRL + SHIFT + D** or, on the **Debug** menu, click **Display Call Stack** or, in the **Console Pane**, type **K** and then press **ENTER**.

To stop debugging

Press **SHIFT + F5** or, on the **Debug** menu, click **Stop Debugger**, or, in the **Console Pane**, type **Q** and then press **ENTER**.

How to step over, step into, and step out while debugging

Stepping is the process of running one statement at a time. You can stop on a line of code, and examine the values of variables and the state of the system. The following table describes common debugging tasks such as stepping over, stepping into, and stepping out.

[+] Expand table

Debugging Task	Description	How to accomplish it in PowerShell ISE
Step Into	Executes the current statement and then stops at the next statement. If the current statement is a function or script call, then the debugger steps into that function or script, otherwise it stops at the next statement.	Press F11 or, on the Debug menu, click Step Into , or in the Console Pane , type S and press ENTER .

Debugging Task	Description	How to accomplish it in PowerShell ISE
Step Over	Executes the current statement and then stops at the next statement. If the current statement is a function or script call, then the debugger executes the whole function or script, and it stops at the next statement after the function call.	Press F10 or, on the Debug menu, click Step Over , or in the Console Pane , type V and press ENTER .
Step Out	Steps out of the current function and up one level if the function is nested. If in the main body, the script is executed to the end, or to the next breakpoint. The skipped statements are executed, but not stepped through.	Press SHIFT + F11 , or on the Debug menu, click Step Out , or in the Console Pane , type O and press ENTER .
Continue	Continues execution to the end, or to the next breakpoint. The skipped functions and invocations are executed, but not stepped through.	Press F5 or, on the Debug menu, click Run/Continue , or in the Console Pane , type C and press ENTER .

How to display the values of variables while debugging

You can display the current values of variables in the script as you step through the code.

To display the values of standard variables

Use one of the following methods:

- In the Script Pane, hover over the variable to display its value as a tool tip.
- In the Console Pane, type the variable name and press **ENTER**.

All panes in ISE are always in the same scope. Therefore, while you are debugging a script, the commands that you type in the Console Pane run in script scope. This allows you to use the Console Pane to find the values of variables and call functions that are defined only in the script.

To display the values of automatic variables

You can use the preceding method to display the value of almost all variables while you are debugging a script. However, these methods don't work for the following automatic

variables.

- `$_`
- `$input`
- `$MyInvocation`
- `$PSBoundParameters`
- `$args`

If you try to display the value of any of these variables, you get the value of that variable for in an internal pipeline the debugger uses, not the value of the variable in the script. You can work around this for a few variables (`$_`, `$input`, `$MyInvocation`, `$PSBoundParameters`, and `$args`) by using the following method:

1. In the script, assign the value of the automatic variable to a new variable.
2. Display the value of the new variable, either by hovering over the new variable in the Script Pane, or by typing the new variable in the Console Pane.

For example, to display the value of the `$MyInvocation` variable, in the script, assign the value to a new variable, such as `$scriptName`, and then hover over or type the `$scriptName` variable to display its value.

PowerShell

```
# In C:\ps-test\MyScript.ps1
$scriptName = $MyInvocation.PSCommandPath
```

PowerShell

```
# In the Console Pane:
.\MyScript.ps1
$scriptName
```

Output

```
C:\ps-test\MyScript.ps1
```

How to Use Profiles in Windows PowerShell ISE

Article • 03/27/2025

This article explains how to use Profiles in Windows PowerShell® Integrated Scripting Environment (ISE). We recommend that before performing the tasks in this section, you review [about_Profiles](#), or in the Console Pane, type, `Get-Help about_Profiles` and press `ENTER`.

A profile is a Windows PowerShell ISE script that runs automatically when you start a new session. You can create one or more Windows PowerShell profiles for Windows PowerShell ISE and use them to add the configure the Windows PowerShell or Windows PowerShell ISE environment, preparing it for your use, with variables, aliases, functions, and color and font preferences that you want available. A profile affects every Windows PowerShell ISE session that you start.

ⓘ Note

The Windows PowerShell execution policy determines whether you can run scripts and load a profile. The default execution policy, "Restricted," prevents all scripts from running, including profiles. If you use the "Restricted" policy, the profile can't load. For more information about execution policy, see [about_Execution_Policies](#).

Selecting a profile to use in the Windows PowerShell ISE

Windows PowerShell ISE supports profiles for the current user and all users. It also supports the Windows PowerShell profiles that apply to all hosts.

The profile that you use is determined by how you use Windows PowerShell and Windows PowerShell ISE.

- If you use only Windows PowerShell ISE to run Windows PowerShell, then save all your items in one of the ISE-specific profiles, such as the **CurrentUserCurrentHost** profile for Windows PowerShell ISE or the **AllUsersCurrentHost** profile for Windows PowerShell ISE.
- If you use multiple host programs to run Windows PowerShell, save your functions, aliases, variables, and commands in a profile that affects all host programs, such as

the `CurrentUserAllHosts` or the `AllUsersAllHosts` profile, and save ISE-specific features, like color and font customization in the `CurrentUserCurrentHost` profile for Windows PowerShell ISE profile or the `AllUsersCurrentHost` profile for Windows PowerShell ISE.

The following are profiles that can be created and used in Windows PowerShell ISE. Each profile is saved to its own specific path.

[+] Expand table

Profile Type	Profile Path
Current user, PowerShell ISE	<code>\$PROFILE.CurrentUserCurrentHost</code> , Or <code>\$PROFILE</code>
All users, PowerShell ISE	<code>\$PROFILE.AllUsersCurrentHost</code>
Current user, All hosts	<code>\$PROFILE.CurrentUserAllHosts</code>
All users, All hosts	<code>\$PROFILE.AllUsersAllHosts</code>

To create a new profile

To create a new "Current user, Windows PowerShell ISE" profile, run this command:

```
PowerShell

if (!(Test-Path -Path $PROFILE)) {
    New-Item -Type File -Path $PROFILE -Force
}
```

To create a new "All users, Windows PowerShell ISE" profile, run this command:

```
PowerShell

if (!(Test-Path -Path $PROFILE.AllUsersCurrentHost)) {
    New-Item -Type File -Path $PROFILE.AllUsersCurrentHost -Force
}
```

To create a new "Current user, All Hosts" profile, run this command:

```
PowerShell

if (!(Test-Path -Path $PROFILE.CurrentUserAllHosts)) {
    New-Item -Type File -Path $PROFILE.CurrentUserAllHosts -Force
}
```

To create a new "All users, All Hosts" profile, type:

PowerShell

```
if (!(Test-Path -Path $PROFILE.AllUsersAllHosts)) {  
    New-Item -Type File -Path $PROFILE.AllUsersAllHosts -Force  
}
```

To edit a profile

1. To open the profile, run the command `psEdit` with the variable that specifies the profile you want to edit. For example, to open the "Current user, Windows PowerShell ISE" profile, type: `psEdit $PROFILE`
2. Add some items to your profile. The following are a few examples to get you started:
 - To change the default background color of the Console Pane to blue, in the profile file type: `$psISE.Options.OutputPaneBackground = 'blue'`. For more information about the `$psISE` variable, see [Windows PowerShell ISE Object Model Reference](#).
 - To change font size to 20, in the profile file type: `$psISE.Options.FontSize =20`
3. To save your profile file, on the **File** menu, click **Save**. Next time you open the Windows PowerShell ISE, your customizations are applied.

How to Use Tab Completion in the Script Pane and Console Pane

Article • 03/27/2025

Tab completion provides automatic help when you are typing in the Script Pane or in the Command Pane. Use the following steps to take advantage of this feature:

To automatically complete a command entry

In the Command Pane or Script Pane, type a few characters of a command and then press `TAB` to select the desired completion text. If multiple items begin with the text that you initially typed, then continue pressing `TAB` until the item you want appears. Tab completion can help with typing a cmdlet name, parameter name, variable name, object property name, or a file path.

ⓘ Note

In the Script Pane, pressing `TAB` will automatically complete a command only when you are editing `.ps1`, `.psd1`, or `.psm1` files. Tab completion works any time when you are typing in the Command Pane.

To automatically complete a cmdlet parameter entry

In the Command Pane or Script pane, type a cmdlet followed by a dash and then press `TAB`.

For example, type `Get-Process -` and then press `TAB` multiple times to display each of the parameters for the cmdlet in turn.

How to Use the Console Pane in the Windows PowerShell ISE

Article • 03/27/2025

The Console pane in the Windows PowerShell Integrated Scripting Environment (ISE) operates exactly like the stand-alone Windows PowerShell ISE console window.

To run a command in the Console Pane, type a command, and then press `ENTER`. To enter multiple commands that you want to execute in sequence, type `SHIFT + ENTER` between commands. See [How to Use Tab Completion in the Script Pane and Console Pane](#) for help in typing commands.

To stop a command, on the toolbar, click **Stop Operation**, or press `CTRL + BREAK`. You can also use `CTRL + C` to stop a command if the context is unambiguous. For example, if some text has been selected in the current Pane, then `CTRL + C` maps to the copy operation.

Beginning in Windows PowerShell v3, the Output pane was combined with the Console pane. This has the benefit of behaving like the stand-alone Windows PowerShell console and eliminates the differences in procedures that were needed when they were separate. You can:

- Select and copy text from the Console pane to the Clipboard for pasting in any other window. To select text, click and hold the mouse in the output pane while dragging the mouse over the text you want to capture. You can also use the cursor arrow keys while holding `SHIFT` to select text. Then press `CTRL + C` or click the **Copy** icon in the toolbar.
- Paste the selected text at a current cursor position. Click the **Paste** icon on the toolbar.
- Clear all the text in the Console pane. To clear the Console pane, you can click the **Clear Console Pane** icon on the toolbar, or run the command `Clear-Host` or its alias, `cls`.

How to Write and Run Scripts in the Windows PowerShell ISE

Article • 03/27/2025

This article describes how to create, edit, run, and save scripts in the Script Pane.

How to create and run scripts

You can open and edit Windows PowerShell files in the Script Pane. Specific file types of interest in Windows PowerShell are script files (`.ps1`), script data files (`.psd1`), and script module files (`.psm1`). These file types are syntax colored in the Script Pane editor. Other common file types you may open in the Script Pane are configuration files (`.ps1xml`), XML files, and text files.

ⓘ Note

The Windows PowerShell execution policy determines whether you can run scripts and load Windows PowerShell profiles and configuration files. The default execution policy, Restricted, prevents all scripts from running, and prevents loading profiles. To change the execution policy to allow profiles to load and be used, see [Set-ExecutionPolicy](#) and [about_Signing](#).

To create a new script file

On the toolbar, click **New**, or on the **File** menu, click **New**. The created file appears in a new file tab under the current PowerShell tab. Remember that the PowerShell tabs are only visible when there are more than one. By default a file of type script (`.ps1`) is created, but it can be saved with a new name and extension. Multiple script files can be created in the same PowerShell tab.

To open an existing script

On the toolbar, click **Open**, or on the **File** menu, click **Open**. In the **Open** dialog box, select the file you want to open. The opened file appears in a new tab.

To close a script tab

Click the **Close** icon (X) of the file tab you want to close or select the **File** menu and click **Close**.

If the file has been altered since it was last saved, you're prompted to save or discard it.

To display the file path

On the file tab, point to the file name. The fully qualified path to the script file appears in a tooltip.

To run a script

On the toolbar, click **Run Script**, or on the **File** menu, click **Run**.

To run a portion of a script

1. In the Script Pane, select a portion of a script.
2. On the **File** menu, click **Run Selection**, or on the toolbar, click **Run Selection**.

To stop a running script

There are several ways to stop a running script.

- Click **Stop Operation** on the toolbar
- Press **CTRL + BREAK**
- Select the **File** menu and click **Stop Operation**.

Pressing **CTRL + C** also works unless some text is currently selected, in which case **CTRL + C** maps to the copy function for the selected text.

How to write and edit text in the Script Pane

You can copy, cut, paste, find, and replace text in the Script Pane. You can also undo and redo the last action you just performed. The keyboard shortcuts for these actions are the same shortcuts used for all Windows applications.

To enter text in the Script Pane

1. Move the cursor to the Script Pane by clicking anywhere in the Script Pane, or by clicking **Go to Script Pane** in the **View** menu.

2. Create a script. Syntax coloring and tab completion provide a richer editing experience in Windows PowerShell ISE.
3. See [How to Use Tab Completion in the Script Pane and Console Pane](#) for details about using the tab completion feature to help in typing.

To find text in the Script Pane

1. To find text anywhere, press **CTRL + F** or, on the **Edit** menu, click **Find in Script**.
2. To find text after the cursor, press **F3** or, on the **Edit** menu, click **Find Next in Script**.
3. To find text before the cursor, press **SHIFT + F3** or, on the **Edit** menu, click **Find Previous in Script**.

To find and replace text in the Script Pane

Press **CTRL + H** or, on the **Edit** menu, click **Replace in Script**. Enter the text you want to find and the replacement text, then press **ENTER**.

To go to a particular line of text in the Script Pane

1. In the Script Pane, press **CTRL + G** or, on the **Edit** menu, click **Go to Line**.
2. Enter a line number.

To copy text in the Script Pane

1. In the Script Pane, select the text that you want to copy.
2. Press **CTRL + C** or, on the toolbar, click the **Copy** icon, or on the **Edit** menu, click **Copy**.

To cut text in the Script Pane

1. In the Script Pane, select the text that you want to cut.
2. Press **CTRL + X** or, on the toolbar, click the **Cut** icon, or on the **Edit** menu, click **Cut**.

To paste text into the Script Pane

Press **CTRL + V** or, on the toolbar, click the **Paste** icon, or on the **Edit** menu, click **Paste**.

To undo an action in the Script Pane

Press **CTRL + Z** or, on the toolbar, click the **Undo** icon, or on the **Edit** menu, click **Undo**.

To redo an action in the Script Pane

Press **CTRL + Y** or, on the toolbar, click the **Redo** icon, or on the **Edit** menu, click **Redo**.

How to save a script

An asterisk appears next to the script name to mark a file that hasn't been saved since it was changed. The asterisk disappears when the file is saved.

To save a script

Press **CTRL + S** or, on the toolbar, click the **Save** icon, or on the **File** menu, click **Save**.

To save and name a script

1. On the **File** menu, click **Save As**. The **Save As** dialog box will appear.
2. In the **File name** box, enter a name for the file.
3. In the **Save as type** box, select a file type. For example, in the **Save as type** box, select '**PowerShell Scripts (*.ps1)**'.
4. Click **Save**.

To save a script in ASCII encoding

By default, Windows PowerShell ISE saves new script files (**.ps1**), script data files (**.psd1**), and script module files (**.psm1**) as Unicode (BigEndianUnicode). To save a script in another encoding, such as ASCII (ANSI), use the **Save** or **SaveAs** methods on the **\$psISE.CurrentFile** object.

The following command saves a new script as **MyScript.ps1** with ASCII encoding.

```
PowerShell
```

```
$psISE.CurrentFile.SaveAs("MyScript.ps1", [System.Text.Encoding]::ASCII)
```

The following command replaces the current script file with a file with the same name, but with ASCII encoding.

```
PowerShell
```

```
$psISE.CurrentFile.Save([System.Text.Encoding]::ASCII)
```

The following command gets the encoding of the current file.

```
PowerShell
```

```
$psISE.CurrentFile.encoding
```

Windows PowerShell ISE supports the following encoding options: ASCII, BigEndianUnicode, Unicode, UTF32, UTF7, UTF8, and Default. The value of the Default option varies with the system.

Windows PowerShell ISE doesn't change the encoding of script files when you use the Save or Save As commands.

Keyboard Shortcuts for the Windows PowerShell ISE

Article • 03/27/2025

Use the following keyboard shortcuts to perform actions in Windows PowerShell Integrated Scripting Environment (ISE). Windows PowerShell ISE is available as part of the Windows Server and Windows client operating systems.

Keyboard shortcuts for editing text

You can use the following keyboard shortcuts when you edit text.

[+] Expand table

Action	Keyboard Shortcuts	Use in
Help	F1	Script Pane Important: You can specify that F1 help comes from Microsoft Learn or downloaded Help (see Update-Help). To select, click Tools, Options, then on the General Settings tab, set or clear Use local help content instead of online content .
Select All	CTRL + A	Script Pane
Copy	CTRL + C	Script Pane, Command Pane, Output Pane
Cut	CTRL + X	Script Pane, Command Pane
Expand or Collapse Outlining	CTRL + M	Script Pane
Find in Script	CTRL + F	Script Pane
Find Next in Script	F3	Script Pane
Find Previous in Script	SHIFT + F3	Script Pane
Find Matching Brace	CTRL +]	Script Pane
Paste	CTRL + V	Script Pane, Command Pane

Action	Keyboard Shortcuts	Use in
Make Lowercase	<code>CTRL + U</code>	Script Pane, Command Pane
Make Uppercase	<code>CTRL + SHIFT + U</code>	Script Pane, Command Pane
Redo	<code>CTRL + Y</code>	Script Pane, Command Pane
Replace in Script	<code>CTRL + H</code>	Script Pane
Save	<code>CTRL + S</code>	Script Pane
Select All	<code>CTRL + A</code>	Script Pane, Command Pane, Output Pane
Show Snippets	<code>CTRL + J</code>	Script Pane, Command Pane
Undo	<code>CTRL + Z</code>	Script Pane, Command Pane
Show Intellisense Help	<code>CTRL + Space</code>	Script Pane
Delete word to left	<code>CTRL + Backspace</code>	Script Pane
Delete word to right	<code>CTRL + Delete</code>	Script Pane

Keyboard shortcuts for running scripts

You can use the following keyboard shortcuts when you run scripts in the Script Pane.

[\[+\] Expand table](#)

Action	Keyboard Shortcut
New	<code>CTRL + N</code>
Open	<code>CTRL + O</code>
Run	<code>F5</code>
Run Selection	<code>F8</code>

Action	Keyboard Shortcut
Stop Execution	<code>CTRL + BREAK</code> . <code>CTRL + C</code> can be used when the context is unambiguous (when there is no text selected).
Tab (to next script)	<code>CTRL + TAB</code> Note: Tab to next script works only when you have a single Windows PowerShell tab open, or when you have more than one Windows PowerShell tab open, but the focus is in the Script Pane.
Tab (to previous script)	<code>CTRL + SHIFT + TAB</code> Note: Tab to previous script works when you have only one Windows PowerShell tab open, or if you have more than one Windows PowerShell tab open, and the focus is in the Script Pane.

Keyboard shortcuts for customizing the view

You can use the following keyboard shortcuts to customize the view in Windows PowerShell ISE. They are accessible from all the panes in the application.

[Expand table](#)

Action	Keyboard Shortcut
Go to Command (v2) or Console (v3 and later) Pane	<code>CTRL + D</code>
Go to Output Pane (v2 only)	<code>CTRL + SHIFT + O</code>
Go to Script Pane	<code>CTRL + I</code>
Show Script Pane	<code>CTRL + R</code>
Hide Script Pane	<code>CTRL + R</code>
Move Script Pane Up	<code>CTRL + 1</code>
Move Script Pane Right	<code>CTRL + 2</code>
Maximize Script Pane	<code>CTRL + 3</code>
Zoom In	<code>CTRL + +</code>
Zoom Out	<code>CTRL + -</code>

Keyboard shortcuts for debugging scripts

You can use the following keyboard shortcuts when you debug scripts.

[Expand table](#)

Action	Keyboard Shortcut	Use in
Run/Continue	F5	Script Pane, when debugging a script
Step Into	F11	Script Pane, when debugging a script
Step Over	F10	Script Pane, when debugging a script
Step Out	SHIFT + F11	Script Pane, when debugging a script
Display Call Stack	CTRL + SHIFT + D	Script Pane, when debugging a script
List Breakpoints	CTRL + SHIFT + L	Script Pane, when debugging a script
Toggle Breakpoint	F9	Script Pane, when debugging a script
Remove All Breakpoints	CTRL + SHIFT + F9	Script Pane, when debugging a script
Stop Debugger	SHIFT + F5	Script Pane, when debugging a script

Note

You can also use the keyboard shortcuts designed for the Windows PowerShell console when you debug scripts in Windows PowerShell ISE. To use these shortcuts, you must type the shortcut in the Command Pane and press `ENTER`.

[Expand table](#)

Action	Keyboard Shortcut	Use in
Continue	C	Console Pane, when debugging a script
Step Into	S	Console Pane, when debugging a script
Step Over	V	Console Pane, when debugging a script
Step Out	O	Console Pane, when debugging a script
Repeat Last Command (for Step Into or Step Over)	ENTER	Console Pane, when debugging a script

Action	Keyboard Shortcut	Use in
Display Call Stack	K	Console Pane, when debugging a script
Stop Debugging	Q	Console Pane, when debugging a script
List the Script	L	Console Pane, when debugging a script
Display Console Debugging Commands	H or ?	Console Pane, when debugging a script

Keyboard shortcuts for Windows PowerShell tabs

You can use the following keyboard shortcuts when you use Windows PowerShell tabs.

[Expand table](#)

Action	Keyboard Shortcut
Close PowerShell Tab	CTRL + W
New PowerShell Tab	CTRL + T
Previous PowerShell tab	CTRL + SHIFT + TAB . This shortcut works only when no files are open on any Windows PowerShell tab.
Next Windows PowerShell tab	CTRL + TAB . This shortcut works only when no files are open on any Windows PowerShell tab.

Keyboard shortcuts for starting and exiting

You can use the following keyboard shortcuts to exit the Windows PowerShell ISE or to start a new Windows PowerShell session outside of the ISE.

[Expand table](#)

Action	Keyboard Shortcut
Exit	ALT + F4 closes the ISE.

Action	Keyboard Shortcut
Start powershell.exe	<code>CTRL + SHIFT + P</code> opens a new Windows PowerShell session outside of the ISE.

Accessibility in Windows PowerShell ISE

Article • 03/27/2025

This topic describes the accessibility features of Windows PowerShell Integrated Scripting Environment (ISE) that you might find helpful.

- [How to change the size and location of the Console and Script Panes](#)
- [Keyboard shortcuts for editing text](#)
- [Keyboard shortcuts for running scripts](#)
- [Keyboard shortcuts for customizing the view](#)
- [Keyboard shortcuts for debugging scripts](#)
- [Keyboard shortcuts for Windows PowerShell tabs](#)
- [Keyboard shortcuts for starting and exiting](#)
- [Breakpoint management with cmdlets](#)

Microsoft is committed to making its products and services easier for everyone to use. The following topics provide information about the features, products, and services that make Windows PowerShell ISE more accessible for people with disabilities.

In addition to accessibility features and utilities in Microsoft Windows, the following features make Windows PowerShell ISE more accessible for people with disabilities:

- Keyboard Shortcuts
- Syntax Coloring Table and the ability to modify several other color settings using the `$psISE.Options` scripting object.
- Text Size Change

How to change the size and location of the Console and Script Panes

You can use the following steps to change the size and location of the Console Pane and the Script Pane. When you open the Windows PowerShell ISE again, the size and location changes you made will be retained.

To resize the Script Pane and Console Pane

1. Pause the pointer on the split line between the Script Pane and Console Pane.

- When the mouse pointer changes to a two-headed arrow, drag the border to change the size of the pane.

To move the Script Pane and Console Pane

Do one of the following:

- To move the Script Pane above the Console Pane, press **CTRL + 1** or, on the toolbar, click the **Show Script Pane Top** icon, or in the **View** menu, click **Show Script Pane Top**.
- To move the Script Pane to the right of the Console Pane, press **CTRL + 2** or, on the toolbar, click the **Show Script Pane Right** icon, or in the **View** menu, click **Show Script Pane Right**.
- To maximize the Script Pane, press **CTRL + 3** or, on the toolbar, click the **Show Script Pane Maximized** icon, or in the **View** menu, click **Show Script Pane Maximized**.
- To maximize the Console Pane and hide the Script Pane, on the far right edge of the row of tabs, click the **Hide Script Pane** icon, in the **View** menu, click to deselect the **Show Script Pane** menu option.
- To display the Script Pane when the Console Pane is maximized, on the far right edge of the row of tabs, click the **Show Script Pane** icon, or in the **View** menu, click to select the **Show Script Pane** menu option.

Keyboard shortcuts for editing text

You can use the following keyboard shortcuts when you edit text.

 Expand table

Action	Keyboard Shortcuts	Use in
Copy	CTRL + C	Script Pane, Console Pane
Cut	CTRL + X	Script Pane, Console Pane
Find in Script	CTRL + F	Script Pane
Find Next in Script	F3	Script Pane
Find Previous in Script	SHIFT + F3	Script Pane

Action	Keyboard Shortcuts	Use in
Paste	<code>CTRL + V</code>	Script Pane, Console Pane
Redo	<code>CTRL + Y</code>	Script Pane, Console Pane
Replace in Script	<code>CTRL + H</code>	Script Pane
Save	<code>CTRL + S</code>	Script Pane
Select All	<code>CTRL + A</code>	Script Pane, Console Pane
Undo	<code>CTRL + Z</code>	Script Pane, Console Pane

Keyboard shortcuts for running scripts

You can use the following keyboard shortcuts when you run scripts in the Script Pane.

[\[+\] Expand table](#)

Action	Keyboard Shortcut
New	<code>CTRL + N</code>
Open	<code>CTRL + O</code>
Run	<code>F5</code>
Run Selection	<code>F8</code>
Stop Execution	<code>CTRL + BREAK</code> . <code>CTRL + C</code> can be used when the context is unambiguous (when there is no text selected).
Tab (to next script)	<code>CTRL + TAB</code> Note: Tab to next script works only when you have a single PowerShell tab open, or when you have more than one PowerShell tab open, but the focus is in the Script Pane.
Tab (to previous script)	<code>CTRL + SHIFT + TAB</code> Note: Tab to previous script works when you have only one PowerShell tab open, or if you have more than one PowerShell tab open, and the focus is in the Script Pane.

Keyboard shortcuts for customizing the view

You can use the following keyboard shortcuts to customize the view in Windows PowerShell ISE. They are accessible from all the panes in the application.

[\[+\] Expand table](#)

Action	Keyboard Shortcut
Go to Console Pane	CTRL + D
Go to Script Pane	CTRL + I
Show Script Pane	CTRL + R
Hide Script Pane	CTRL + R
Move Script Pane Up	CTRL + 1
Move Script Pane Right	CTRL + 2
Maximize Script Pane	CTRL + 3
Zoom In	CTRL + PLUS
Zoom Out	CTRL + MINUS

Keyboard shortcuts for debugging scripts

You can use the following keyboard shortcuts when you debug scripts.

[\[+\] Expand table](#)

Action	Keyboard Shortcut	Use in
Run/Continue	F5	Script Pane, when debugging a script
Step Into	F11	Script Pane, when debugging a script
Step Over	F10	Script Pane, when debugging a script
Step Out	SHIFT + F11	Script Pane, when debugging a script
Display Call Stack	CTRL + SHIFT + D	Script Pane, when debugging a script
List Breakpoints	CTRL + SHIFT + L	Script Pane, when debugging a script
Toggle Breakpoint	F9	Script Pane, when debugging a script
Remove All Breakpoints	CTRL + SHIFT + F9	Script Pane, when debugging a script
Stop Debugger	SHIFT + F5	Script Pane, when debugging a script

 **Note**

You can also use the keyboard shortcuts designed for the Windows PowerShell console when you debug scripts in Windows PowerShell ISE. To use these shortcuts, you must type the shortcut in the Console Pane and press **ENTER**.

 [Expand table](#)

Action	Keyboard Shortcut	Use in
Continue	C	Console Pane, when debugging a script
Step Into	S	Console Pane, when debugging a script
Step Over	V	Console Pane, when debugging a script
Step Out	O	Console Pane, when debugging a script
Repeat Last Command(Step Into/Over)	ENTER	Console Pane, when debugging a script
Display Call Stack	K	Console Pane, when debugging a script
Stop Debugging	Q	Console Pane, when debugging a script
List the Script	L	Console Pane, when debugging a script
Display Console Debugging Commands	H or ?	Console Pane, when debugging a script

Keyboard shortcuts for Windows PowerShell tabs

You can use the following keyboard shortcuts when you use Windows PowerShell tabs.

 [Expand table](#)

Action	Keyboard Shortcut
Close PowerShell Tab	<code>CTRL + W</code>
New PowerShell Tab	<code>CTRL + T</code>
Previous PowerShell tab	<code>CTRL + SHIFT + TAB</code> (Only when no files are open on any PowerShell tab)
Next Windows PowerShell tab	<code>CTRL + TAB</code> (Only when no files are open on any PowerShell tab)

Keyboard shortcuts for starting and exiting

You can use the following keyboard shortcuts to start the Windows PowerShell console (`powershell.exe`) or to exit Windows PowerShell ISE.

[\[+\] Expand table](#)

Action	Keyboard Shortcut
Exit	<code>ALT + F4</code>
Start <code>powershell.exe</code> (Windows PowerShell console)	<code>CTRL + SHIFT + P</code>

Breakpoint Management

For the visually impaired, breakpoint information is available through the cmdlets for managing breakpoints, such as [Get-PSBreakpoint](#) and [Set-PSBreakpoint](#). For more information please see 'How to manage breakpoints' in [How to Debug Scripts in the Windows PowerShell ISE](#).

Purpose of the Windows PowerShell ISE Scripting Object Model

Article • 03/27/2025

Objects are associated with the form and function of Windows PowerShell Integrated Scripting Environment (ISE). The object model reference provides details about the member properties and methods that these objects expose. Examples are provided to show how you can use scripts to directly access these methods and properties. The scripting object model makes the following range of tasks easier.

Customizing the appearance of Windows PowerShell ISE

You can use the object model to modify the application settings and options. For example, you can modify them as follows:

- Change the color of errors, warnings, verbose outputs, and debug outputs.
- Get or set the background colors for the Command pane, the Output pane, and the Script pane.
- Set the foreground color for the Output pane.
- Set the font name and font size for Windows PowerShell ISE.
- Configure warnings. This setting includes warnings that are issued when a file is opened in multiple PowerShell tabs or when a script in the file is run before the file has been saved.
- Switch between a view where the Script pane and the Output pane are side-by-side and a view where the Script pane is on top of the Output pane.
- Dock the Command pane to the bottom or the top of the Output pane.

Enhancing the functionality of Windows PowerShell ISE

You can use the object model to enhance the functionality of Windows PowerShell ISE. For example, you can:

- Add and modify the instance of Windows PowerShell ISE itself. For example, to change the menus, you can add new menu items and map the new menu items to scripts.

- Create scripts that perform some of the tasks that you can perform by using the menu commands and buttons in Windows PowerShell ISE. For example, you can add, remove, or select a PowerShell tab.
- Complement tasks that can be performed by using menu commands and buttons. For example, you can rename a PowerShell tab.
- Manipulate text buffers for the Command pane, the Output pane, and the Script pane that are associated with a file. For example, you can:
 - Get or set all text.
 - Get or set a text selection.
 - Run a script or run a selected portion of a script.
 - Scroll a line into view.
 - Insert text at a caret position.
 - Select a block of text.
 - Get the last line number.
- Perform file operations. For example, you can:
 - Open a file, save a file, or save a file by using a different name.
 - Determine whether a file has been changed after it was last saved.
 - Get the file name.
 - Select a file.

Automating tasks

You can use the scripting object model to create keyboard shortcuts for frequent operations.

The ISE Object Model Hierarchy

Article • 03/27/2025

This article shows the hierarchy of objects that are part of Windows PowerShell Integrated Scripting Environment (ISE). Windows PowerShell ISE is included in Windows PowerShell 3.0, 4.0, and 5.1. Click an object to take you to the reference documentation for the class that defines the object.

\$psISE Object

The `$psISE` object is the [root object](#) of the Windows PowerShell ISE object hierarchy. Located at the top level, it makes the following objects available for scripting:

\$psISE.CurrentFile

The `$psISE.CurrentFile` object is an instance of the [ISEFile](#) class.

\$psISE.CurrentPowerShellTab

The `$psISE.CurrentPowerShellTab` object is an instance of the [PowerShellTab](#) class.

\$psISE.CurrentVisibleHorizontalTool

The `$psISE.CurrentVisibleHorizontalTool` object is an instance of the [ISEAddOnTool](#) class. It represents the installed add-on tool that's currently docked to the top edge of the Windows PowerShell ISE window.

\$psISE.CurrentVisibleVerticalTool

The `$psISE.CurrentVisibleVerticalTool` object is an instance of the [ISEAddOnTool](#) class. It represents the installed add-on tool that's currently docked to the right-hand edge of the Windows PowerShell ISE window.

\$psISE.Options

The `$psISE.Options` object is an instance of the [ISEOptions](#) class. The ISEOptions object represents various settings for Windows PowerShell ISE. It's an instance of the

Microsoft.PowerShell.Host.ISE.ISEOptions class.

\$psISE.PowerShellTabs

The `$psISE.PowerShellTabs` object is an instance of the [PowerShellTabCollection](#) class. It's a collection of all the currently open PowerShell tabs that represent the available Windows PowerShell run environments on the local computer or on connected remote computers. Each member in the collection is an instance of the [PowerShellTab](#) class.

The ObjectModelRoot Object

Article • 03/27/2025

The `$psISE` object, which is the principal root object in Windows PowerShell Integrated Scripting Environment (ISE) is an instance of the `Microsoft.PowerShell.Host.ISE.ObjectModelRoot` class. This topic describes the properties of the `.ObjectModelRoot` object.

Properties

CurrentFile

Supported in Windows PowerShell ISE 2.0 and later.

The read-only property that gets the file, which is associated with this host object that currently has the focus.

CurrentPowerShellTab

Supported in Windows PowerShell ISE 2.0 and later.

The read-only property that gets the PowerShell tab that has the focus.

CurrentVisibleHorizontalTool

Supported in Windows PowerShell ISE 2.0 and later.

The read-only property that gets the currently visible Windows PowerShell ISE add-on tool that's located in the horizontal tool pane at the bottom of the editor.

CurrentVisibleVerticalTool

Supported in Windows PowerShell ISE 2.0 and later.

The read-only property that gets the currently visible Windows PowerShell ISE add-on tool that's located in the vertical tool pane on the right side of the editor.

Options

Supported in Windows PowerShell ISE 2.0 and later.

The read-only property that gets the various options that can change settings in Windows PowerShell ISE.

PowerShellTabs

Supported in Windows PowerShell ISE 2.0 and later.

The read-only property that gets the collection of the PowerShell tabs, which are open in Windows PowerShell ISE. By default, this object contains one PowerShell tab. However, you can add more PowerShell tabs to this object by using scripts or by using the menus in Windows PowerShell ISE.

The ISEAddOnToolCollection Object

Article • 03/27/2025

The **ISEAddOnToolCollection** object is a collection of **ISEAddOnTool** objects. An example is the `$psISE.CurrentPowerShellTab.VerticalAddOnTools` object.

Methods

Add(Name, ControlType, [IsVisible])

Supported in Windows PowerShell ISE 3.0 and later, and not present in earlier versions.

Adds a new add-on tool to the collection. It returns the newly added add-on tool.

Before you run this command, you must install the add-on tool on the local computer and load the assembly.

- **Name** - String - Specifies the display name of the add-on tool that's added to Windows PowerShell ISE.
- **ControlType** - Type - Specifies the control that's added.
- **[IsVisible]** - optional Boolean - If set to `$true`, the add-on tool is immediately visible in the associated tool pane.

PowerShell

```
# Load a DLL with an add-on and then add it to the ISE
[Reflection.Assembly]::LoadFile("C:\testISESimpleSolution\ISESimpleSolution.dll")
$psISE.CurrentPowerShellTab.VerticalAddOnTools.Add("Solutions",
[ISESimpleSolution.Solution], $true)
```

Remove(Item)

Supported in Windows PowerShell ISE 3.0 and later, and not present in earlier versions.

Removes the specified add-on tool from the collection.

- **Item** - Microsoft.PowerShell.Host.ISE.ISEAddOnTool - Specifies the object to be removed from Windows PowerShell ISE.

PowerShell

```
# Load a DLL with an add-on and then add it to the ISE
[Reflection.Assembly]::LoadFile("C:\test\ISESimpleSolution\ISESimpleSolution
.dll")
$psISE.CurrentPowerShellTab.VerticalAddOnTools.Add("Solutions",
[ISESimpleSolution.Solution], $true)
```

SetSelectedPowerShellTab(psTab)

Supported in Windows PowerShell ISE 3.0 and later, and not present in earlier versions.

Selects the PowerShell tab that the **psTab** parameter specifies.

- **psTab** - Microsoft.PowerShell.Host.ISE.PowerShellTab -The PowerShell tab to select.

PowerShell

```
$newTab = $psISE.PowerShellTabs.Add()
# Change the DisplayName of the new PowerShell tab.
$newTab.DisplayName = 'Brand New Tab'
```

Remove(psTab)

Supported in Windows PowerShell ISE 3.0 and later, and not present in earlier versions.

Removes the PowerShell tab that the **psTab** parameter specifies.

- **psTab** - Microsoft.PowerShell.Host.ISE.PowerShellTab - The PowerShell tab to remove.

PowerShell

```
$newTab = $psISE.PowerShellTabs.Add()
Change the DisplayName of the new PowerShell tab.
$newTab.DisplayName = 'This tab will go away in 5 seconds'
sleep 5
$psISE.PowerShellTabs.Remove($newTab)
```

The ISEAddOnTool Object

Article • 03/27/2025

An **ISEAddonTool** object represents an installed add-on tool that provides additional functionality to Windows PowerShell ISE. An example is the **Commands** tool that you can display by clicking **View**, then **Show Command Add-on**. This tool is then accessible to you by manipulating the various available **ISEAddOnTool** objects.

Each add-on tool can be associated with either the vertical pane or the horizontal pane. The vertical pane is docked to the right edge of Windows PowerShell ISE. The horizontal pane is docked to the bottom edge.

Each PowerShell tab in Windows PowerShell ISE can have its own set of add-on tools installed. See [\\$psISE.CurrentPowerShellTab.HorizontalAddOnTools](#) and [\\$psISE.CurrentPowerShellTab.VerticalAddOnTools](#) to access the collection of tools available to the currently selected tab or the same properties on any of the **PowerShellTab** objects in the [\\$psISE.PowerShellTabs](#) collection object.

Methods

There are no Windows PowerShell ISE-specific methods available for objects of this class.

Properties

Control

Supported in Windows PowerShell ISE 3.0 and later, and not present in earlier versions.

The **Control** property provides read access to many of the details of the Commands add-on tool.

PowerShell

```
# View the properties of the Commands add-on tool.  
# (assumes that it's visible in the vertical pane)  
$psISE.CurrentVisibleVerticalTool.Control
```

Output

IsSealed                   : False  
Dispatcher                 : System.Windows.Threading.Dispatcher
```

isVisible

Supported in Windows PowerShell ISE 3.0 and later, and not present in earlier versions.

The Boolean property that indicates whether the add-on tool is currently visible in its assigned pane. If it's visible, you can set the **IsVisible** property to `$false` to hide the tool, or set the **IsVisible** property to `$true` to make an add-on tool visible on its PowerShell tab. Note that after an add-on tool is hidden, it's no longer accessible through the **CurrentVisibleHorizontalTool** or **CurrentVisibleVerticalTool** objects, and therefore can't be made visible by using this property on that object.

PowerShell

```
# Hide the current tool in the vertical tool pane
$psISE.CurrentVisibleVerticalTool.IsVisible = $false
# Show the first tool on the currently selected PowerShell tab
$psISE.CurrentPowerShellTab.VerticalAddOnTools[0].IsVisible = $true
```

Name

Supported in Windows PowerShell ISE 3.0 and later, and not present in earlier versions.

The read-only property that gets the name of the add-on tool.

PowerShell

```
# Gets the name of the visible vertical pane add-on tool.
$psISE.CurrentVisibleVerticalTool.Name
```

Output

Commands

The ISEEditor Object

Article • 03/27/2025

An **ISEEditor** object is an instance of the `Microsoft.PowerShell.Host.ISE.ISEEditor` class. The Console pane is an **ISEEditor** object. Each **ISEFile** object has an associated **ISEEditor** object. The following sections list the methods and properties of an **ISEEditor** object.

Methods

Clear()

Supported in Windows PowerShell ISE 2.0 and later.

Clears the text in the editor.

PowerShell

```
# Clears the text in the Console pane.  
$psISE.CurrentPowerShellTab.ConsolePane.Clear()
```

EnsureVisible(int lineNumber)

Supported in Windows PowerShell ISE 2.0 and later.

Scrolls the editor so that the line that corresponds to the specified `lineNumber` parameter value is visible. It throws an exception if the specified line number is outside the range of 1,last line number, which defines the valid line numbers.

- `lineNumber` - The number of the line that's to be made visible.

PowerShell

```
# Scrolls the text in the Script pane so that the fifth line is in view.  
$psISE.CurrentFile.Editor.EnsureVisible(5)
```

Focus()

Supported in Windows PowerShell ISE 2.0 and later.

Sets the focus to the editor.

PowerShell

```
# Sets focus to the Console pane.  
$psISE.CurrentPowerShellTab.ConsolePane.Focus()
```

GetLineLength(int lineNumber)

Supported in Windows PowerShell ISE 2.0 and later.

Gets the line length as an integer for the line that's specified by the line number.

- **lineNumber** - The number of the line of which to get the length.
- **Returns** - The line length for the line at the specified line number.

PowerShell

```
# Gets the length of the first line in the text of the Command pane.  
$psISE.CurrentPowerShellTab.ConsolePane.GetLineLength(1)
```

GoToMatch()

Supported in Windows PowerShell ISE 3.0 and later, and not present in earlier versions.

Moves the caret to the matching character if the **CanGoToMatch** property of the editor object is `$true`, which occurs when the caret is immediately before an opening parenthesis, bracket, or brace

- `(, [, {` - or immediately after a closing parenthesis, bracket, or brace - `),], }`. The caret is placed before an opening character or after a closing character. If the **CanGoToMatch** property is `$false`, then this method does nothing.

PowerShell

```
# Goes to the matching character if CanGoToMatch() is $true  
$psISE.CurrentPowerShellTab.ConsolePane.GoToMatch()
```

InsertText(text)

Supported in Windows PowerShell ISE 2.0 and later.

Replaces the selection with text or inserts text at the current caret position.

- **text** - String - The text to insert.

See the [Scripting Example](#) later in this topic.

Select(startLine, startColumn, endLine, endColumn)

Supported in Windows PowerShell ISE 2.0 and later.

Selects the text from the **startLine**, **startColumn**, **endLine**, and **endColumn** parameters.

- **startLine** - Integer - The line where the selection starts.
- **startColumn** - Integer - The column within the start line where the selection starts.
- **endLine** - Integer - The line where the selection ends.
- **endColumn** - Integer - The column within the end line where the selection ends.

See the [Scripting Example](#) later in this topic.

SelectCaretLine()

Supported in Windows PowerShell ISE 2.0 and later.

Selects the entire line of text that currently contains the caret.

PowerShell

```
# First, set the caret position on line 5.  
$psISE.CurrentFile.Editor.SetCaretPosition(5,1)  
# Now select that entire line of text  
$psISE.CurrentFile.Editor.SelectCaretLine()
```

SetCaretPosition(lineNumber, columnNumber)

Supported in Windows PowerShell ISE 2.0 and later.

Sets the caret position at the line number and the column number. It throws an exception if either the caret line number or the caret column number are out of their respective valid ranges.

- **lineNumber** - Integer - The caret line number.
- **columnNumber** - Integer - The caret column number.

PowerShell

```
# Set the CaretPosition.  
$psISE.CurrentFile.Editor.SetCaretPosition(5,1)
```

ToggleOutliningExpansion()

Supported in Windows PowerShell ISE 3.0 and later, and not present in earlier versions.

Causes all the outline sections to expand or collapse.

PowerShell

```
# Toggle the outlining expansion  
$psISE.CurrentFile.Editor.ToggleOutliningExpansion()
```

Properties

CanGoToMatch

Supported in Windows PowerShell ISE 3.0 and later, and not present in earlier versions.

The read-only Boolean property to indicate whether the caret is next to a parenthesis, bracket, or brace - `()`, `[]`, `{}`. If the caret is immediately before the opening character or immediately after the closing character of a pair, then this property value is `$true`. Otherwise, it's `$false`.

PowerShell

```
# Test to see if the caret is next to a parenthesis, bracket, or brace  
$psISE.CurrentFile.Editor.CanGoToMatch
```

CaretColumn

Supported in Windows PowerShell ISE 2.0 and later.

The read-only property that gets the column number that corresponds to the position of the caret.

PowerShell

```
# Get the CaretColumn.  
$psISE.CurrentFile.Editor.CaretColumn
```

CaretLine

Supported in Windows PowerShell ISE 2.0 and later.

The read-only property that gets the number of the line that contains the caret.

PowerShell

```
# Get the CaretLine.  
$psISE.CurrentFile.Editor.CaretLine
```

CaretLineText

Supported in Windows PowerShell ISE 2.0 and later.

The read-only property that gets the complete line of text that contains the caret.

PowerShell

```
# Get all of the text on the line that contains the caret.  
$psISE.CurrentFile.Editor.CaretLineText
```

LineCount

Supported in Windows PowerShell ISE 2.0 and later.

The read-only property that gets the line count from the editor.

PowerShell

```
# Get the LineCount.  
$psISE.CurrentFile.Editor.LineCount
```

SelectedText

Supported in Windows PowerShell ISE 2.0 and later.

The read-only property that gets the selected text from the editor.

See the [Scripting Example](#) later in this topic.

Text

Supported in Windows PowerShell ISE 2.0 and later.

The read/write property that gets or sets the text in the editor.

See the [Scripting Example](#) later in this topic.

Scripting Example

PowerShell

```
# This illustrates how you can use the length of a line to
# select the entire line and shows how you can make it lowercase.
# You must run this in the Console pane. It will not run in the Script pane.
# Begin by getting a variable that points to the editor.
$myEditor = $psISE.CurrentFile.Editor
# Clear the text in the current file editor.
$myEditor.Clear()

# Make sure the file has five lines of text.
$myEditor.InsertText("LINE1 `n")
$myEditor.InsertText("LINE2 `n")
$myEditor.InsertText("LINE3 `n")
$myEditor.InsertText("LINE4 `n")
$myEditor.InsertText("LINE5 `n")

# Use the GetLineLength method to get the length of the third line.
$endColumn = $myEditor.GetLineLength(3)
# Select the text in the first three lines.
$myEditor.Select(1, 1, 3, $endColumn + 1)
$selection = $myEditor.SelectedText
# Clear all the text in the editor.
$myEditor.Clear()
# Add the selected text back, but in lower case.
$myEditor.InsertText($selection.ToLower())
```

The ISEFileCollection Object

Article • 03/27/2025

The **ISEFileCollection** object is a collection of **ISEFile** objects. An example is the `$psISE.CurrentPowerShellTab.Files` collection.

Methods

Add([FullPath])

Supported in Windows PowerShell ISE 2.0 and later.

Creates and returns a new untitled file and adds it to the collection. The **IsUntitled** property of the newly created file is `$true`.

- **[FullPath]** - Optional string - The fully specified path of the file. An exception is generated if you include the **FullPath** parameter and a relative path, or if you use a file name instead of the full path.

PowerShell

```
# Adds a new untitled file to the collection of files in the current
# PowerShell tab.
$newFile = $psISE.CurrentPowerShellTab.Files.Add()

# Adds a file specified by its full path to the collection of files in the
# current
# PowerShell tab.
$psISE.CurrentPowerShellTab.Files.Add("$PSHOME\Examples\profile.ps1")
```

Remove(File, [Force])

Supported in Windows PowerShell ISE 2.0 and later.

Removes a specified file from the current PowerShell tab.

File - String The **ISEFile** file that you want to remove from the collection. If the file hasn't been saved, this method throws an exception. Use the **Force** switch parameter to force the removal of an unsaved file.

[Force] - optional Boolean If set to `$true`, grants permission to remove the file even if it hasn't been saved after last use. The default is `$false`.

PowerShell

```
# Removes the first opened file from the file collection associated with the
# current
# PowerShell tab. If the file hasn't yet been saved, then an exception is
generated.
$firstfile = $psISE.CurrentPowerShellTab.Files[0]
$psISE.CurrentPowerShellTab.Files.Remove($firstfile)

# Removes the first opened file from the file collection associated with the
# current
# PowerShell tab, even if it hasn't been saved.
$firstfile = $psISE.CurrentPowerShellTab.Files[0]
$psISE.CurrentPowerShellTab.Files.Remove($firstfile, $true)
```

SetSelectedFile(**selectedFile**)

Supported in Windows PowerShell ISE 2.0 and later.

Selects the file that's specified by the **SelectedFile** parameter.

SelectedFile - Microsoft.PowerShell.Host.ISE.ISEFile The ISEFile file that you want to select.

PowerShell

```
# Selects the specified file.
$firstfile = $psISE.CurrentPowerShellTab.Files[0]
$psISE.CurrentPowerShellTab.Files.SetSelectedFile($firstfile)
```

The ISEFile Object

Article • 03/27/2025

An **ISEFile** object represents a file in Windows PowerShell Integrated Scripting Environment (ISE). It's an instance of the **Microsoft.PowerShell.Host.ISE.ISEFile** class. This topic lists its member methods and member properties. The `$psISE.CurrentFile` and the files in the `Files` collection in a PowerShell tab are all instances of the **Microsoft.PowerShell.Host.ISE.ISEFile** class.

Methods

Save([saveEncoding])

Supported in Windows PowerShell ISE 2.0 and later.

Saves the file to disk.

`[saveEncoding]` - optional [System.Text.Encoding](#) An optional character encoding parameter to be used for the saved file. The default value is **UTF8**.

Exceptions

- **System.IO.IOException**: The file couldn't be saved.

PowerShell

```
# Save the file using the default encoding (UTF8)
$psISE.CurrentFile.Save()

# Save the file as ASCII.
$psISE.CurrentFile.Save([System.Text.Encoding]::ASCII)

# Gets the current encoding.
$myfile = $psISE.CurrentFile
$myfile.Encoding
```

SaveAs(filename, [saveEncoding])

Supported in Windows PowerShell ISE 2.0 and later.

Saves the file with the specified file name and encoding.

`filename` - String The name to be used to save the file.

`[saveEncoding]` - optional `System.Text.Encoding` An optional character encoding parameter to be used for the saved file. The default value is `UTF8`.

Exceptions

- `System.ArgumentNullException`: The `filename` parameter is null.
- `System.ArgumentException`: The `filename` parameter is empty.
- `System.IO.IOException`: The file couldn't be saved.

PowerShell

```
# Save the file with a full path and name.  
$fullpath = "C:\temp\newname.txt"  
$psISE.CurrentFile.SaveAs($fullPath)  
# Save the file with a full path and name and explicitly as UTF8.  
$psISE.CurrentFile.SaveAs($fullPath, [System.Text.Encoding]::UTF8)
```

Properties

DisplayName

Supported in Windows PowerShell ISE 2.0 and later.

The read-only property that gets the string that contains the display name of this file. The name is shown on the **File** tab at the top of the editor. The presence of an asterisk (*) at the end of the name indicates that the file has changes that haven't been saved.

PowerShell

```
# Shows the display name of the file.  
$psISE.CurrentFile.DisplayName
```

Editor

Supported in Windows PowerShell ISE 2.0 and later.

The read-only property that gets the [editor object](#) that's used for the specified file.

PowerShell

```
# Gets the editor and the text.  
$psISE.CurrentFile.Editor.Text
```

Encoding

Supported in Windows PowerShell ISE 2.0 and later.

The read-only property that gets the original file encoding. This is a **System.Text.Encoding** object.

```
PowerShell  
  
# Shows the encoding for the file.  
$psISE.CurrentFile.Encoding
```

FullPath

Supported in Windows PowerShell ISE 2.0 and later.

The read-only property that gets the string that specifies the full path of the opened file.

```
PowerShell  
  
# Shows the full path for the file.  
$psISE.CurrentFile.FullPath
```

IsSaved

Supported in Windows PowerShell ISE 2.0 and later.

The read-only Boolean property that returns `$true` if the file has been saved after it was last modified.

```
PowerShell  
  
# Determines whether the file has been saved since it was last modified.  
$myfile = $psISE.CurrentFile  
$myfile.IsSaved
```

IsUntitled

Supported in Windows PowerShell ISE 2.0 and later.

The read-only property that returns `$true` if the file has never been given a title.

PowerShell

```
# Determines whether the file has never been given a title.  
$psISE.CurrentFile.IsUntitled  
$psISE.CurrentFile.SaveAs("temp.txt")  
$psISE.CurrentFile.IsUntitled
```

The ISEMenuItemCollection Object

Article • 03/27/2025

An **ISEMenuItemCollection** object is a collection of **ISEMenuItem** objects. It's an instance of the **Microsoft.PowerShell.Host.ISE.ISEMenuItemCollection** class. An example is the `$psISE.CurrentPowerShellTab.AddOnsMenu.Submenus` object that's used to customize the **Add-On** menu in Windows PowerShell® Integrated Scripting Environment (ISE).

Method

Add(**DisplayName**, **Action**, **Shortcut**)

Supported in Windows PowerShell ISE 2.0 and later.

Adds a menu item to the collection.

- **DisplayName** - String - The display name of the menu to be added.
- **Action** - System.Management.Automation.ScriptBlock - The object that specifies the action that's associated with this menu item.
- **Shortcut** - System.Windows.Input.KeyGesture - The keyboard shortcut for the action.
- **Returns** - The **ISEMenuItem** object that was just added.

PowerShell

```
# Create an Add-ons menu with a fast access key and a shortcut.
# Note the use of "_" as opposed to the "&" for mapping to the fast access
key
# letter for the menu item.
$menuAdded = $psISE.CurrentPowerShellTab.AddOnsMenu.Submenus.Add('_Process',
    {Get-Process}, 'Alt+P')
```

Clear()

Supported in Windows PowerShell ISE 2.0 and later.

Removes all submenus from the menu item.

PowerShell

```
# Remove all custom submenu items from the AddOns menu
$psISE.CurrentPowerShellTab.AddOnsMenu.Submenus.Clear()
```

The ISEMenuItem Object

Article • 03/27/2025

An **ISEMenuItem** object is an instance of the **Microsoft.PowerShell.Host.ISE.ISEMenuItem** class. All menu objects on the **Add-ons** menu are instances of the **Microsoft.PowerShell.Host.ISE.ISEMenuItem** class.

Properties

DisplayName

Supported in Windows PowerShell ISE 2.0 and later.

The read-only property that gets the display name of the menu item.

PowerShell

```
# Get the display name of the Add-ons menu item
$psISE.CurrentPowerShellTab.AddOnsMenu.Submenus.Clear()
$psISE.CurrentPowerShellTab.AddOnsMenu.Submenus.Add('_Process', {Get-
    Process}, 'Alt+P')
$psISE.CurrentPowerShellTab.AddOnsMenu.DisplayName
```

Action

Supported in Windows PowerShell ISE 2.0 and later.

The read-only property that gets the block of script. It invokes the action when you click the menu item.

PowerShell

```
# Get the action associated with the first submenu item.
$psISE.CurrentPowerShellTab.AddOnsMenu.Submenus.Clear()
$psISE.CurrentPowerShellTab.AddOnsMenu.Submenus.Add('_Process', {Get-
    Process}, 'Alt+P')
$psISE.CurrentPowerShellTab.AddOnsMenu.Submenus[0].Action

# Invoke the script associated with the first submenu item
$psISE.CurrentPowerShellTab.AddOnsMenu.Submenus[0].Action.Invoke()
```

Shortcut

Supported in Windows PowerShell ISE 2.0 and later.

The read-only property that gets the Windows input keyboard shortcut for the menu item.

PowerShell

```
# Get the shortcut for the first submenu item.  
$psISE.CurrentPowerShellTab.AddOnsMenu.Submenus.Clear()  
$psISE.CurrentPowerShellTab.AddOnsMenu.Submenus.Add('_Process', {Get-  
Process}, 'Alt+P')  
$psISE.CurrentPowerShellTab.AddOnsMenu.Submenus[0].Shortcut
```

Submenus

Supported in Windows PowerShell ISE 2.0 and later.

The read-only property that gets the [list of submenus](#) of the menu item.

PowerShell

```
# List the submenus of the Add-ons menu  
$psISE.CurrentPowerShellTab.AddOnsMenu.Submenus.Clear()  
$psISE.CurrentPowerShellTab.AddOnsMenu.Submenus.Add('_Process', {Get-  
Process}, 'Alt+P')  
$psISE.CurrentPowerShellTab.AddOnsMenu.Submenus
```

Scripting example

To better understand the use of the Add-ons menu and its scriptable properties, read through the following scripting example.

PowerShell

```
# This is a scripting example that shows the use of the Add-ons menu.  
# Clear the Add-ons menu if any entries currently exist  
$psISE.CurrentPowerShellTab.AddOnsMenu.Submenus.Clear()  
  
# Add an Add-ons menu item with a shortcut and fast access key.  
# Note the use of "_" as opposed to the "&" for mapping to the fast access  
key letter  
# for the menu item.  
$menuAdded = $psISE.CurrentPowerShellTab.AddOnsMenu.SubMenus.Add('_Process',  
{Get-Process}, 'Alt+P')  
# Add a nested menu - a parent and a child submenu item.  
$parentAdded = $psISE.CurrentPowerShellTab.AddOnsMenu.Submenus.Add('Parent',
```

```
$null, $null)  
$parentAdded.SubMenus.Add('_Dir', {dir}, 'Alt+D')
```

The ISEOptions Object

Article • 04/30/2025

The **ISEOptions** object represents various settings for Windows PowerShell ISE. It's an instance of the **Microsoft.PowerShell.Host.ISE.ISEOptions** class.

The **ISEOptions** object provides the following methods and properties.

Methods

RestoreDefaultConsoleTokenColors()

Supported in Windows PowerShell ISE 3.0 and later, and not present in earlier versions.

Restores the default values of the token colors in the Console pane.

PowerShell

```
# Changes the color of the commands in the Console pane to red and then restores
# it to its default value.
$psISE.Options.ConsoleTokenColors["Command"] = 'red'
$psISE.Options.RestoreDefaultConsoleTokenColors()
```

RestoreDefaults()

Supported in Windows PowerShell ISE 2.0 and later.

Restores the default values of all options settings in the Console pane. It also resets the behavior of various warning messages that provide the standard check box to prevent the message from being shown again.

PowerShell

```
# Changes the background color in the Console pane and then restores it to its
# default value.
$psISE.Options.ConsolePaneBackgroundColor = 'orange'
$psISE.Options.RestoreDefaults()
```

RestoreDefaultTokenColors()

Supported in Windows PowerShell ISE 2.0 and later.

Restores the default values of the token colors in the Script pane.

PowerShell

```
# Changes the color of the comments in the Script pane to red and then restores it
# to its default value.
$psISE.Options.TokenColors["Comment"] = 'red'
$psISE.Options.RestoreDefaultTokenColors()
```

RestoreDefaultXmlTokenColors()

Supported in Windows PowerShell ISE 3.0 and later, and not present in earlier versions.

Restores the default values of the token colors for XML elements that are displayed in Windows PowerShell ISE. Also see [XmlAttributeColors](#).

PowerShell

```
# Changes the color of the comments in XML data to red and then restores it
# to its default value.
$psISE.Options.XmlTokenColors["Comment"] = 'red'
$psISE.Options.RestoreDefaultXmlTokenColors()
```

Properties

AutoSaveMinuteInterval

Supported in Windows PowerShell ISE 3.0 and later, and not present in earlier versions.

Specifies the number of minutes between automatic save operations of your files by Windows PowerShell ISE. The default value is 2 minutes. The value is an integer.

PowerShell

```
# Changes the number of minutes between automatic save operations to every 3
minutes.
$psISE.Options.AutoSaveMinuteInterval = 3
```

CommandPaneBackgroundColor

This feature is present in Windows PowerShell ISE 2.0, but was removed or renamed in later versions of the ISE. For later versions, see [ConsolePaneBackgroundColor](#).

Specifies the background color for the Command pane. It's an instance of the **System.Windows.Media.Color** class.

PowerShell

```
# Changes the background color of the Command pane to orange.  
$psISE.Options.CommandPaneBackgroundColor = 'orange'
```

CommandPaneUp

This feature is present in Windows PowerShell ISE 2.0, but was removed or renamed in later versions of the ISE.

Specifies whether the Command pane is located above the Output pane.

PowerShell

```
# Moves the Command pane to the top of the screen.  
$psISE.Options.CommandPaneUp = $true
```

ConsolePaneBackgroundColor

Supported in Windows PowerShell ISE 3.0 and later, and not present in earlier versions.

Specifies the background color for the Console pane. It's an instance of the **System.Windows.Media.Color** class.

PowerShell

```
# Changes the background color of the Console pane to red.  
$psISE.Options.ConsolePaneBackgroundColor = 'red'
```

ConsolePaneForegroundColor

Supported in Windows PowerShell ISE 3.0 and later, and not present in earlier versions.

Specifies the foreground color of the text in the Console pane.

PowerShell

```
# Changes the foreground color of the text in the Console pane to yellow.  
$psISE.Options.ConsolePaneForegroundColor = 'yellow'
```

ConsolePaneTextColorBackgroundColor

Supported in Windows PowerShell ISE 3.0 and later, and not present in earlier versions.

Specifies the background color of the text in the Console pane.

PowerShell

```
# Changes the background color of the Console pane text to pink.  
$psISE.Options.ConsolePaneTextColorBackgroundColor = 'pink'
```

ConsoleTokenColors

Supported in Windows PowerShell ISE 3.0 and later, and not present in earlier versions.

Specifies the colors of the IntelliSense tokens in the Windows PowerShell ISE Console pane. This property is a dictionary object that contains name/value pairs of token types and colors for the Console pane. To change the colors of the IntelliSense tokens in the Script pane, see [TokenColors](#). To reset the colors to the default values, see [RestoreDefaultConsoleTokenColors](#). Token colors can be set for the following: `Attribute`, `Command`, `CommandArgument`, `CommandParameter`, `Comment`, `GroupEnd`, `GroupStart`, `Keyword`, `LineContinuation`, `LoopLabel`, `Member`, `NewLine`, `Number`, `Operator`, `Position`, `StatementSeparator`, `String`, `Type`, `Unknown`, `Variable`.

PowerShell

```
# Sets the color of commands to green.  
$psISE.Options.ConsoleTokenColors[ "Command" ] = 'green'  
# Sets the color of keywords to magenta.  
$psISE.Options.ConsoleTokenColors[ "Keyword" ] = 'magenta'
```

DebugBackgroundColor

Supported in Windows PowerShell ISE 2.0 and later.

Specifies the background color for the debug text that appears in the Console pane. It's an instance of the `System.Windows.Media.Color` class.

PowerShell

```
# Changes the background color for the debug text that appears in the Console pane  
# to blue.  
$psISE.Options.DebugBackgroundColor = '#0000FF'
```

DebugForegroundColor

Supported in Windows PowerShell ISE 2.0 and later.

Specifies the foreground color for the debug text that appears in the Console pane. It's an instance of the `System.Windows.Media.Color` class.

PowerShell

```
# Changes the foreground color for the debug text that appears in the Console
# pane to yellow.
$psISE.Options.DebugForegroundColor = 'yellow'
```

DefaultOptions

Supported in Windows PowerShell ISE 2.0 and later.

A collection of properties that specify the default values to be used when the Reset methods are used.

PowerShell

```
# Displays the name of the default options. This example is from ISE 4.0.
$psISE.Options.DefaultOptions
```

Output

```
SelectedScriptPaneState : Top
ShowDefaultSnippets : True

UseEnterToSelectInScriptPaneIntellisense : True
```

ErrorBackgroundColor

Supported in Windows PowerShell ISE 2.0 and later.

Specifies the background color for error text that appears in the Console pane. It's an instance of the [System.Windows.Media.Color](#) class.

PowerShell

```
# Changes the background color for the error text that appears in the Console pane
# to black.
$psISE.Options.ErrorBackgroundColor = 'black'
```

ErrorForegroundColor

Supported in Windows PowerShell ISE 2.0 and later.

Specifies the foreground color for error text that appears in the Console pane. It's an instance of the [System.Windows.Media.Color](#) class.

PowerShell

```
# Changes the foreground color for the error text that appears in the console pane
# to green.
```

```
$psISE.Options.ErrorForegroundColor = 'green'
```

FontName

Supported in Windows PowerShell ISE 2.0 and later.

Specifies the font name currently in use in both the Script pane and the Console pane.

PowerShell

```
# Changes the font used in both panes.  
$psISE.Options.FontName = 'Courier New'
```

FontSize

Supported in Windows PowerShell ISE 2.0 and later.

Specifies the font size as an integer. It's used in the Script pane, the Command pane, and the Output pane. The valid range of values is 8 through 32.

PowerShell

```
# Changes the font size in all panes.  
$psISE.Options.FontSize = 20
```

IntellisenseTimeoutInSeconds

Supported in Windows PowerShell ISE 3.0 and later, and not present in earlier versions.

Specifies the number of seconds that IntelliSense uses to try to resolve the currently typed text. After this number of seconds, IntelliSense times out and enables you to continue typing. The default value is 3 seconds. The value is an integer.

PowerShell

```
# Changes the number of seconds for IntelliSense syntax recognition to 5.  
$psISE.Options.IntellisenseTimeoutInSeconds = 5
```

MruCount

Supported in Windows PowerShell ISE 3.0 and later, and not present in earlier versions.

Specifies the number of recently opened files that Windows PowerShell ISE tracks and displays at the bottom of the **File Open** menu. The default value is 10. The value is an integer.

PowerShell

```
# Changes the number of recently used files that appear at the bottom of the
# File Open menu to 5.
$psISE.Options.MruCount = 5
```

OutputPaneBackgroundColor

This feature is present in Windows PowerShell ISE 2.0, but was removed or renamed in later versions of the ISE. For later versions, see [ConsolePaneBackgroundColor](#).

The read/write property that gets or sets the background color for the Output pane itself. It's an instance of the **System.Windows.Media.Color** class.

PowerShell

```
# Changes the background color of the Output pane to gold.
$psISE.Options.OutputPaneBackgroundColor = 'gold'
```

OutputPaneTextForegroundColor

This feature is present in Windows PowerShell ISE 2.0, but was removed or renamed in later versions of the ISE. For later versions, see [ConsolePaneForegroundColor](#).

The read/write property that changes the foreground color of the text in the Output pane in Windows PowerShell ISE 2.0.

PowerShell

```
# Changes the foreground color of the text in the Output Pane to blue.
$psISE.Options.OutputPaneTextForegroundColor = 'blue'
```

OutputPaneTextBackgroundColor

This feature is present in Windows PowerShell ISE 2.0, but was removed or renamed in later versions of the ISE. For later versions, see [ConsolePaneTextBackgroundColor](#).

The read/write property that changes the background color of the text in the Output pane.

PowerShell

```
# Changes the background color of the Output pane text to pink.  
$psISE.Options.OutputPaneTextColor = 'pink'
```

ScriptPaneBackgroundColor

Supported in Windows PowerShell ISE 2.0 and later.

The read/write property that gets or sets the background color for files. It's an instance of the **System.Windows.Media.Color** class.

PowerShell

```
# Sets the color of the script pane background to yellow.  
$psISE.Options.ScriptPaneBackgroundColor = 'yellow'
```

ScriptPaneForegroundColor

Supported in Windows PowerShell ISE 2.0 and later.

The read/write property that gets or sets the foreground color for non-script files in the Script pane. To set the foreground color for script files, use the [TokenColors](#).

PowerShell

```
# Sets the foreground to color of non-script files in the script pane to green.  
$psISE.Options.ScriptPaneTextColor = 'green'
```

SelectedScriptPaneState

Supported in Windows PowerShell ISE 2.0 and later.

The read/write property that gets or sets the position of the Script pane on the display. The string can be either 'Maximized', 'Top', or 'Right'.

PowerShell

```
# Moves the Script Pane to the top.  
$psISE.Options.SelectedScriptPaneState = 'Top'  
# Moves the Script Pane to the right.  
$psISE.Options.SelectedScriptPaneState = 'Right'  
# Maximizes the Script Pane  
$psISE.Options.SelectedScriptPaneState = 'Maximized'
```

ShowDefaultSnippets

Supported in Windows PowerShell ISE 3.0 and later, and not present in earlier versions.

Specifies whether the `Ctrl + J` list of snippets includes the starter set that's included in Windows PowerShell. When set to `$false`, only user-defined snippets appear in the `Ctrl + J` list. The default value is `$true`.

PowerShell

```
# Hide the default snippets from the Ctrl+J list.  
$psISE.Options.ShowDefaultSnippets = $false
```

ShowIntellisenseInConsolePane

Supported in Windows PowerShell ISE 3.0 and later, and not present in earlier versions.

Specifies whether IntelliSense offers syntax, parameter, and value suggestions in the Console pane. The default value is `$true`.

PowerShell

```
# Turn off IntelliSense in the console pane.  
$psISE.Options.ShowIntellisenseInConsolePane = $false
```

ShowIntellisenseInScriptPane

Supported in Windows PowerShell ISE 3.0 and later, and not present in earlier versions.

Specifies whether IntelliSense offers syntax, parameter, and value suggestions in the Script pane. The default value is `$true`.

PowerShell

```
# Turn off IntelliSense in the Script pane.  
$psISE.Options.ShowIntellisenseInScriptPane = $false
```

ShowLineNumbers

Supported in Windows PowerShell ISE 3.0 and later, and not present in earlier versions.

Specifies whether the Script pane displays line numbers in the left margin. The default value is \$true.

PowerShell

```
# Turn off line numbers in the Script pane.  
$psISE.Options.ShowLineNumbers = $false
```

ShowOutlining

Supported in Windows PowerShell ISE 3.0 and later, and not present in earlier versions.

Specifies whether the Script pane displays expandable and collapsible brackets next to sections of code in the left margin. When they're displayed, you can click the minus - icons next to a block of text to collapse it or click the plus + icon to expand a block of text. The default value is \$true.

PowerShell

```
# Turn off outlining in the Script pane.  
$psISE.Options.ShowOutlining = $false
```

ShowToolBar

Supported in Windows PowerShell ISE 2.0 and later.

Specifies whether the ISE toolbar appears at the top of the Windows PowerShell ISE window. The default value is \$true.

PowerShell

```
# Show the toolbar.  
$psISE.Options.ShowToolBar = $true
```

ShowWarningBeforeSavingOnRun

Supported in Windows PowerShell ISE 2.0 and later.

Specifies whether a warning message appears when a script is saved automatically before it's run. The default value is \$true.

PowerShell

```
# Enable the warning message when an attempt
# is made to run a script without saving it first.
$psISE.Options.ShowWarningBeforeSavingOnRun = $true
```

ShowWarningForDuplicateFiles

Supported in Windows PowerShell ISE 2.0 and later.

Specifies whether a warning message appears when the same file is opened in different PowerShell tabs. If set to `$true`, to open the same file in multiple tabs displays this message: "A copy of this file is open in another Windows PowerShell tab. Changes made to this file will affect all open copies." The default value is `$true`.

PowerShell

```
# Enable the warning message when a file is
# opened in multiple PowerShell tabs.
$psISE.Options.ShowWarningForDuplicateFiles = $true
```

TokenColors

Supported in Windows PowerShell ISE 2.0 and later.

Specifies the colors of the IntelliSense tokens in the Windows PowerShell ISE Script pane. This property is a dictionary object that contains name/value pairs of token types and colors for the Script pane. To change the colors of the IntelliSense tokens in the Console pane, see [ConsoleTokenColors](#). To reset the colors to the default values, see [RestoreDefaultTokenColors](#). Token colors can be set for the following: Attribute, Command, CommandArgument, CommandParameter, Comment, GroupEnd, GroupStart, Keyword, LineContinuation, LoopLabel, Member, NewLine, Number, Operator, Position, StatementSeparator, String, Type, Unknown, Variable.

PowerShell

```
# Sets the color of commands to green.
$psISE.Options.TokenColors["Command"] = "green"
# Sets the color of keywords to magenta.
$psISE.Options.TokenColors["Keyword"] = "magenta"
```

UseEnterToSelectInConsolePanelIntellisense

Supported in Windows PowerShell ISE 3.0 and later, and not present in earlier versions.

Specifies whether you can use the Enter key to select an IntelliSense provided option in the Console pane. The default value is `$true`.

PowerShell

```
# Turn off using the ENTER key to select an IntelliSense provided option in the
# Console pane.
$psISE.Options.UseEnterToSelectInConsolePaneIntellisense = $false
```

UseEnterToSelectInScriptPanelIntellisense

Supported in Windows PowerShell ISE 3.0 and later, and not present in earlier versions.

Specifies whether you can use the Enter key to select an IntelliSense-provided option in the Script pane. The default value is `$true`.

PowerShell

```
# Turn on using the Enter key to select an IntelliSense provided option in the
# Console pane.
$psISE.Options.UseEnterToSelectInConsolePaneIntellisense = $true
```

UseLocalHelp

Supported in Windows PowerShell ISE 3.0 and later, and not present in earlier versions.

Specifies whether the locally installed Help or the online Help appears when you press `F1` with the cursor positioned in a keyword. If set to `$true`, then a pop-up window shows content from the locally installed Help. You can install the Help files by running the `Update-Help` command. If set to `$false`, then your browser opens to a page on Microsoft Learn.

PowerShell

```
# Sets the option for the online help to be displayed.
$psISE.Options.UseLocalHelp = $false
# Sets the option for the local Help to be displayed.
$psISE.Options.UseLocalHelp = $true
```

VerboseBackgroundColor

Supported in Windows PowerShell ISE 2.0 and later.

Specifies the background color for verbose text that appears in the Console pane. It's a **System.Windows.Media.Color** object.

PowerShell

```
# Changes the background color for verbose text to blue.  
$psISE.Options.VerboseBackgroundColor = '#0000FF'
```

VerboseForegroundColor

Supported in Windows PowerShell ISE 2.0 and later.

Specifies the foreground color for verbose text that appears in the Console pane. It's a **System.Windows.Media.Color** object.

PowerShell

```
# Changes the foreground color for verbose text to yellow.  
$psISE.Options.VerboseForegroundColor = 'yellow'
```

WarningBackgroundColor

Supported in Windows PowerShell ISE 2.0 and later.

Specifies the background color for warning text that appears in the Console pane. It's a **System.Windows.Media.Color** object.

PowerShell

```
# Changes the background color for warning text to blue.  
$psISE.Options.WarningBackgroundColor = '#0000FF'
```

WarningForegroundColor

Supported in Windows PowerShell ISE 2.0 and later.

Specifies the foreground color for warning text that appears in the Output pane. It's a **System.Windows.Media.Color** object.

PowerShell

```
# Changes the foreground color for warning text to yellow.
```

```
$psISE.Options.WarningForegroundColor = 'yellow'
```

XmlTokenColors

Supported in Windows PowerShell ISE 3.0 and later, and not present in earlier versions.

Specifies a dictionary object that contains name/value pairs of token types and colors for XML content that's displayed in Windows PowerShell ISE. Token colors can be set for the following: Attribute, Command, CommandArgument, CommandParameter, Comment, GroupEnd, GroupStart, Keyword, LineContinuation, LoopLabel, Member, NewLine, Number, Operator, Position, StatementSeparator, String, Type, Unknown, Variable. Also see [RestoreDefaultXmlTokenColors](#).

PowerShell

```
# Sets the color of XML element names to green.  
$psISE.Options.XmlTokenColors["ElementName"] = 'green'  
# Sets the color of XML comments to magenta.  
$psISE.Options.XmlTokenColors["Comment"] = 'magenta'
```

Zoom

Supported in Windows PowerShell ISE 3.0 and later, and not present in earlier versions.

Specifies the relative size of text in both the Console and Script panes. The default value is 100. Smaller values cause the text in Windows PowerShell ISE to appear smaller while larger numbers cause text to appear larger. The value is an integer that ranges from 20 to 400.

PowerShell

```
# Changes the text in the Windows PowerShell ISE to be double its normal size.  
$psISE.Options.Zoom = 200
```

The ISESnippetCollection Object

Article • 03/27/2025

The **ISESnippetCollection** object is a collection of **ISESnippet** objects. The files collection that's associated with a **PowerShellTab** object is a member of this class. An example is the `$psISE.CurrentPowerShellTab.Files` collection.

Methods

Load(FilePathName)

Supported in Windows PowerShell ISE 3.0 and later, and not present in earlier versions.

Loads a `snippets.ps1xml` file that contains user-defined snippets. The easiest way to create snippets is to use the `New-IseSnippet` cmdlet, which automatically stores them in your profile folder so that they're loaded every time that you start Windows PowerShell ISE.

- **FilePathName** - String - The path and file name to a `snippets.ps1xml` file that contains snippet definitions.

PowerShell

```
# Loads a custom snippet file into the current PowerShell tab.
$joinPathSplat = @{
    Path = ( Split-Path $PROFILE)
    ChildPath = 'Snippets\MySnips.snippets.ps1xml'
    AdditionalChildPath =
}
$snipPath = Join-Path @joinPathSplat
```

The ISESnippetObject

Article • 03/27/2025

An **ISESnippet** object is an instance of the `Microsoft.PowerShell.Host.ISE.ISESnippet` class. The members of the `$psISE.CurrentPowerShellTab.Snippets` collection are all examples of **ISESnippet** objects. The easiest way to create a snippet is to use the [New-IseSnippet](#) cmdlet.

Properties

Author

Supported in Windows PowerShell ISE 3.0 and later, and not present in earlier versions.

The read-only property that gets the name of the author of the snippet.

PowerShell

```
# Get the author of the first snippet item
$psISE.CurrentPowerShellTab.Snippets.Item(0).Author
```

CodeFragment

Supported in Windows PowerShell ISE 3.0 and later, and not present in earlier versions.

The read-only property that gets the code fragment to be inserted into the editor.

PowerShell

```
# Get the code fragment associated with the first snippet item.
$psISE.CurrentPowerShellTab.Snippets.Item(0).CodeFragment
```

Shortcut

Supported in Windows PowerShell ISE 3.0 and later, and not present in earlier versions.

The read-only property that gets the Windows keyboard shortcut for the menu item.

PowerShell

```
# Get the shortcut for the first submenu item.  
$psISE.CurrentPowerShellTab.AddOnsMenu.Submenus.Clear()  
$psISE.CurrentPowerShellTab.AddOnsMenu.Submenus.Add('_Process', {Get-  
Process}, 'Alt+P')  
$psISE.CurrentPowerShellTab.AddOnsMenu.Submenus[0].Shortcut
```

The PowerShellTabCollection Object

Article • 03/27/2025

The **PowerShellTab** collection object is a collection of **PowerShellTab** objects. Each **PowerShellTab** object functions as a separate runtime environment. It's an instance of Microsoft.PowerShell.Host.ISE.PowerShellTabs class. An example is the `$psISE.PowerShellTabs` object.

Methods

Add()

Supported in Windows PowerShell ISE 2.0 and later.

Adds a new PowerShell tab to the collection. It returns the newly added tab.

PowerShell

```
$newTab = $psISE.PowerShellTabs.Add()  
$newTab.DisplayName = 'Brand New Tab'
```

Remove(**Microsoft.PowerShell.Host.ISE.PowerShellTab** **psTab**)

Supported in Windows PowerShell ISE 2.0 and later.

Removes the tab that's specified by the **psTab** parameter.

- **psTab** - The PowerShell tab to remove.

PowerShell

```
$newTab = $psISE.PowerShellTabs.Add()  
Change the DisplayName of the new PowerShell tab.  
$newTab.DisplayName = 'This tab will go away in 5 seconds'  
sleep 5  
$psISE.PowerShellTabs.Remove($newTab)
```

SetSelectedPowerShellTab(**Microsoft.PowerShell.Host.ISE.** **PowerShellTab** **psTab**)

Supported in Windows PowerShell ISE 2.0 and later.

Selects the PowerShell tab that's specified by the **psTab** parameter to make it the currently active PowerShell tab.

- **psTab** - The PowerShell tab to select.

```
PowerShell

# Save the current tab in a variable and rename it
$oldTab = $psISE.CurrentPowerShellTab
$psISE.CurrentPowerShellTab.DisplayName = 'Old Tab'
# Create a new tab and give it a new display name
$newTab = $psISE.PowerShellTabs.Add()
$newTab.DisplayName = 'Brand New Tab'
# Switch back to the original tab
$psISE.PowerShellTabs.SelectedPowerShellTab = $oldTab
```

The PowerShellTab Object

Article • 03/27/2025

The **PowerShellTab** object represents a Windows PowerShell runtime environment.

Methods

Invoke(Script)

Supported in Windows PowerShell ISE 2.0 and later.

Runs the given script in the PowerShell tab.

ⓘ Note

This method only works on other PowerShell tabs, not the PowerShell tab from which it's run. It doesn't return any object or value. If the code modifies any variable, then those changes persist on the tab against which the command was invoked.

- **Script** - System.Management.Automation.ScriptBlock or String - The script block to run.

PowerShell

```
# Manually create a second PowerShell tab before running this script.  
# Return to the first PowerShell tab and type the following command  
$psISE.PowerShellTabs[1].Invoke({dir})
```

InvokeSynchronous(Script, [useNewScope], millisecondsTimeout)

Supported in Windows PowerShell ISE 3.0 and later, and not present in earlier versions.

Runs the given script in the PowerShell tab.

ⓘ Note

This method only works on other PowerShell tabs, not the PowerShell tab from which it's run. The script block is run and any value that's returned from the script is

returned to the run environment from which you invoked the command. If the command takes longer to run than the **millisecondsTimeout** value specifies, then the command fails with an exception: "The operation has timed out."

- **Script** - System.Management.Automation.ScriptBlock or String - The script block to run.
- **[useNewScope]** - Optional Boolean that defaults to `$true` - If set to `$true`, then a new scope is created within which to run the command. It doesn't modify the runtime environment of the PowerShell tab that's specified by the command.
- **[millisecondsTimeout]** - Optional integer that defaults to `500`. - If the command doesn't finish within the specified time, then the command generates a **TimeoutException** with the message "The operation has timed out."

PowerShell

```
# Create a new PowerShell tab and then switch back to the first
$psISE.PowerShellTabs.Add()
$psISE.PowerShellTabs.setSelectedPowerShellTab($psISE.PowerShellTabs[0])

# Invoke a simple command on the other tab, in its own scope
$psISE.PowerShellTabs[1].InvokeSynchronous('$x=1', $false)
# You can switch to the other tab and type '$x' to see that the value is
# saved there.

# This example sets a value in the other tab (in a different scope)
# and returns it through the pipeline to this tab to store in $a
$a = $psISE.PowerShellTabs[1].InvokeSynchronous('$z=3;$z')

# This example runs a command that takes longer than the allowed timeout
# value
# and measures how long it runs so that you can see the impact
Measure-Command {$psISE.PowerShellTabs[1].InvokeSynchronous('sleep 10',
    $false, 5000)}
```

Properties

AddOnsMenu

Supported in Windows PowerShell ISE 2.0 and later.

The read-only property that gets the Add-ons menu for the PowerShell tab.

PowerShell

```
# Clear the Add-ons menu if one exists.  
$psISE.CurrentPowerShellTab.AddOnsMenu.SubMenus.Clear()  
# Create an AddOns menu with an accessor.  
# Note the use of "_" as opposed to the "&" for mapping to the fast key  
letter for the menu item.  
$menuAdded = $psISE.CurrentPowerShellTab.AddOnsMenu.SubMenus.Add('Process',  
    {Get-Process}, 'Alt+P')  
# Add a nested menu.  
$parentAdded = $psISE.CurrentPowerShellTab.AddOnsMenu.SubMenus.Add('Parent',  
    $null, $null)  
$parentAdded.SubMenus.Add('Dir', {dir}, 'Alt+D')  
# Show the Add-ons menu on the current PowerShell tab.  
$psISE.CurrentPowerShellTab.AddOnsMenu
```

CanInvoke

Supported in Windows PowerShell ISE 2.0 and later.

The read-only Boolean property that returns a `$true` value if a script can be invoked with the [Invoke\(Script \)](#) method.

PowerShell

```
# CanInvoke will be false if the PowerShell  
# tab is running a script that takes a while, and you  
# check its properties from another PowerShell tab. It's  
# always false if checked on the current PowerShell tab.  
# Manually create a second PowerShell tab before running this script.  
# Return to the first tab and type  
$secondTab = $psISE.PowerShellTabs[1]  
$secondTab.CanInvoke  
$secondTab.Invoke({sleep 20})  
$secondTab.CanInvoke
```

ConsolePane

Supported in Windows PowerShell ISE 3.0 and later, and not present in earlier versions. In Windows PowerShell ISE 2.0 this was named **CommandPane**.

The read-only property that gets the Console pane [editor](#) object.

PowerShell

```
# Gets the Console Pane editor.  
$psISE.CurrentPowerShellTab.ConsolePane
```

DisplayName

Supported in Windows PowerShell ISE 2.0 and later.

The read-write property that gets or sets the text that's displayed on the PowerShell tab. By default, tabs are named "PowerShell #", where the # represents a number.

PowerShell

```
$newTab = $psISE.PowerShellTabs.Add()  
# Change the DisplayName of the new PowerShell tab.  
$newTab.DisplayName = 'Brand New Tab'
```

ExpandedScript

Supported in Windows PowerShell ISE 2.0 and later.

The read-write Boolean property that determines whether the Script pane is expanded or hidden.

PowerShell

```
# Toggle the expanded script property to see its effect.  
$psISE.CurrentPowerShellTab.ExpandedScript =  
!$psISE.CurrentPowerShellTab.ExpandedScript
```

Files

Supported in Windows PowerShell ISE 2.0 and later.

The read-only property that gets the [collection of script files](#) that are open in the PowerShell tab.

PowerShell

```
$newFile = $psISE.CurrentPowerShellTab.Files.Add()  
$newFile.Editor.Text = "a`r`nb"  
# Gets the line count  
$newFile.Editor.LineCount
```

Output

This feature is present in Windows PowerShell ISE 2.0, but was removed or renamed in later versions of the ISE. In later versions of Windows PowerShell ISE, you can use the **ConsolePane** object for the same purposes.

The read-only property that gets the Output pane of the current [editor](#).

```
PowerShell

# Clears the text in the Output pane.
$psISE.CurrentPowerShellTab.Output.Clear()
```

Prompt

Supported in Windows PowerShell ISE 2.0 and later.

The read-only property that gets the current prompt text. Note: the `prompt` function can be overridden by the user's profile. If the result is other than a simple string, then this property returns nothing.

```
PowerShell

# Gets the current prompt text.
$psISE.CurrentPowerShellTab.Prompt
```

ShowCommands

Supported in Windows PowerShell ISE 3.0 and later, and not present in earlier versions.

The read-write property that indicates if the Commands pane is currently displayed.

```
PowerShell

# Gets the current status of the Commands pane and stores it in the $a
variable
$a = $psISE.CurrentPowerShellTab.ShowCommands
# if $a is $false, then turn the Commands pane on by changing the value to
$true
if (!$a) {$psISE.CurrentPowerShellTab.ShowCommands = $true}
```

StatusText

Supported in Windows PowerShell ISE 2.0 and later.

The read-only property that gets the **PowerShellTab** status text.

PowerShell

```
# Gets the current status text,  
$psISE.CurrentPowerShellTab.StatusText
```

HorizontalAddOnToolsPaneOpened

Supported in Windows PowerShell ISE 3.0 and later, and not present in earlier versions.

The read-only property that indicates whether the horizontal Add-Ons tool pane is currently open.

PowerShell

```
# Gets the current state of the horizontal Add-ons tool pane.  
$psISE.CurrentPowerShellTab.HorizontalAddOnToolsPaneOpened
```

VerticalAddOnToolsPaneOpened

Supported in Windows PowerShell ISE 3.0 and later, and not present in earlier versions.

The read-only property that indicates whether the vertical Add-Ons tool pane is currently open.

PowerShell

```
# Turns on the Commands pane  
$psISE.CurrentPowerShellTab.ShowCommands = $true  
# Gets the current state of the vertical Add-ons tool pane.  
$psISE.CurrentPowerShellTab.VerticalAddOnToolsPaneOpened
```

Other Useful Scripting Objects

Article • 03/27/2025

The following objects provide additional scripting functionality in Windows PowerShell ISE. They aren't part of the `$psISE` hierarchy.

Useful Scripting objects

\$psUnsupportedConsoleApplications

There are some limitations on how Windows PowerShell ISE interacts with console applications. A command or an automation script that requires user intervention might not work the way it works from the Windows PowerShell console. You might want to block these commands or scripts from running in the Windows PowerShell ISE Command pane. The `$psUnsupportedConsoleApplications` object keeps a list of such commands. If you try to run the commands in this list, you get a message that they aren't supported. The following script adds an entry to the list.

```
PowerShell

# List the unsupported commands
$psUnsupportedConsoleApplications

# Add a command to this list
$psUnsupportedConsoleApplications.Add('Mycommand')

# Show the augmented list of commands
$psUnsupportedConsoleApplications
```

\$psLocalHelp

This is a dictionary object that maintains a context-sensitive mapping between Help topics and their associated links in the local compiled HTML Help file. It's used to locate the local Help for a particular topic. You can add or delete topics from this list. The following code example shows some example key-value pairs that are contained in `$psLocalHelp`.

```
PowerShell

# See the local help map
$psLocalHelp | Format-List
```

Output

```
Key    : Add-Computer
Value  : WindowsPowerShellHelp.chm::/html/093f660c-b8d5-43cf-aa0c-
54e5e54e76f9.htm
```

```
Key    : Add-Content
Value  : WindowsPowerShellHelp.chm::/html/0c836a1b-f389-4e9a-9325-
0f415686d194.htm
```

The following script adds an entry to the list.

PowerShell

```
$psLocalHelp.Add("Get-MyNoun", "C:\MyFolder\MyHelpChm.chm::/html/0198854a-
1298-57ae-aa0c-87b5e5a84712.htm")
```

\$psOnlineHelp

This is a dictionary object that maintains a context-sensitive mapping between topic titles of Help topics and their associated external URLs. It's used to locate the Help for a particular topic on the web. You can add or delete topics from this list.

PowerShell

```
$psOnlineHelp | Format-List
```

Output

```
Key    : Add-Computer
Value  : https://go.microsoft.com/fwlink/?LinkID=135194
```

```
Key    : Add-Content
Value  : https://go.microsoft.com/fwlink/?LinkID=113278
```

The following script adds an entry to the list.

PowerShell

```
$psOnlineHelp.Add("Get-MyNoun", "https://www.mydomain.com/MyNoun.html")
```

Purpose of the Windows PowerShell ISE Scripting Object Model

Starting Windows PowerShell

Article • 03/27/2025

Windows PowerShell is a scripting engine embedded into multiple hosts. The most common hosts are the interactive command-line `powershell.exe` and the Interactive Scripting Environment `powershell_ise.exe`.

PowerShell binary name

PowerShell version 6 and higher uses .NET (Core). Supported versions are available on Windows, macOS, and Linux.

Beginning in PowerShell 6, the PowerShell binary named `pwsh.exe` for Windows and `pwsh` for macOS and Linux. You can start PowerShell preview versions using `pwsh-preview`. For more information, see [About pwsh](#).

To find cmdlet reference and installation documentation for PowerShell 7, use the following links:

Expand table

Document	Link
Cmdlet reference	PowerShell Module Browser
Windows installation	Installing PowerShell on Windows
macOS installation	Installing PowerShell on macOS
Linux installation	Installing PowerShell on Linux

To view content for other PowerShell versions, see [How to use the PowerShell documentation](#).

Run from the Start Menu

- Open the Start menu, type Windows PowerShell, select Windows PowerShell, then select Open.

Run from the Command Prompt

In Windows Command shell, Windows PowerShell, or Windows PowerShell ISE, to start Windows PowerShell, type: `PowerShell`.

You can also use the parameters of the `powershell.exe` program to customize the session. For more information, see [about_PowerShell_exe](#).

Run with administrative privileges

Open the **Start** menu, type **Windows PowerShell**, select **Windows PowerShell**, and then select **Run as administrator**.

How to Start Windows PowerShell ISE on Earlier Releases of Windows

Use any of the following methods to start Windows PowerShell ISE.

Run from the Start Menu

- Open the **Start** menu, type **ISE**, select **Windows PowerShell ISE**, then select **Open**.

At the Command Prompt

In Windows Command shell, Windows PowerShell, or Windows PowerShell ISE, to start Windows PowerShell, type: `PowerShell_ISE`. In Windows PowerShell, you can use the alias `ise`.

Run with administrative privileges

Select **Start**, type **ISE**, right-click **Windows PowerShell ISE**, and then click **Run as administrator**.

Starting the 32-Bit Version of Windows PowerShell

64-bit versions of Windows include a 32-bit version of Windows PowerShell, **Windows PowerShell (x86)**, in addition to the 64-bit version. The 64-bit version runs by default.

However, you might occasionally need to run **Windows PowerShell (x86)**, such as when you're using a module that requires the 32-bit version or when you're connecting

remotely to a 32-bit computer.

To start a 32-bit version of Windows PowerShell, use any of the following procedures.

- Select **Start**, type **Windows PowerShell**, select **Windows PowerShell (x86)**, then select **Open**.

Windows Management Framework

Article • 03/27/2025

Windows Management Framework (WMF) provides a consistent management interface for Windows. WMF provides a seamless way to manage various versions of Windows client and Windows Server. WMF installer packages contain updates to management functionality and are available for older versions of Windows.

Note

WMF 5.1 is the only supported version of WMF and is included in all currently supported versions of Windows. This information in this article provides a history of WMF versions.

WMF installation adds and/or updates the following features:

- Windows PowerShell
- Windows PowerShell Desired State Configuration (DSC)
- Windows PowerShell Integrated Script Environment (ISE)
- Windows Remote Management (WinRM)
- Windows Management Instrumentation (WMI)
- Windows PowerShell Web Services (Management OData IIS Extension)
- Software Inventory Logging (SIL)
- Server Manager CIM Provider

WMF Release Notes

To learn about the enhancements in Windows PowerShell and other components, see the release notes for each version of WMF:

- [WMF 5.1](#)

PowerShell security features

Article • 05/22/2025

PowerShell has several features designed to improve the security of your scripting environment.

Execution policy

PowerShell's execution policy is a safety feature that controls the conditions under which PowerShell loads configuration files and runs scripts. This feature helps prevent the execution of malicious scripts. You can use a Group Policy setting to set execution policies for computers and users. Execution policies only apply to the Windows platform.

For more information, see [about_Execution_Policies](#).

Use of the `SecureString` class

PowerShell has several cmdlets that support the use of the `System.Security.SecureString` class. And, as with any .NET class, you can use `SecureString` in your own scripts. However, Microsoft doesn't recommend using `SecureString` for new development. Microsoft recommends that you avoid using passwords and rely on other means to authenticate, such as certificates or Windows authentication.

PowerShell continues to support the `SecureString` class for backward compatibility. Using a `SecureString` is still more secure than using a plain text string. PowerShell still relies on the `SecureString` type to avoid accidentally exposing the contents to the console or in logs. Use `SecureString` carefully, because it can be easily converted to a plain text string. For a full discussion about using `SecureString`, see the [System.Security.SecureString class](#) documentation.

Module and script block logging

Module Logging allows you to enable logging for selected PowerShell modules. This setting is effective in all sessions on the computer. PowerShell records pipeline execution events for the specified modules in the Windows PowerShell event log.

Script Block Logging enables logging for the processing of commands, script blocks, functions, and scripts - whether invoked interactively, or through automation. PowerShell logs this information to the **Microsoft-Windows-PowerShell/Operational** event log.

For more information, see the following articles:

- [about_Group_Policy_Settings](#)
- [about_Logging_Windows](#)
- [about_Logging_Non-Windows](#)

AMSI Support

The Windows Antimalware Scan Interface (AMSI) is an API that allows applications to pass actions to an antimalware scanner, such as Windows Defender, to scan for malicious payloads. Beginning with PowerShell 5.1, PowerShell running on Windows 10 (and higher) passes all script blocks to AMSI.

PowerShell 7.3 extends the data it sends to AMSI for inspection. It now includes all .NET method invocations.

For more information about AMSI, see [How AMSI helps](#).

Constrained language mode

`ConstrainedLanguage` mode protects your system by limiting the cmdlets and .NET types allowed in a PowerShell session. For a full description, see [about_Language_Modes](#).

Application Control

Windows 10 includes two technologies, [App Control for Business](#) and [AppLocker](#) that you can use to control applications. PowerShell detects if a system wide application control policy is being enforced. The policy applies certain behaviors when running script blocks, script files, or loading module files to prevent arbitrary code execution on the system.

App Control for Business is designed as a security feature under the servicing criteria defined by the Microsoft Security Response Center (MSRC). App Control is the preferred application control system for Windows.

For more information about how PowerShell supports AppLocker and App Control, see [Use App Control to secure PowerShell](#).

Software Bill of Materials (SBOM)

Beginning with PowerShell 7.2, all install packages contain a Software Bill of Materials (SBOM). The PowerShell team also produces SBOMs for modules that they own but ship independently from PowerShell.

You can find SBOM files in the following locations:

- In PowerShell, find the SBOM at `$PSHOME/_manifest/spdx_2.2/manifest.spdx.json`.
- For modules, find the SBOM in the module's folder under
`_manifest/spdx_2.2/manifest.spdx.json`.

The creation and publishing of the SBOM is the first step to modernize Federal Government cybersecurity and enhance software supply chain security. For more information about this initiative, see the blog post [Generating SBOMs with SPDX at Microsoft](#).

Security Servicing Criteria

PowerShell follows the [Microsoft Security Servicing Criteria for Windows](#). Only security features meet the criteria for servicing.

Use App Control to secure PowerShell

Article • 10/21/2024

Windows 10 includes two technologies, [App Control for Business](#) and [AppLocker](#), that you can use to control applications. They allow you to create a lockdown experience to help secure your PowerShell environment.

AppLocker builds on the application control features of Software Restriction Policies. AppLocker allows you to create rules to allow or deny apps for specific users or groups. You identify the apps based on unique properties of the files.

Application Control for Business, introduced in Windows 10 as Windows Defender Application Control (WDAC), allows you to control which drivers and applications are allowed to run on Windows.

Lockdown policy detection

PowerShell detects both AppLocker and App Control for Business system wide policies. AppLocker doesn't have way to query the policy enforcement status. To detect if a system wide application control policy is being enforced by AppLocker, PowerShell creates two temporary files and tests if they can be executed. The filenames use the following name format:

- `$Env:TEMP/_PSAppLockerTest_\<random-8dot3-name>.ps1`
- `$Env:TEMP/_PSAppLockerTest_\<random-8dot3-name>.psm1`

App Control for Business is the preferred application control system for Windows. App Control provides APIs that allow you to discover the policy configuration. App Control is designed as a security feature under the servicing criteria defined by the Microsoft Security Response Center (MSRC). For more information, see [Application Controls for Windows](#) and [App Control and AppLocker feature availability](#).

ⓘ Note

When [choosing between App Control or AppLocker](#), we recommend that you implement application control using App Control for Business rather than AppLocker. Microsoft is no longer investing in AppLocker. Although AppLocker may continue to receive security fixes, it won't receive feature enhancements.

App Control policy enforcement

When PowerShell runs under an App Control policy, its behavior changes based on the defined security policy. Under an App Control policy, PowerShell runs trusted scripts and modules allowed by the policy in `FullLanguage` mode. All other scripts and script blocks are untrusted and run in `ConstrainedLanguage` mode. PowerShell throws errors when the untrusted scripts attempt to perform actions that aren't allowed in `ConstrainedLanguage` mode. It can be difficult to know why a script failed to run correctly in `ConstrainedLanguage` mode.

App Control policy auditing

PowerShell 7.4 added a new feature to support App Control policies in **Audit** mode. In audit mode, PowerShell runs the untrusted scripts in `ConstrainedLanguage` mode without errors, but logs messages to the event log instead. The log messages describe what restrictions would apply if the policy were in **Enforce** mode.

History of changes

Windows PowerShell 5.1 was the first version of PowerShell to support App Control. The security features of App Control and AppLocker improve with each new release of PowerShell. The following sections describe how this support changed in each version of PowerShell. The changes are cumulative, so the features described in the later versions include those from earlier versions.

Changes in PowerShell 7.4

On Windows, when PowerShell runs under an App Control policy, its behavior changes based on the defined security policy. Under an App Control policy, PowerShell runs trusted scripts and modules allowed by the policy in `FullLanguage` mode. All other scripts and script blocks are untrusted and run in `ConstrainedLanguage` mode.

PowerShell throws errors when the untrusted scripts attempt to perform disallowed actions. It's difficult to know why a script fails to run correctly in `ConstrainedLanguage` mode.

PowerShell 7.4 now supports App Control policies in **Audit** mode. In audit mode, PowerShell runs the untrusted scripts in `ConstrainedLanguage` mode but logs messages to the event log instead of throwing errors. The log messages describe what restrictions would apply if the policy were in **Enforce** mode.

Changes in PowerShell 7.3

- PowerShell 7.3 now supports the ability to block or allow PowerShell script files via the App Control API.

Changes in PowerShell 7.2

- There was a corner-case scenario in AppLocker where you only have **Deny** rules and constrained mode isn't used to enforce the policy that allows you to bypass the execution policy. Beginning in PowerShell 7.2, a change was made to ensure AppLocker rules take precedence over a `Set-ExecutionPolicy -ExecutionPolicy Bypass` command.
- PowerShell 7.2 now disallows the use of the `Add-Type` cmdlet in a `NoLanguage` mode PowerShell session on a locked down machine.
- PowerShell 7.2 now disallows scripts from using COM objects in AppLocker system lockdown conditions. Cmdlets that use COM or DCOM internally aren't affected.

How App Control works with PowerShell

Article • 10/21/2024

This article explains how **App Control for Business** secures PowerShell and the restrictions it imposes. The secure behavior of PowerShell varies based on the version of Windows and PowerShell you're using.

How PowerShell detects a system lockdown policy

PowerShell detects both **AppLocker** and **App Control for Business** system wide policies. AppLocker is deprecated. App Control is the preferred application control system for Windows.

Legacy App Control policy enforcement detection

PowerShell uses the legacy App Control `W1dpGetLockdownPolicy` API to discover two things:

- System wide policy enforcement: `None`, `Audit`, `Enforce`
- Individual file policy: `None`, `Audit` (allowed by policy), `Enforce` (not allowed by policy)

All versions of PowerShell (v5.1 - v7.x) support this App Control policy detection.

Latest App Control policy enforcement detection

App Control introduced new APIs in recent versions of Windows. Beginning with version 7.3, PowerShell uses the new `W1dpCanExecuteFile` API to decide how a file should be handled. Windows PowerShell 5.1 doesn't support this new API. The new API takes precedence over the legacy API for individual files. However, PowerShell continues to use the legacy API to get the system wide policy configuration. If the new API isn't available, PowerShell falls back to the old API behavior.

The new API provides the following information for each file:

- `WLDP_CAN_EXECUTE_ALLOWED`
- `WLDP_CAN_EXECUTE_BLOCKED`
- `WLDP_CAN_EXECUTE_REQUIRE_SANDBOX`

PowerShell behavior under lockdown policy

PowerShell can run in both interactive and non-interactive modes.

- In interactive mode, PowerShell is a command-line application that takes users command-line input as commands or scripts to run. Results are displayed back to the user.
- In non-interactive mode, PowerShell loads modules and runs script files without user input. Result data streams are either ignored or redirected to a file.

Interactive mode running under policy enforcement

PowerShell runs commands in `ConstrainedLanguage` mode. This mode prevents interactive users from running certain commands or executing arbitrary code. For more information about the restrictions in this mode, see the [PowerShell restrictions under lockdown policy](#) section of this article.

Noninteractive mode running under policy enforcement

When PowerShell runs a script or loads a module, it uses the App Control API to get the policy enforcement for the file.

PowerShell version 7.3 or higher uses the `W1dpCanExecuteFile` API if available. This API returns one of the following results:

- `WLDP_CAN_EXECUTE_ALLOWED`: The file is approved by policy and is used in `FullLanguage` mode with a few restrictions.
- `WLDP_CAN_EXECUTE_BLOCKED`: The file isn't approved by policy. PowerShell throws an error when the file is run or loaded.
- `WLDP_CAN_EXECUTE_REQUIRE_SANDBOX`: The file isn't approved by the policy but it can still be run or loaded in `ConstrainedLanguage` mode.

In Windows PowerShell 5.1 or if `W1dpCanExecuteFile` API isn't available, PowerShell's per file behavior is:

- `None`: The file is run loaded in `FullLanguage` mode with a few restrictions.
- `Audit`: The file is run or loaded in `FullLanguage` mode with no restrictions. In PowerShell 7.4 or higher, the policy logs restriction information to the Windows event logs.
- `Enforce`: The file is run or loaded in `ConstrainedLanguage` mode.

PowerShell restrictions under lockdown policy

When PowerShell detects the system is under a App Control lockdown policy, it applies restrictions even if the script is trusted and running in `FullLanguage` mode. These restrictions prevent known behaviors of PowerShell that could result in arbitrary code execution on a locked-down system. The lockdown policy enforces the following restrictions:

- Module dot-sourcing with wildcard function export restriction

Any module that uses script dot-sourcing and exports functions using wildcard names results in an error. Blocking wildcard exports prevents script injection from a malicious user who can plant an untrusted script that gets dot-sourced into a trusted module. The malicious script could then gain access to the trusted module's private functions.

Security recommendation: Never use script dot-sourcing in a module and always export module functions with explicit names (no wildcard characters).

- Nested module with wildcard function export restriction

If a parent module exports functions using function name wildcard characters, PowerShell removes any function name in a nested module from the function export list. Blocking wildcard exports from nested modules prevents accidental exporting of dangerous nested functions through wildcard name matching.

Security recommendation: Always export module functions with explicit names (no wildcard characters).

- Interactive shell parameter type conversion

When the system is locked down, interactive PowerShell sessions run in `ConstrainedLanguage` mode to prevent arbitrary code execution. Trusted modules loaded into the session run in `FullLanguage` mode. If a trusted module cmdlet uses complex types for its parameters, type conversion during parameter binding can fail if the conversion isn't allowed across trust boundaries. The failure occurs when PowerShell tries to convert a value by running a type constructor. Type constructors aren't allowed to run in `ConstrainedLanguage` mode.

In this example, parameter binding type conversion is normally allowed, but fails when run in `ConstrainedLanguage` mode. The `ConnectionPort` type constructor isn't allowed:

```
PowerShell

PS> Create-ConnectionOnPort -Connection 22
Create-ConnectionOnPort: Cannot bind parameter 'Connection'. Cannot convert
the "22"
value of type "System.Int32" to type "ConnectionPort".
```

- `Enter-PSTokenHost` cmdlet disallowed

The `Enter-PSTokenHost` cmdlet is disabled and throws an error if used. This command is used for attach-and-debug sessions. It allows you to connect to any other PowerShell

session on the local machine. The cmdlet is disabled to prevent information disclosure and arbitrary code execution.

PowerShell restrictions under constrained language mode

Script or function that isn't approved by the App Control policy is untrusted. When you run an untrusted command, PowerShell either blocks the command from running (new behavior) or runs the command in `ConstrainedLanguage` mode. The following restrictions apply to

`ConstrainedLanguage` mode:

- `Add-Type` cmdlet disallowed

Blocking `Add-Type` prevents the execution of arbitrary .NET code.

- `Import-LocalizedData` cmdlet restricted

Blocking the `SupportedCommand` parameter of `Import-LocalizedData` prevents the execution of arbitrary code.

- `Invoke-Expression` cmdlet restricted

All script blocks passed to the `Invoke-Expression` cmdlet are run in `ConstrainedLanguage` mode to prevent arbitrary code execution.

- `New-Object` cmdlet restricted

The `New-Object` cmdlet is restricted to use only allowed .NET and COM types, to prevent access to untrusted types.

- `ForEach-Object` cmdlet restriction

Type method invocation for variables passed to the `ForEach-Object` is disallowed for any .NET type not in the approved list. In general, `ConstrainedLanguage` mode disallows any object method invocation except for approved .NET types to prevent access to untrusted .NET types.

- `Export-ModuleMember` cmdlet restriction

Using `Export-ModuleMember` cmdlet to export functions in a nested module script file where the child module isn't trusted and the parent module is trusted, results in an error. Blocking this scenario prevents a malicious untrusted module from exporting dangerous functions from a trusted module.

- `New-Module` cmdlet restriction

When you run `New-Module` in a trusted script, any script block provided by the `ScriptBlock` parameter is marked to run in `ConstrainedLanguage` mode to prevent the injection of arbitrary code into a trusted execution context.

- `Configuration` keyword not allowed

The `Configuration` language keyword isn't allowed in `ConstrainedLanguage` mode to prevent code injection attacks.

- `class` keyword not allowed

The `class` language keyword isn't allowed in `ConstrainedLanguage` mode to prevent the injection of arbitrary code.

- Script Block processing scope restrictions

Child script blocks aren't allowed to run in parent script block scopes if the script blocks have different trust levels. For example, you create a child relationship when you dot-source one script into another. Blocking this scenario prevents an untrusted script from getting access to dangerous functions in the trusted script scope.

- Prevent command discovery of untrusted script functions

PowerShell command discovery doesn't return functions from an untrusted source, such as an untrusted script or module, to a trusted function. Blocking discovery of untrusted commands prevents code injection through command planting.

- Hashtable to object conversion not allowed

`ConstrainedLanguage` mode blocks hashtable to object conversions in the `Data` sections of PowerShell data (`.psd1`) files to prevent potential code injection attacks.

- Automatic type conversion restricted

`ConstrainedLanguage` mode blocks automatic type conversion except for a small set of approved safe types to prevent potential code injection attacks.

- Implicit module function export restriction

If a module doesn't explicitly export functions, PowerShell implicitly exports all defined module functions automatically as a convenience feature. In `ConstrainedLanguage` mode, implicit exports no longer occur when a module is loaded across trust boundaries.

Blocking implicit exports prevents unintended exposure of dangerous module functions not meant for public use.

- Script files can't be imported as modules

PowerShell allows you to import script files (`.ps1`) as a module. All defined functions become publicly accessible. `ConstrainedLanguage` mode blocks importation of script file to prevent unintended exposure of dangerous script functions.

- Setting variables `AllScope` restriction

`ConstrainedLanguage` mode disables the ability to set `AllScope` on variables. Limiting the scope of variables prevents the variables from interfering with the session state of trusted commands.

- Type method invocation not allowed

`ConstrainedLanguage` mode doesn't allow method invocation on unapproved types.

Blocking methods on unapproved types prevents invocation of .NET type methods that might be dangerous or allow code injection.

- Type property setters not allowed

`ConstrainedLanguage` mode restricts invocation of property setters on unapproved types.

Blocking property setters on unapproved types prevents code injection attacks.

- Type creation not allowed

`ConstrainedLanguage` mode blocks type creation on unapproved types to block untrusted constructors that could allow code injection.

- Module scope operator not allowed

`ConstrainedLanguage` mode doesn't allow the use of the module scope operator. For example: `& (Get-Module MyModule) MyFunction`. Blocking the module scope operator prevents access to module private functions and variables.

Further reading

How to use App Control to secure PowerShell

Article • 10/21/2024

This article describes how to set up a **App Control for Business** policy. You can configure the policy to enforce or audit the policy's rule. In audit mode, PowerShell behavior doesn't change but it logs Event ID 16387 messages to the `PowerShellCore/Analytic` event log. In enforcement mode, PowerShell applies the policy's restrictions.

This article assumes you're using a test machine so that you can test PowerShell behavior under a machine wide App Control policy before you deploy the policy in your environment.

Create an App Control policy

An App Control policy is described in an XML file, which contains information about policy options, files allowed, and signing certificates recognized by the policy. When the policy is applied, only approved files are allowed to load and run. PowerShell either blocks unapproved script files from running or runs them in `ConstrainedLanguage` mode, depending on policy options.

You create and manipulate App Control policy using the **ConfigCI** module, which is available on all supported Windows versions. This Windows PowerShell module can be used in Windows PowerShell 5.1 or in PowerShell 7 through the **Windows Compatibility** layer. It's easier to use this module in Windows PowerShell. The policy you create can be applied to any version of PowerShell.

Steps to create an App Control policy

For testing, you just need to create a default policy and a self signed code signing certificate.

1. Create a default policy

```
PowerShell  
New-CIPolicy -Level PcaCertificate -FilePath .\SystemCIPolicy.xml -UserPEs
```

This command creates a default policy file called `SystemCIPolicy.xml` that allows all Microsoft code-signed files to run.

 Note

Running this command can take up to two hours because it must scan the entire test machine.

2. Disable Audit Mode in default policy

A new policy is always created in `Audit` mode. To test policy enforcement, you need to disable Audit mode when you apply the policy. Edit the `SystemCIPolicy.xml` file using a text editor like `notepad.exe` or Visual Studio Code (VS Code). Comment out the `Audit mode` option.

XML

```
<!--
<Rule>
  <Option>Enabled:Audit Mode</Option>
</Rule>
-->
```

3. Create a self-signed code signing certificate

You need a code signing certificate to sign any test binaries or script files that you want to run on your test machine. The `New-SelfSignedCertificate` is provided by the **PKI** module. For best results, you should run this command in Windows PowerShell 5.1.

PowerShell

```
$newSelfSignedCertificateSplat = @{
    DnsName = $Env:COMPUTERNAME
    CertStoreLocation = "Cert:\CurrentUser\My\" 
    Type = 'CodeSigningCert'
}
$cert = New-SelfSignedCertificate @newSelfSignedCertificateSplat
Export-Certificate -Cert $cert -FilePath C:\certs\signing.cer
Import-Certificate -FilePath C:\certs\signing.cer -CertStoreLocation
"Cert:\CurrentUser\Root\
$cert = Get-ChildItem Cert:\CurrentUser\My\ -CodeSigningCert

dir C:\bin\PowerShell\pwsh.exe | Set-AuthenticodeSignature -Certificate $cert
```

4. Add the code signing certificate to the policy

Use the following command to add the new code signing certificate to the policy.

PowerShell

```
Add-SignerRule -FilePath .\SystemCIPolicy.xml -CertificatePath
```

```
C:\certs\signing.cer -User
```

5. Convert the XML policy file to a policy enforcement binary file

Finally, you need to convert the XML file to a binary file used by App Control to apply a policy.

PowerShell

```
ConvertFrom-CIPolicy -XmlFilePath .\SystemCIPolicy.xml -BinaryFilePath  
.\\SIPolicy.p7b
```

6. Apply the App Control policy

To apply the policy to your test machine, copy the `SIPolicy.p7b` file to the required system location, `C:\Windows\System32\CodeIntegrity`.

ⓘ Note

Some policies definition must be copied to a subfolder such as

`C:\Windows\System32\CodeIntegrity\CiPolicies`. For more information, see [App Control Admin Tips & Known Issues](#).

7. Disable the App Control policy

To disable the policy, rename the `SIPolicy.p7b` file. If you need to do more testing, you can change the name back to reenable the policy.

PowerShell

```
Rename-Item -Path .\\SIPolicy.p7b -NewName .\\SIPolicy.p7b.off
```

Test using App Control policy auditing

PowerShell 7.4 added a new feature to support App Control policies in **Audit** mode. In audit mode, PowerShell runs the untrusted scripts in `ConstrainedLanguage` mode without errors, but logs messages to the event log instead. The log messages describe what restrictions would apply if the policy were in **Enforce** mode.

Viewing audit events

PowerShell logs audit events to the **PowerShellCore/Analytic** event log. The log isn't enabled by default. To enable the log, open the **Windows Event Viewer**, right-click on the **PowerShellCore/Analytic** log and select **Enable Log**.

Alternatively, you can run the following command from an elevated PowerShell session.

```
PowerShell  
  
wevtutil.exe sl PowerShellCore/Analytic /enabled:true /quiet
```

You can view the events in the Windows Event Viewer or use the `Get-WinEvent` cmdlet to retrieve the events.

```
PowerShell  
  
Get-WinEvent -LogName PowerShellCore/Analytic -Oldest |  
    Where-Object Id -EQ 16387 | Format-List
```

```
Output  
  
TimeCreated : 4/19/2023 10:11:07 AM  
ProviderName : PowerShellCore  
Id          : 16387  
Message      : App Control Audit.  
  
    Title: Method or Property Invocation  
    Message: Method or Property 'WriteLine' on type 'System.Console' invocation  
will not  
        be allowed in ConstrainedLanguage mode.  
        At C:\scripts\Test1.ps1:3 char:1  
        + [System.Console]::WriteLine("pwd!")  
        + ~~~~~  
FullyQualifiedId: MethodOrPropertyInvocationNotAllowed
```

The event message includes the script position where the restriction would be applied. This information helps you understand where you need to change your script so that it runs under the App Control policy.

ⓘ Important

Once you have reviewed the audit events, you should disable the Analytic log. Analytic logs grow quickly and consume large amounts of disk space.

Viewing audit events in the PowerShell debugger

If you set the `$DebugPreference` variable to `Break` for an interactive PowerShell session, PowerShell breaks into the command-line script debugger at the current location in the script where the audit event occurred. The breakpoint allows you to debug your code and inspect the current state of the script in real time.

Preventing script injection attacks

Article • 04/01/2024

PowerShell scripts, like other programming languages, can be vulnerable to injection attacks. An injection attack occurs when a user provides input to a vulnerable function that includes extra commands. The vulnerable function runs the extra commands, which can be a serious security vulnerability. For example, a malicious user could abuse the vulnerable function to run arbitrary code on a remote computer, possibly compromising that computer and gaining access to other machines on the network.

Once you are aware of the issue, there are several ways to protect against injection attacks.

Example of vulnerable code

PowerShell code injection vulnerabilities involve user input that contains script code. The user input is added to vulnerable script where it's parsed and run by PowerShell.

```
PowerShell

function Get-ProcessById
{
    param ($ProcId)

    Invoke-Expression -Command "Get-Process -Id $ProcId"
}
```

The `Get-ProcessById` function looks up a local process by its Id value. It takes a `$ProcId` parameter argument of any type. The `$ProcId` is then converted to a string and inserted into another script that's parsed and run using the `Invoke-Expression` cmdlet. This function works fine when a valid process Id integer is passed in.

```
PowerShell

Get-ProcessById $PID

  NPM(K)   PM(M)   WS(M)   CPU(s)      Id  SI ProcessName
  -----  -----  -----  -----  --  --  -----
  97      50.09   132.72   1.20     12528  3  pwsh
```

However, the `$ProcId` parameter doesn't specify a type. It accepts any arbitrary string value that can include other commands.

```
PowerShell
```

```
Get-ProcessById "$PID; Write-Host 'pwnd!'"
```

In this example, the function correctly retrieved the process identified by `$PID`, but also ran the injected script `Write-Host 'pwnd!'`.

```
Output
```

NPM(K)	PM(M)	WS(M)	CPU(s)	Id	SI	ProcessName
-----	-----	-----	-----	--	--	-----
92	45.66	122.52	1.06	21736	3	pwsh
pwnd!						

Ways to guard against injection attacks

There are several ways to guard against an injection attack.

Use typed input

You can specify a type for the `$ProcId` argument.

```
PowerShell
```

```
function Get-ProcessById
{
    param ([int] $ProcId)

    Invoke-Expression -Command "Get-Process -Id $ProcId"
}
Get-ProcessById "$PID; Write-Host 'pwnd!'"
```

```
Output
```

```
Get-ProcessById:
Line |
7 | Get-ProcessById "$PID; Write-Host 'pwnd!'" |
| ~~~~~
| Cannot process argument transformation on parameter 'ProcId'. Cannot
convert value
"8064; Write-Host 'pwnd!'" to type "System.Int32". Error: "The input string
'8064; Write-Host 'pwnd!'
was not in a correct format."
```

Here, the `$ProcId` input parameter is restricted to an integer type, so an error occurs when a string is passed in that can't be converted to an integer.

Don't use `Invoke-Expression`

Instead of using `Invoke-Expression`, directly call `Get-Process`, and let PowerShell's parameter binder validate the input.

```
PowerShell

function Get-ProcessById
{
    param ($ProcId)

    Get-Process -Id $ProcId
}
Get-ProcessById "$PID; Write-Host 'pwnd!'"
```

Output

```
Get-Process:
Line |
 5 |     Get-Process -Id $ProcId
   |     ~~~~~
   | Cannot bind parameter 'Id'. Cannot convert value "8064; Write-Host
'pwnd!'" to type
[System.Int32]. Error: "The input string '8064; Write-Host 'pwnd!' was not
in a correct
format."
```

As a best practice, you should avoid using `Invoke-Expression`, especially when handling user input. `Invoke-Expression` is dangerous because it parses and runs whatever string content you provide, making it vulnerable to injection attacks. It's better to rely on PowerShell parameter binding.

Wrap strings in single quotes

However, there are times when using `Invoke-Expression` is unavoidable and you also need to handle user string input. You can safely handle user input using single quotes around each string input variable. The single quote ensures that PowerShell's parser treats the user input as a single string literal.

PowerShell

```

function Get-ProcessById
{
    param ($ProcId)

    Invoke-Expression -Command "Get-Process -Id '$ProcId'"

}

Get-ProcessById "$PID; Write-Host 'pwnd!'"
```

Output

```

Get-Process: Cannot bind parameter 'Id'. Cannot convert value "8064; Write-
Host " to type
"System.Int32". Error: "The input string '8064; Write-Host' was not in a
correct format."
```

However, this version of the function isn't yet completely safe from injection attacks. A malicious user can still use single quotes in their input to inject code.

PowerShell

```
Get-ProcessById "$PID'; Write-Host 'pwnd!';'"
```

This example uses single quotes in the user input to force the function to run three separate statements, one of which is arbitrary code injected by the user.

Output

NPM(K)	PM(M)	WS(M)	CPU(s)	Id	SI	ProcessName
97	46.08	183.10	1.08	2524	3	pwsh
pwnd!						

Use the `EscapeSingleQuotedStringContent()` method

To protect against the user inserting their own single quote characters to exploit the function you must use the `EscapeSingleQuotedStringContent()` API. This is a static public method of the PowerShell

`System.Management.Automation.Language.CodeGeneration` class. This method makes the user input safe by escaping any single quotes included in the user input.

PowerShell

```
function Get-ProcessById
{
    param ($ProcId)

    $ProcIdClean = [System.Management.Automation.Language.CodeGeneration]::
        EscapeSingleQuotedStringContent("$ProcId")
    Invoke-Expression -Command "Get-Process -Id '$ProcIdClean'"
}

Get-ProcessById "$PID"; Write-Host 'pwnd!'; ''
```

Output

```
Get-Process: Cannot bind parameter 'Id'. Cannot convert value "8064"; Write-
Host 'pwnd!'; '' to type
"System.Int32". Error: "The input string '8064'; Write-Host 'pnd!'; '' was
not in a correct format."
```

For more information, see [EscapeSingleQuotedStringContent\(\)](#).

Detecting vulnerable code with Injection Hunter

Injection Hunter is a module written by Lee Holmes that contains PowerShell Script Analyzer rules for detecting code injection vulnerabilities. Use one of the following commands to install the module from the PowerShell Gallery:

PowerShell

```
# Use PowerShellGet v2.x
Install-Module InjectionHunter

# Use PowerShellGet v3.x
Install-PSResource InjectionHunter
```

You can use this to automate security analysis during builds, continuous integration processes, deployments, and other scenarios.

PowerShell

```
$RulePath = (Get-Module -List InjectionHunter).Path
Invoke-ScriptAnalyzer -CustomRulePath $RulePath -Path .\Invoke-Dangerous.ps1
```

Output

RuleName	Severity	ScriptName	Line	Message
-----	-----	-----	-----	-----
InjectionRisk.InvokeExpression	Warning	Invoke-Dan	3	Possible
script injection risk via the		gerous.ps1		
Expression cmdlet. Untrusted input can cause				Invoke-
PowerShell expressions to be run.				arbitrary
may be used directly for dynamic parameter				Variables
splatting can be used for dynamic				arguments,
names, and the invocation operator can be				parameter
dynamic command names. If content escaping				used for
needed, PowerShell has several valid quote				is truly
characters, so [System.Management.Automation.Languag				
e.CodeGeneration]::Escape* should be used.				

For more information, see [PSScriptAnalyzer](#).

Just Enough Administration

Article • 04/01/2024

Just Enough Administration (JEA) is a security technology that enables delegated administration for anything managed by PowerShell. With JEA, you can:

- **Reduce the number of administrators on your machines** using virtual accounts or group-managed service accounts to perform privileged actions on behalf of regular users.
- **Limit what users can do** by specifying which cmdlets, functions, and external commands they can run.
- **Better understand what your users are doing** with transcripts and logs that show you exactly which commands a user executed during their session.

Why is JEA important?

Highly privileged accounts used to administer your servers pose a serious security risk. Should an attacker compromise one of these accounts, they could launch [lateral attacks](#) across your organization. Each compromised account gives an attacker access to even more accounts and resources, and puts them one step closer to stealing company secrets, launching a denial-of-service attack, and more.

It's not always easy to remove administrative privileges, either. Consider the common scenario where the DNS role is installed on the same machine as your Active Directory Domain Controller. Your DNS administrators require local administrator privileges to fix issues with the DNS server. But to do so, you must make them members of the highly privileged **Domain Admins** security group. This approach effectively gives DNS Administrators control over your whole domain and access to all resources on that machine.

JEA addresses this problem through the principle of **Least Privilege**. With JEA, you can configure a management endpoint for DNS administrators that gives them access only to the PowerShell commands they need to get their job done. This means you can provide the appropriate access to repair a poisoned DNS cache or restart the DNS server without unintentionally giving them rights to Active Directory, or to browse the file system, or run potentially dangerous scripts. Better yet, when the JEA session is configured to use temporary privileged virtual accounts, your DNS administrators can connect to the server using **non-admin** credentials and still run commands that typically require admin privileges. JEA enables you to remove users from widely privileged local/domain administrator roles and carefully control what they can do on each machine.

Next steps

To learn more about the requirements to use JEA, see the [Prerequisites](#) article.

Samples and DSC resource

Sample JEA configurations and the JEA DSC resource can be found in the [JEA GitHub repository](#).

JEA Prerequisites

Article • 04/01/2024

Just Enough Administration is a feature included in PowerShell 5.0 and higher. This article describes the prerequisites that must be satisfied to start using JEA.

Check which version of PowerShell is installed

To check which version of PowerShell is installed on your system, check the

`$PSVersionTable` variable in a Windows PowerShell prompt.

```
PowerShell
$PSVersionTable.PSVersion
Output
Major   Minor   Build   Revision
-----  -----  -----  -----
5       1        14393  1000
```

JEA is available with PowerShell 5.0 and higher. For full functionality, it's recommended that you install the latest version of PowerShell available for your system. The following table describes JEA's availability on Windows Server:

[] Expand table

Server Operating System	JEA Availability
Windows Server 2016+	Preinstalled
Windows Server 2012 R2	Full functionality with WMF 5.1
Windows Server 2012	Full functionality with WMF 5.1
Windows Server 2008 R2	Reduced functionality ¹ with WMF 5.1

You can also use JEA on your home or work computer:

[] Expand table

Client Operating System	JEA Availability
Windows 10 1607+	Preinstalled
Windows 10 1603, 1511	Preinstalled, with reduced functionality ²
Windows 10 1507	Not available
Windows 8, 8.1	Full functionality with WMF 5.1
Windows 7	Reduced functionality ¹ with WMF 5.1

- ¹ JEA can't be configured to use group-managed service accounts on Windows Server 2008 R2 or Windows 7. Virtual accounts and other JEA features *are* supported.
- ² The following JEA features aren't supported on Windows 10 versions 1511 and 1603:
 - Running as a group-managed service account
 - Conditional access rules in session configurations
 - The user drive
 - Granting access to local user accounts

To get support for these features, update Windows to version 1607 (Anniversary Update) or higher.

Install Windows Management Framework

If you're running an older version of PowerShell, you may need to update your system with the latest Windows Management Framework (WMF) update. For more information, see the [WMF documentation](#).

It's recommended that you test your workload's compatibility with WMF before upgrading all of your servers.

Windows 10 users should install the latest feature updates to obtain the current version of Windows PowerShell.

Enable PowerShell Remoting

PowerShell Remoting provides the foundation on which JEA is built. It's necessary to ensure PowerShell Remoting is enabled and properly secured before you can use JEA. For more information, see [WinRM Security](#).

PowerShell Remoting is enabled by default on Windows Server 2012 and higher. You can enable PowerShell Remoting by running the following command in an elevated PowerShell window.

```
PowerShell
Enable-PSRemoting
```

Enable PowerShell module and script block logging (optional)

The following steps enable logging for all PowerShell actions on your system. PowerShell Module Logging isn't required for JEA, however it's recommended you turn on logging to ensure the commands users run are logged in a central location.

You can configure the PowerShell Module Logging policy using Group Policy.

1. Open the Local Group Policy Editor on a workstation or a Group Policy Object in the Group Policy Management Console on an Active Directory Domain Controller
2. Navigate to **Computer Configuration\Administrative Templates\Windows Components\Windows PowerShell**
3. Double-click on **Turn on Module Logging**
4. Click **Enabled**
5. In the Options section, click on **Show** next to **Module Names**
6. Type `*` in the pop-up window to log commands from all modules.
7. Click **OK** to set the policy
8. Double-click on **Turn on PowerShell Script Block Logging**
9. Click **Enabled**
10. Click **OK** to set the policy
11. (On domain-joined machines only) Run `gpupdate` or wait for Group Policy to process the updated policy and apply the settings

You can also enable system-wide PowerShell transcription through Group Policy.

JEA Role Capabilities

Article • 04/01/2024

When creating a JEA endpoint, you need to define one or more role capabilities that describe what someone can do in a JEA session. A role capability is a PowerShell data file with the `.psrc` extension that lists all the cmdlets, functions, providers, and external programs that are made available to connecting users.

Determine which commands to allow

The first step in creating a role capability file is to consider what the users need access to. The requirements gathering process can take a while, but it's important. Giving users access to too few cmdlets and functions can prevent them from getting their job done. Allowing access to too many cmdlets and functions can allow users to do more than you intended and weaken your security stance.

How you go about this process depends on your organization and goals. The following tips can help ensure you're on the right path.

1. **Identify** the commands users are using to get their jobs done. This may involve surveying IT staff, checking automation scripts, or analyzing PowerShell session transcripts and logs.
2. **Update** use of command-line tools to PowerShell equivalents, where possible, for the best auditing and JEA customization experience. External programs can't be constrained as granularly as native PowerShell cmdlets and functions in JEA.
3. **Restrict** the scope of the cmdlets to only allow specific parameters or parameter values. This is especially important if users should manage only part of a system.
4. **Create** custom functions to replace complex commands or commands that are difficult to constrain in JEA. A simple function that wraps a complex command or applies additional validation logic can offer additional control for admins and end-user simplicity.
5. **Test** the scoped list of allowable commands with your users or automation services, and adjust as necessary.

Examples of potentially dangerous commands

Careful selection of commands is important to ensure the JEA endpoint doesn't allow the user to elevate their permissions.

 **Important**

Essential information required for user successCommands in a JEA session are often run with elevated privileges.

The following list contains examples of commands that can be used maliciously if allowed in an unconstrained state. This isn't an exhaustive list and should only be used as a cautionary starting point.

- Risk: Granting the connecting user admin privileges to bypass JEA

Example:

```
PowerShell  
  
Add-LocalGroupMember -Member 'CONTOSO\jdoe' -Group 'Administrators'
```

Related commands:

- Add-ADGroupMember
 - Add-LocalGroupMember
 - net.exe
 - dsadd.exe
- Risk: Running arbitrary code, such as malware, exploits, or custom scripts to bypass protections

Example:

```
PowerShell  
  
Start-Process -FilePath '\\san\share\malware.exe'
```

Related commands:

- Start-Process
- New-Service
- Invoke-Item
- Invoke-WmiMethod
- Invoke-CimMethod
- Invoke-Expression
- Invoke-Command
- New-ScheduledTask
- Register-ScheduledJob

Create a role capability file

You can create a new PowerShell role capability file with the [New-PSRoleCapabilityFile](#) cmdlet.

```
PowerShell
```

```
New-PSRoleCapabilityFile -Path .\MyFirstJEARole.psrc
```

You should edit the created role capability file to allow only the commands required for the role. The PowerShell help documentation contains several examples of how you can configure the file.

Allowing PowerShell cmdlets and functions

To authorize users to run PowerShell cmdlets or functions, add the cmdlet or function name to the **VisibleCmdlets** or **VisibleFunctions** fields. If you aren't sure whether a command is a cmdlet or function, you can run `Get-Command <name>` and check the **CommandType** property in the output.

```
PowerShell
```

```
VisibleCmdlets = @('Restart-Computer', 'Get-NetIPAddress')
```

Sometimes the scope of a specific cmdlet or function is too broad for your users' needs. A DNS admin, for example, may only need access to restart the DNS service. In multi-tenant environments, tenants have access to self-service management tools. Tenants should be limited to managing their own resources. For these cases, you can restrict which parameters are exposed from the cmdlet or function.

```
PowerShell
```

```
VisibleCmdlets = @{
    Name      = 'Restart-Computer'
    Parameters = @{ Name = 'Name' }
}
```

In more advanced scenarios, you may also need to restrict the values a user may use with these parameters. Role capabilities let you define a set of values or a regular expression pattern that determine what input is allowed.

```
PowerShell
```

```
VisibleCmdlets = @(
    @{
        Name      = 'Restart-Service'
        Parameters = @{ Name = 'Name'; ValidateSet = @('Dns', 'Spooler') }
    }
    @{
        Name      = 'Start-Website'
        Parameters = @{ Name = 'Name'; ValidatePattern = 'HR_*' }
    }
)
```

ⓘ Note

The [common PowerShell parameters](#) are always allowed, even if you restrict the available parameters. You shouldn't explicitly list them in the `Parameters` field.

The list below describes the various ways you can customize a visible cmdlet or function. You can mix and match any of the below in the `VisibleCmdlets` field.

- **Use case:** Allow the user to run `My-Func` without any restrictions on the parameters.

```
PowerShell
@{ Name = 'My-Func' }
```

- **Use case:** Allow the user to run `My-Func` from the module `MyModule` without any restrictions on the parameters.

```
PowerShell
@{ Name = 'MyModule\My-Func' }
```

- **Use case:** Allow the user to run any cmdlet or function with the verb `My`.

```
PowerShell
@{ Name = 'My-*' }
```

- **Use case:** Allow the user to run any cmdlet or function with the noun `Func`.

```
PowerShell
```

```
@{ Name = '*-Func' }
```

- **Use case:** Allow the user to run `My-Func` with the `Param1` and `Param2` parameters. Any value can be supplied to the parameters.

PowerShell

```
@{ Name = 'My-Func'; Parameters = @{ Name = 'Param1'}, @{ Name = 'Param2' } }
```

- **Use case:** Allow the user to run `My-Func` with the `Param1` parameter. Only `Value1` and `Value2` can be supplied to the parameter.

PowerShell

```
@{
    Name      = 'My-Func'
    Parameters = @{ Name = 'Param1'; ValidateSet = @('Value1',
    'Value2') }
}
```

- **Use case:** Allow the user to run `My-Func` with the `Param1` parameter. Any value starting with `contoso` can be supplied to the parameter.

PowerShell

```
@{
    Name      = 'My-Func'
    Parameters = @{ Name = 'Param1'; ValidatePattern = 'contoso.*' }
}
```

⚠ Warning

For best security practices, it isn't recommended to use wildcards when defining visible cmdlets or functions. Instead, you should explicitly list each trusted command to ensure no other commands that share the same naming scheme are unintentionally authorized.

You can't apply both a `ValidatePattern` and `ValidateSet` to the same cmdlet or function.

If you do, the `ValidatePattern` overrides the `ValidateSet`.

For more information about `ValidatePattern`, check out [this Hey, Scripting Guy! post](#) and the [PowerShell Regular Expressions](#) reference content.

Allowing external commands and PowerShell scripts

To allow users to run executables and PowerShell scripts (`.ps1`) in a JEA session, you have to add the full path to each program in the `VisibleExternalCommands` field.

PowerShell

```
VisibleExternalCommands = @(
    'C:\Windows\System32\whoami.exe'
    'C:\Program Files\Contoso\Scripts\UpdateITSoftware.ps1'
)
```

Where possible, use PowerShell cmdlet or function equivalents for any external executables you authorize since you have control over the parameters allowed with PowerShell cmdlets and functions.

Many executables allow you to read the current state and then change it by providing different parameters.

For example, consider the role of a file server admin that manages network shares hosted on a system. One way of managing shares is to use `net share`. However, allowing `net.exe` is dangerous because the user could use the command to gain admin privileges with the command `net group Administrators unprivilegedjeauser /add`. A more secure option is to allow the `Get-SmbShare` cmdlet, which achieves the same result but has a much more limited scope.

When making external commands available to users in a JEA session, always specify the complete path to the executable. This prevents the execution of similarly named and potentially malicious programs located elsewhere on the system.

Allowing access to PowerShell providers

By default, no PowerShell providers are available in JEA sessions. This reduces the risk of sensitive information and configuration settings being disclosed to the connecting user.

When necessary, you can allow access to the PowerShell providers using the `VisibleProviders` command. For a full list of providers, run `Get-PSProvider`.

PowerShell

```
VisibleProviders = 'Registry'
```

For simple tasks that require access to the file system, registry, certificate store, or other sensitive providers, consider writing a custom function that works with the provider on the user's behalf. The functions, cmdlets, and external programs available in a JEA session aren't subject to the same constraints as JEA. They can access any provider by default. Also consider using the [user drive](#) when users need to copy files to or from a JEA endpoint.

Creating custom functions

You can author custom functions in a role capability file to simplify complex tasks for your end users. Custom functions are also useful when you require advanced validation logic for cmdlet parameter values. You can write simple functions in the **FunctionDefinitions** field:

PowerShell

```
VisibleFunctions = 'Get-TopProcess'

FunctionDefinitions = @{
    Name      = 'Get-TopProcess'
    ScriptBlock = {
        param($Count = 10)

        Get-Process |
            Sort-Object -Property CPU -Descending |
            Microsoft.PowerShell.Utility\Select-Object -First $Count
    }
}
```

Important

Don't forget to add the name of your custom functions to the **VisibleFunctions** field so they can be run by the JEA users.

The body (script block) of custom functions runs in the default language mode for the system and isn't subject to JEA's language constraints. This means that functions can access the file system and registry, and run commands that weren't made visible in the role capability file. Take care to avoid running arbitrary code when using parameters. Avoid piping user input directly into cmdlets like `Invoke-Expression`.

In the above example, notice that the fully qualified module name (FQMN) `Microsoft.PowerShell.Utility\Select-Object` was used instead of the shorthand `Select-Object`. Functions defined in role capability files are still subject to the scope of JEA sessions, which includes the proxy functions JEA creates to constrain existing commands.

By default, `Select-Object` is a constrained cmdlet in all JEA sessions that doesn't allow the selection of arbitrary properties on objects. To use the unconstrained `Select-Object` in functions, you must explicitly request the full implementation using the FQMN. Any constrained cmdlet in a JEA session has the same constraints when invoked from a function. For more information, see [about_Command_Precedence](#).

If you're writing several custom functions, it's more convenient to put them in a PowerShell script module. You make those functions visible in the JEA session using the `VisibleFunctions` field like you would with built-in and third-party modules.

For tab completion to work properly in JEA sessions you must include the built-in function `TabExpansion2` in the `VisibleFunctions` list.

Make the role capabilities available to a configuration

Prior to PowerShell 6, for PowerShell to find a role capability file it must be stored in a `RoleCapabilities` folder in a PowerShell module. The module can be stored in any folder included in the `$Env:PSModulePath` environment variable, however you shouldn't place it in `$Env:SystemRoot\System32` or a folder where untrusted users could modify the files.

The following example creates a PowerShell script module called `ContosoJEA` in the `$Env:ProgramFiles` path to host the role capabilities file.

```
PowerShell

# Create a folder for the module
$modulePath = Join-Path $Env:ProgramFiles
"WindowsPowerShell\Modules\ContosoJEA"
New-Item -ItemType Directory -Path $modulePath

# Create an empty script module and module manifest.
# At least one file in the module folder must have the same name as the
# folder itself.
$rootModulePath = Join-Path $modulePath "ContosoJEAFunctions.psm1"
$moduleManifestPath = Join-Path $modulePath "ContosoJEA.psdi"
New-Item -ItemType File -Path $RootModulePath
```

```
New-ModuleManifest -Path $moduleManifestPath -RootModule  
"ContosoJEAFunctions.psm1"  
  
# Create the RoleCapabilities folder and copy in the PSRC file  
$rcFolder = Join-Path $modulePath "RoleCapabilities"  
New-Item -ItemType Directory $rcFolder  
Copy-Item -Path .\MyFirstJEARole.ps1 -Destination $rcFolder
```

For more information about PowerShell modules, see [Understanding a PowerShell Module](#).

Starting in PowerShell 6, the **RoleDefinitions** property was added to the session configuration file. This property lets you specify the location of a role configuration file for your role definition. See the examples in [New-PSSessionConfigurationFile](#).

Updating role capabilities

You can edit a role capability file to update the settings at any time. Any new JEA sessions started after the role capability has been updated will reflect the revised capabilities.

This is why controlling access to the role capabilities folder is so important. Only highly trusted administrators should be allowed to change role capability files. If an untrusted user can change role capability files, they can easily give themselves access to cmdlets that allow them to elevate their privileges.

For administrators looking to lock down access to the role capabilities, ensure Local System has read-only access to the role capability files and containing modules.

How role capabilities are merged

Users are granted access to all matching role capabilities in the [session configuration file](#) when they enter a JEA session. JEA tries to give the user the most permissive set of commands allowed by any of the roles.

VisibleCmdlets and VisibleFunctions

The most complex merge logic affects cmdlets and functions, which can have their parameters and parameter values limited in JEA.

The rules are as follows:

1. If a cmdlet is only made visible in one role, it's visible to the user with any applicable parameter constraints.
2. If a cmdlet is made visible in more than one role, and each role has the same constraints on the cmdlet, the cmdlet is visible to the user with those constraints.
3. If a cmdlet is made visible in more than one role, and each role allows a different set of parameters, the cmdlet and all the parameters defined across every role are visible to the user. If one role doesn't have constraints on the parameters, all parameters are allowed.
4. If one role defines a validate set or validate pattern for a cmdlet parameter, and the other role allows the parameter but doesn't constrain the parameter values, the validate set or pattern is ignored.
5. If a validate set is defined for the same cmdlet parameter in more than one role, all values from all validate sets are allowed.
6. If a validate pattern is defined for the same cmdlet parameter in more than one role, any values that match any of the patterns are allowed.
7. If a validate set is defined in one or more roles, and a validate pattern is defined in another role for the same cmdlet parameter, the validate set is ignored and rule (6) applies to the remaining validate patterns.

Below is an example of how roles are merged according to these rules:

PowerShell

```
# Role A Visible Cmdlets
$roleA = @{
    VisibleCmdlets = @(
        'Get-Service'
        @{
            Name      = 'Restart-Service'
            Parameters = @{
                Name = 'DisplayName'; ValidateSet = 'DNS Client'
            }
        }
    )
}

# Role B Visible Cmdlets
$roleB = @{
    VisibleCmdlets = @(
        @{
            Name      = 'Get-Service';
            Parameters = @{
                Name = 'DisplayName'; ValidatePattern = 'DNS.*'
            }
        }
        @{
            Name      = 'Restart-Service'
            Parameters = @{
                Name = 'DisplayName'; ValidateSet = 'DNS Server'
            }
        }
    )
}
```

```

        )
    }

# Resulting permissions for a user who belongs to both role A and B
# - The constraint in role B for the DisplayName parameter on Get-Service
#   is ignored because of rule #4
# - The ValidateSets for Restart-Service are merged because both roles use
#   ValidateSet on the same parameter per rule #5
$mergedAandB = @{
    VisibleCmdlets = @(
        'Get-Service'
        @{
            Name = 'Restart-Service';
            Parameters = @{
                Name = 'DisplayName'
                ValidateSet = 'DNS Client', 'DNS Server'
            }
        }
    )
}

```

VisibleExternalCommands, VisibleAliases, VisibleProviders, ScriptsToProcess

All other fields in the role capability file are added to a cumulative set of allowable external commands, aliases, providers, and startup scripts. Any command, alias, provider, or script available in one role capability is available to the JEA user.

Be careful to ensure that the combined set of providers from one role capability and cmdlets/functions/commands from another don't allow users unintentional access to system resources. For example, if one role allows the `Remove-Item` cmdlet and another allows the `FileSystem` provider, you are at risk of a JEA user deleting arbitrary files on your computer. Additional information about identifying users' effective permissions can be found in the [auditing JEA](#) article.

JEA Session Configurations

Article • 04/01/2024

A JEA endpoint is registered on a system by creating and registering a PowerShell session configuration file. Session configurations define who can use the JEA endpoint and which roles they have access to. They also define global settings that apply to all users of the JEA session.

Create a session configuration file

To register a JEA endpoint, you must specify how that endpoint is configured. There are many options to consider. The most important options are:

- Who has access to the JEA endpoint
- Which roles they may be assigned
- Which identity JEA uses under the covers
- The name of the JEA endpoint

These options are defined in a PowerShell data file with a `.pssc` extension known as a PowerShell session configuration file. The session configuration file can be edited using any text editor.

Run the following command to create a blank template configuration file.

PowerShell

```
New-PSSessionConfigurationFile -SessionType RestrictedRemoteServer -Path  
.\\MyJEAEndpoint.pssc
```

Tip

Only the most common configuration options are included in the template file by default. Use the `-Full` switch to include all applicable settings in the generated PSSC.

The `-SessionType RestrictedRemoteServer` field indicates that the session configuration is used by JEA for secure management. Sessions of this type operate in **NoLanguage** mode and only have access to the following default commands (and aliases):

- `Clear-Host` (`cls`, `clear`)

- `Exit-PSSession` (`exsn`, `exit`)
- `Get-Command` (`gcm`)
- `Get-FormatData`
- `Get-Help`
- `Measure-Object` (`measure`)
- `Out-Default`
- `Select-Object` (`select`)

No PowerShell providers are available, nor are any external programs (executables or scripts).

For more information about language modes, see [about_Language_Modes](#).

Choose the JEA identity

Behind the scenes, JEA needs an identity (account) to use when running a connected user's commands. You define which identity JEA uses in the session configuration file.

Local Virtual Account

Local virtual accounts are useful when all roles defined for the JEA endpoint are used to manage the local machine and a local administrator account is sufficient to run the commands successfully. Virtual accounts are temporary accounts that are unique to a specific user and only last for the duration of their PowerShell session. On a member server or workstation, virtual accounts belong to the local computer's **Administrators** group. On an Active Directory Domain Controller, virtual accounts belong to the domain's **Domain Admins** group.

```
PowerShell

# Setting the session to use a virtual account
RunAsVirtualAccount = $true
```

If the roles defined by the session configuration don't require full administrative privilege, you can specify the security groups to which the virtual account will belong. On a member server or workstation, the specified security groups must be local groups, not groups from a domain.

When one or more security groups are specified, the virtual account isn't assigned to the local or domain administrators group.

```
PowerShell
```

```
# Setting the session to use a virtual account that only belongs to the
NetworkOperator and NetworkAuditor local groups
RunAsVirtualAccount = $true
RunAsVirtualAccountGroups = 'NetworkOperator', 'NetworkAuditor'
```

ⓘ Note

Virtual accounts are temporarily granted the Logon as a service right in the local server security policy. If one of the VirtualAccountGroups specified has already been granted this right in the policy, the individual virtual account will no longer be added and removed from the policy. This can be useful in scenarios such as domain controllers where revisions to the domain controller security policy are closely audited. This is only available in Windows Server 2016 with the November 2018 or later rollup and Windows Server 2019 with the January 2019 or later rollup.

Group-managed service account

A group-managed service account (GMSA) is the appropriate identity to use when JEA users need to access network resources such as file shares and web services. GMSAs give you a domain identity that's used to authenticate with resources on any machine within the domain. The rights that a GMSA provides are determined by the resources you're accessing. You don't have admin rights on any machines or services unless the machine or service administrator has explicitly granted those rights to the GMSA.

PowerShell

```
# Configure JEA sessions to use the GMSA in the local computer's domain
# with the sAMAccountName of 'MyJEAGMSA'
GroupManagedServiceAccount = 'Domain\MyJEAGMSA'
```

GMSAs should only be used when necessary:

- It's difficult to trace back actions to a user when using a GMSA. Every user shares the same run-as identity. You must review PowerShell session transcripts and logs to correlate individual users with their actions.
- The GMSA may have access to many network resources that the connecting user doesn't need access to. Always try to limit effective permissions in a JEA session to follow the principle of least privilege.

ⓘ Note

Group managed service accounts are only available on domain-joined machines using PowerShell 5.1 or newer.

For more information about securing a JEA session, see the [security considerations](#) article.

Session transcripts

It's recommended that you configure a JEA endpoint to automatically record transcripts of users' sessions. PowerShell session transcripts contain information about the connecting user, the run as identity assigned to them, and the commands run by the user. They can be useful to an auditing team who needs to understand who made a specific change to a system.

To configure automatic transcription in the session configuration file, provide a path to a folder where the transcripts should be stored.

PowerShell

```
TranscriptDirectory = 'C:\ProgramData\JEAConfiguration\Transcripts'
```

Transcripts are written to the folder by the **Local System** account, which requires read and write access to the directory. Standard users should have no access to the folder. Limit the number of security administrators that have access to audit the transcripts.

User drive

If your connecting users need to copy files to or from the JEA endpoint, you can enable the user drive in the session configuration file. The user drive is a **PSDrive** that's mapped to a unique folder for each connecting user. This folder allows users to copy files to or from the system without giving them access to the full file system or exposing the **FileSystem** provider. The user drive contents are persistent across sessions to accommodate situations where network connectivity may be interrupted.

PowerShell

```
MountUserDrive = $true
```

By default, the user drive allows you to store a maximum of 50MB of data per user. You can limit the amount of data a user can consume with the *UserDriveMaximumSize* field.

PowerShell

```
# Enables the user drive with a per-user limit of 500MB (524288000 bytes)
MountUserDrive = $true
UserDriveMaximumSize = 524288000
```

If you don't want data in the user drive to be persistent, you can configure a scheduled task on the system to automatically clean up the folder every night.

 **Note**

The user drive is only available in PowerShell 5.1 or newer.

For more information about PSDrives, see [Managing PowerShell drives](#).

Role definitions

Role definitions in a session configuration file define the mapping of **users** to **roles**. Every user or group included in this field is granted permission to the JEA endpoint when it's registered. Each user or group can be included as a key in the hashtable only once, but can be assigned multiple roles. The name of the role capability should be the name of the role capability file, without the `.psrc` extension.

PowerShell

```
RoleDefinitions = @{
    'CONTOSO\JEA_DNS_ADMIN'      = @{ RoleCapabilities = 'DnsAdmin',
    'DnsOperator', 'DnsAuditor' }
    'CONTOSO\JEA_DNS_OPERATORS' = @{ RoleCapabilities = 'DnsOperator',
    'DnsAuditor' }
    'CONTOSO\JEA_DNS_AUDITORS' = @{ RoleCapabilities = 'DnsAuditor' }
}
```

If a user belongs to more than one group in the role definition, they get access to the roles of each. When two roles grant access to the same cmdlets, the most permissive parameter set is granted to the user.

When specifying local users or groups in the role definitions field, be sure to use the computer name, not **localhost** or wildcards. You can check the computer name by inspecting the `$Env:COMPUTERNAME` variable.

PowerShell

```
RoleDefinitions = @{
    'MyComputerName\MyLocalGroup' = @{
        RoleCapabilities = 'DnsAuditor'
    }
}
```

Role capability search order

As shown in the example above, role capabilities are referenced by the base name of the role capability file. The base name of a file is the filename without the extension. If multiple role capabilities are available on the system with the same name, PowerShell uses its implicit search order to select the effective role capability file. JEA does **not** give access to all role capability files with the same name.

JEA uses the `$Env:PSModulePath` environment variable to determine which paths to scan for role capability files. Within each of those paths, JEA looks for valid PowerShell modules that contain a "RoleCapabilities" subfolder. As with importing modules, JEA prefers role capabilities that are shipped with Windows to custom role capabilities with the same name.

For all other naming conflicts, precedence is determined by the order in which Windows enumerates the files in the directory. The order isn't guaranteed to be alphabetical. The first role capability file found that matches the specified name is used for the connecting user. Since the role capability search order isn't deterministic, it's **strongly recommended** that role capabilities have unique filenames.

Conditional access rules

All users and groups included in the **RoleDefinitions** field are automatically granted access to JEA endpoints. Conditional access rules allow you to refine this access and require users to belong to additional security groups that don't impact the roles to which they're assigned. This is useful when you want to integrate a just-in-time privileged access management solution, smartcard authentication, or other multifactor authentication solution with JEA.

Conditional access rules are defined in the **RequiredGroups** field in a session configuration file. There, you can provide a hashtable (optionally nested) that uses 'And' and 'Or' keys to construct your rules. Here are some examples of how to use this field:

PowerShell

```
# Example 1: Connecting users must belong to a security group called
#"elevated-jea"
RequiredGroups = @{ And = 'elevated-jea' }
```

```
# Example 2: Connecting users must have signed on with 2 factor  
authentication or a smart card  
# The 2 factor authentication group name is "2FA-logon" and the smart card  
group  
# name is "smartcard-logon"  
RequiredGroups = @{ Or = '2FA-logon', 'smartcard-logon' }  
  
# Example 3: Connecting users must elevate into "elevated-jea" with their  
JIT system and  
# have logged on with 2FA or a smart card  
RequiredGroups = @{ And = 'elevated-jea', @{ Or = '2FA-logon', 'smartcard-  
logon' } }
```

ⓘ Note

Conditional access rules are only available in PowerShell 5.1 or newer.

Other properties

Session configuration files can also do everything a role capability file can do, just without the ability to give connecting users access to different commands. If you want to allow all users access to specific cmdlets, functions, or providers, you can do so right in the session configuration file. For a full list of supported properties in the session configuration file, run `Get-Help New-PSSessionConfigurationFile -Full`.

Testing a session configuration file

You can test a session configuration using the [Test-PSSessionConfigurationFile](#) cmdlet. It's recommended that you test your session configuration file if you've manually edited the `.pssc` file. Testing ensures the syntax is correct. If a session configuration file fails this test, it can't be registered on the system.

Sample session configuration file

The following example shows how to create and validate a session configuration for JEA. The role definitions are created and stored in the `$roles` variable for convenience and readability. it isn't a requirement to do so.

PowerShell

```
$roles = @{  
    'CONTOSO\JEA_DNS_ADMIN' = @{ RoleCapabilities = 'DnsAdmin',
```

```
'DnsOperator', 'DnsAuditor' }
    'CONTOSO\JEA_DNS_OPERATORS' = @{
        RoleCapabilities = 'DnsOperator',
        'DnsAuditor' }
        'CONTOSO\JEA_DNS_AUDITORS' = @{
            RoleCapabilities = 'DnsAuditor' }
    }

$parameters = @{
    SessionType = 'RestrictedRemoteServer'
    Path = '.\JEAConfig.pssc'
    RunAsVirtualAccount = $true
    TranscriptDirectory = 'C:\ProgramData\JEAConfiguration\Transcripts'
    RoleDefinitions = $roles
    RequiredGroups = @{
        Or = '2FA-logon', 'smartcard-logon' }
}
New-PSSessionConfigurationFile @parameters
Test-PSSessionConfigurationFile -Path .\JEAConfig.pssc # should yield True
```

Updating session configuration files

To change the properties of a JEA session configuration, including the mapping of users to roles, you must [unregister](#). Then, [re-register](#) the JEA session configuration using an updated session configuration file.

Next steps

- [Register a JEA configuration](#)
- [Author JEA roles](#)

Registering JEA Configurations

Article • 04/01/2024

Once you have your [role capabilities](#) and [session configuration file](#) created, the last step is to register the JEA endpoint. Registering the JEA endpoint with the system makes the endpoint available for use by users and automation engines.

Single machine configuration

For small environments, you can deploy JEA by registering the session configuration file using the [Register-PSSessionConfiguration](#) cmdlet.

Before you begin, ensure that the following prerequisites have been met:

- One or more roles has been created and placed in the **RoleCapabilities** folder of a PowerShell module.
- A session configuration file has been created and tested.
- The user registering the JEA configuration has administrator rights on the system.
- You've selected a name for your JEA endpoint.

The name of the JEA endpoint is required when users connect to the system using JEA. The [Get-PSSessionConfiguration](#) cmdlet lists the names of the endpoints on a system. Endpoints that start with `microsoft` are typically shipped with Windows. The `microsoft.powershell` endpoint is the default endpoint used when connecting to a remote PowerShell endpoint.

PowerShell

```
Get-PSSessionConfiguration | Select-Object Name
```

Output

Name

<code>microsoft.powershell</code>
<code>microsoft.powershell.workflow</code>
<code>microsoft.powershell132</code>

Run the following command to register the endpoint.

PowerShell

```
Register-PSSessionConfiguration -Path .\MyJEAConfig.pssc -Name  
'JEA Maintenance' -Force
```

⚠️ Warning

The previous command restarts the WinRM service on the system. This terminates all PowerShell remoting sessions and any ongoing DSC configurations. We recommended you take production machines offline before running the command to avoid disrupting business operations.

After registration, you're ready to [use JEA](#). You may delete the session configuration file at any time. The configuration file isn't used after registration of the endpoint.

Multi-machine configuration with DSC

When deploying JEA on multiple machines, the simplest deployment model uses the [JEA Desired State Configuration \(DSC\)](#) resource to quickly and consistently deploy JEA on each machine.

To deploy JEA with DSC, ensure the following prerequisites are met:

- One or more role capabilities have been authored and added to a PowerShell module.
- The PowerShell module containing the roles is stored on a (read-only) file share accessible by each machine.
- Settings for the session configuration have been determined. You don't need to create a session configuration file when using the JEA DSC resource.
- You have credentials that allow administrative actions on each machine or access to the DSC pull server used to manage the machines.
- You've downloaded the [JEA DSC resource ↗](#).

Create a DSC configuration for your JEA endpoint on a target machine or pull server. In this configuration, the **JustEnoughAdministration** DSC resource defines the session configuration file and the **File** resource copies the role capabilities from the file share.

The following properties are configurable using the DSC resource:

- Role Definitions
- Virtual account groups
- Group-managed service account name
- Transcript directory

- User drive
- Conditional access rules
- Startup scripts for the JEA session

The syntax for each of these properties in a DSC configuration is consistent with the PowerShell session configuration file.

Below is a sample DSC configuration for a general server maintenance module. It assumes that a valid PowerShell module containing role capabilities is located on the `\myfileshare\JEA` file share.

```
PowerShell

Configuration JEAMaintenance
{
    Import-DscResource -Module JustEnoughAdministration,
    PSDesiredStateConfiguration

    File MaintenanceModule
    {
        SourcePath = "\myfileshare\JEA\ContosoMaintenance"
        DestinationPath = "C:\Program
Files\WindowsPowerShell\Modules\ContosoMaintenance"
        Checksum = "SHA-256"
        Ensure = "Present"
        Type = "Directory"
        Recurse = $true
    }

    JeaEndpoint JEAMaintenanceEndpoint
    {
        EndpointName = "JEAMaintenance"
        RoleDefinitions = "@{ 'CONTOSO\JEAMaintenanceAuditors' = @{
RoleCapabilities = 'GeneralServerMaintenance-Audit' };
'CONTOSO\JEAMaintenanceAdmins' = @{ RoleCapabilities =
'GeneralServerMaintenance-Audit', 'GeneralServerMaintenance-Admin' } }"
        TranscriptDirectory = 'C:\ProgramData\JEAConfiguration\Transcripts'
        DependsOn = '[File]MaintenanceModule'
    }
}
```

Next, the configuration is applied on a system by directly invoking the [Local Configuration Manager](#) or updating the [pull server configuration](#).

The DSC resource also allows you to replace the default **Microsoft.PowerShell** endpoint. When replaced, the resource automatically registers a backup endpoint named **Microsoft.PowerShell.Restricted**. The backup endpoint has the default WinRM ACL that allows Remote Management Users and local Administrators group members to access it.

Unregistering JEA configurations

The [Unregister-PSSessionConfiguration](#) cmdlet removes a JEA endpoint. Unregistering a JEA endpoint prevents new users from creating new JEA sessions on the system. It also allows you to update a JEA configuration by re-registering an updated session configuration file using the same endpoint name.

PowerShell

```
# Unregister the JEA endpoint called "ContosoMaintenance"
Unregister-PSSessionConfiguration -Name 'ContosoMaintenance' -Force
```

⚠ Warning

Unregistering a JEA endpoint causes the WinRM service to restart. This interrupts most remote management operations in progress, including other PowerShell sessions, WMI invocations, and some management tools. Only unregister PowerShell endpoints during planned maintenance windows.

Using JEA

Article • 04/01/2024

This article describes the various ways you can connect to and use a JEA endpoint.

Using JEA interactively

If you're testing your JEA configuration or have simple tasks for users, you can use JEA the same way you would a regular PowerShell remoting session. For complex remoting tasks, it's recommended to use [implicit remoting](#). Implicit remoting allows users to operate with the data objects locally.

To use JEA interactively, you need:

- The name of the computer you're connecting to (can be the local machine)
- The name of the JEA endpoint registered on that computer
- Credentials that have access to the JEA endpoint on that computer

Given that information, you can start a JEA session using the [New-PSSession](#) or [Enter-PSSession](#) cmdlets.

```
PowerShell

$sessionParams = @{
    ComputerName      = 'localhost'
    ConfigurationName = 'JEAMaintenance'
    Credential        = Get-Credential
}
Enter-PSSession @sessionParams
```

If the current user account has access to the JEA endpoint, you can omit the **Credential** parameter.

When the PowerShell prompt changes to `[localhost]: PS>` you know that you're now interacting with the remote JEA session. You can run `Get-Command` to check which commands are available. Consult with your administrator to learn if there are any restrictions on the available parameters or allowed parameter values.

Remember, JEA sessions operate in `NoLanguage` mode. Some of the ways you typically use PowerShell may not be available. For instance, you can't use variables to store data or inspect the properties on objects returned from cmdlets. The following example shows two approaches to get the same commands to work in `NoLanguage` mode.

PowerShell

```
# Using variables is prohibited in NoLanguage mode. The following will not work:  
# $vm = Get-VM -Name 'SQL01'  
# Start-VM -VM $vm  
  
# You can use pipes to pass data through to commands that accept input from the pipeline  
Get-VM -Name 'SQL01' | Start-VM  
  
# You can also wrap subcommands in parentheses and enter them inline as arguments  
Start-VM -VM (Get-VM -Name 'SQL01')  
  
# You can also use parameter sets that don't require extra data to be passed in  
Start-VM -VMName 'SQL01'
```

For more complex command invocations that make this approach difficult, consider using [implicit remoting](#) or [creating custom functions](#) that wrap the functionality you require. For more information on `NoLanguageMode`, see [about_Language_Modes](#).

Using JEA with implicit remoting

PowerShell has an implicit remoting model that lets you import proxy cmdlets from a remote machine and interact with them as if they were local commands. Implicit remoting is explained in this *Hey, Scripting Guy!* [blog post](#). Implicit remoting is useful when working with JEA because it allows you to work with JEA cmdlets in a full language mode. You can use tab completion, variables, manipulate objects, and even use local scripts to automate tasks against a JEA endpoint. Anytime you invoke a proxy command, the data is sent to the JEA endpoint on the remote machine and executed there.

Implicit remoting works by importing cmdlets from an existing PowerShell session. You can optionally choose to prefix the nouns of each proxy cmdlet with a string of your choosing. The prefix allows you to distinguish the commands that are for the remote system. A temporary script module containing all the proxy commands is created and imported for the duration of your local PowerShell session.

PowerShell

```
# Create a new PSSession to your JEA endpoint  
$jeaSession = New-PSSession -ComputerName 'SERVER01' -ConfigurationName 'JEA  
Maintenance'  
  
# Import the entire PSSession and prefix each imported cmdlet with "JEA"
```

```
Import-PSSession -Session $jeaSession -Prefix 'JEA'

# Invoke "Get-Command" on the remote JEA endpoint using the proxy cmdlet
Get-JEACmdlet
```

ⓘ Important

Some systems may not be able to import an entire JEA session due to constraints in the default JEA cmdlets. To get around this, only import the commands you need from the JEA session by explicitly providing their names to the `-CommandName` parameter. A future update will address the issue with importing entire JEA sessions on affected systems.

If you're unable to import a JEA session because of JEA constraints on the default parameters, follow the steps below to filter out the default commands from the imported set. You can continue use commands like `Select-Object`, but you'll just use the local version installed on your computer instead of the one imported from the remote JEA session.

PowerShell

```
# Create a new PSSession to your JEA endpoint
$jeaSession = New-PSSession -ComputerName 'SERVER01' -ConfigurationName
'JEMaintenance'

# Get a list of all the commands on the JEA endpoint
$commands = Invoke-Command -Session $jeaSession -ScriptBlock { Get-Command }

# Filter out the default cmdlets
$jeaDefaultCmdlets = @(
    'Clear-Host'
    'Exit-PSSession'
    'Get-Command'
    'Get-FormatData'
    'Get-Help'
    'Measure-Object'
    'Out-Default'
    'Select-Object'
)
$filteredCommands = $commands | Where-Object { $jeaDefaultCmdlets -
notcontains $_ }

# Import only commands explicitly added in role capabilities and prefix each
# imported cmdlet with "JEA"
Import-PSSession -Session $jeaSession -Prefix 'JEA' -CommandName
$filteredCommands
```

You can also persist the proxied cmdlets from implicit remoting using [Export-PSSession](#). For more information about implicit remoting, see the documentation for [Import-PSSession](#) and [Import-Module](#).

Using JEA programmatically

JEA can also be used in automation systems and in user applications, such as in-house helpdesk apps and websites. The approach is the same as that for building apps that talk to unconstrained PowerShell endpoints. Ensure the program is designed to work with limitation imposed by JEA.

For simple, one-off tasks, you can use [Invoke-Command](#) to run commands in a JEA session.

PowerShell

```
Invoke-Command -ComputerName 'SERVER01' -ConfigurationName 'JEAMaintenance'
-ScriptBlock {
    Get-Process
    Get-Service
}
```

To check which commands are available for use when you connect to a JEA session, run [Get-Command](#) and iterate through the results to check for the allowed parameters.

PowerShell

```
$commandParameters = @{
    ComputerName      = 'SERVER01'
    ConfigurationName = 'JEAMaintenance'
    ScriptBlock       = { Get-Command }
}
Invoke-Command @commandParameters |
    Where-Object { $_. CommandType -in @('Function', 'Cmdlet') } |
        Format-Table Name, Parameters
```

If you're building a C# app, you can create a PowerShell runspace that connects to a JEA session by specifying the configuration name in a [WSManConnectionInfo](#) object.

C#

```
// using System.Management.Automation;
var computerName = "SERVER01";
var configName   = "JEAMaintenance";
// See
https://learn.microsoft.com/dotnet/api/system.management.automation.pscreden
```

```

tial
var creds      = // create a PSCredential object here

WSManConnectionInfo connectionInfo = new WSManConnectionInfo(
    false,           // Use SSL
    computerName,   // Computer name
    5985,           // WSMAN Port
    "/wsman",       // WSMAN Path
    string.Format(  // Connection URI with config name
        CultureInfo.InvariantCulture,
        "http://schemas.microsoft.com/powershell/{0}",
        configName
    ),
    creds           // Credentials
);

// Now, use the connection info to create a runspace where you can run the
// commands
using (Runspace runspace = RunspaceFactory.CreateRunspace(connectionInfo))
{
    // Open the runspace
    runspace.Open();

    using (PowerShell ps = PowerShell.Create())
    {
        // Set the PowerShell object to use the JEA runspace
        ps.Runspace = runspace;

        // Now you can add and invoke commands
        ps.AddCommand("Get-Command");
        foreach (var result in ps.Invoke())
        {
            Console.WriteLine(result);
        }
    }

    // Close the runspace
    runspace.Close();
}

```

Using JEA with PowerShell Direct

Hyper-V in Windows 10 and Windows Server 2016 offers [PowerShell Direct](#), a feature that allows Hyper-V administrators to manage virtual machines with PowerShell regardless of the network configuration or remote management settings on the virtual machine.

You can use PowerShell Direct with JEA to give a Hyper-V administrator limited access to your VM. This can be useful if you lose network connectivity to your VM and need a

datacenter admin to fix the network settings.

No additional configuration is required to use JEA over PowerShell Direct. However, the guest operating system running inside the virtual machine must be Windows 10, Windows Server 2016, or higher. The Hyper-V admin can connect to the JEA endpoint by using the `-VMName` or `-VMId` parameters on PSRemoting cmdlets:

PowerShell

```
$sharedParams = @{
    ConfigurationName = 'NICMaintenance'
    Credential       = Get-Credential -UserName 'localhost\JEAformyHoster'
}
# Entering a JEA session using PowerShell Direct when the VM name is unique
Enter-PSSession -VMName 'SQL01' @sharedParams

# Entering a JEA session using PowerShell Direct using VM ids
$vm = Get-VM -VMName 'MyVM' | Select-Object -First 1
Enter-PSSession -VMId $vm.VMId @sharedParams
```

It's recommended you create a dedicated user account with the minimum rights needed to manage the system for use by a Hyper-V administrator. Remember, even an unprivileged user can sign into a Windows machine by default, including using unconstrained PowerShell. That allows them to browse the file system and learn more about your OS environment. To lock down a Hyper-V administrator and limit them to only access a VM using PowerShell Direct with JEA, you must deny local logon rights to the Hyper-V admin's JEA account.

JEA Security Considerations

Article • 04/01/2024

JEA helps you improve your security posture by reducing the number of permanent administrators on your machines. JEA uses a PowerShell session configuration to create a new entry point for users to manage the system. Users who need elevated, but not unlimited, access to the machine to do administrative tasks can be granted access to the JEA endpoint. Since JEA allows these users to run administrative commands without having full administrator access, you can then remove those users from highly privileged security groups.

Run-As account

Each JEA endpoint has a designated **run-as** account under which the connecting user's actions are executed. This account is configurable in the [session configuration file](#), and the account you choose has a significant bearing on the security of your endpoint.

Virtual accounts are the recommended way of configuring the **run-as** account. Virtual accounts are one-time, temporary local accounts that are created for the connecting user to use during the duration of their JEA session. As soon as their session is terminated, the virtual account is destroyed and can't be used anymore. The connecting user doesn't know the credentials for the virtual account. The virtual account can't be used to access the system via other means like Remote Desktop or an unconstrained PowerShell endpoint.

By default, virtual accounts are members of the local **Administrators** group on the machine. This membership gives them full rights to manage anything on the system, but no rights to manage resources on the network. When the user connects to other machines from the JEA session, the user context is that of the local computer account, not the virtual account.

Domain controllers are a special case since there isn't a local **Administrators** group. Instead, virtual accounts belong to **Domain Admins** and can manage the directory services on the domain controller. The domain identity is still restricted for use on the domain controller where the JEA session was instantiated. Any network access appears to come from the domain controller computer object instead.

In both cases, you may assign the virtual account to specific security groups, especially when the task can be done without local or domain administrator privileges. If you already have a security group defined for your administrators, grant the virtual account membership to that group. Group membership for virtual accounts is limited to local

security groups on workstation and member servers. On domain controllers, virtual accounts must be members of domain security groups. Once the virtual account has been added to one or more security groups, it no longer belongs to the default groups (local or domain administrators).

The following table summarizes the possible configuration options and resulting permissions for virtual accounts:

[+] Expand table

Computer type	Virtual account group configuration	Local user context	Network user context
Domain controller	Default	Domain user, member of <code><DOMAIN>\Domain Admins</code>	Computer account
Domain controller	Domain groups A and B	Domain user, member of <code><DOMAIN>\A, <DOMAIN>\B</code>	Computer account
Member server or workstation	Default	Local user, member of <code>BUILTIN\Administrators</code>	Computer account
Member server or workstation	Local groups C and D	Local user, member of <code><COMPUTER>\C and <COMPUTER>\D</code>	Computer account

When you look at Security audit and Application event logs, you see that each JEA user session has a unique virtual account. This unique account helps you track user actions in a JEA endpoint back to the original user who ran the command. Virtual account names follow the format `WinRM Virtual`

`Users\WinRM_VA_<ACCOUNTNUMBER>_<DOMAIN>_<sAMAccountName>` For example, if user **Alice** in domain **Contoso** restarts a service in a JEA endpoint, the username associated with any service control manager events would be `WinRM Virtual`

`Users\WinRM_VA_1_contoso_alice.`

Group-managed service accounts (gMSAs) are useful when a member server needs to have access to network resources in the JEA session. For example, when a JEA endpoint is used to control access to a REST API service hosted on a different machine. It's easy to write functions to invoke the REST APIs, but you need a network identity to authenticate with the API. Using a group-managed service account makes the second hop possible while maintaining control over which computers can use the account. The security group (local or domain) memberships of the gMSA defined the effective permissions for the gMSA account.

When a JEA endpoint is configured to use a gMSA, the actions of all JEA users appear to come from the same gMSA. The only way to trace actions back to a specific user is to identify the set of commands run in a PowerShell session transcript.

Pass-through credentials are used when you don't specify a **run-as** account. PowerShell uses the connecting user's credential to run commands on the remote server. To use pass-through credentials, you must grant the connecting user direct access to privileged management groups. This configuration is **NOT** recommended for JEA. If the connecting user already has administrator privileges, they can bypass JEA and manage the system using other access methods.

Standard run-as accounts allow you to specify any user account under which the entire PowerShell session runs. Session configurations using fixed **run-as** accounts (with the `-RunAsCredential` parameter) aren't JEA-aware. Role definitions no longer function as expected. Every user authorized to access the endpoint is assigned the same role.

You shouldn't use a **RunAsCredential** on a JEA endpoint because it's difficult to trace actions back to specific users and lacks support for mapping users to roles.

WinRM Endpoint ACL

As with regular PowerShell remoting endpoints, each JEA endpoint has a separate access control list (ACL) that controls who can authenticate with the JEA endpoint. If improperly configured, trusted users may not be able to access the JEA endpoint, and untrusted users may have access. The WinRM ACL doesn't affect the mapping of users to JEA roles. Mapping is controlled by the **RoleDefinitions** field in the session configuration file used to register the endpoint.

By default, when a JEA endpoint has multiple role capabilities, the WinRM ACL is configured to allow access to all mapped users. For example, a JEA session configured using the following commands grants full access to `CONTOSO\JEA_Lev1` and `CONTOSO\JEA_Lev2`.

PowerShell

```
$roles = @{ 'CONTOSO\JEA_Lev1' = 'Lev1Role'; 'CONTOSO\JEA_Lev2' = 'Lev2Role' }
New-PSSessionConfigurationFile -Path '.\jea.pssc' -SessionType
RestrictedRemoteServer -RoleDefinitions $roles -RunAsVirtualAccount
Register-PSSessionConfiguration -Path '.\jea.pssc' -Name 'MyJEAEndpoint'
```

You can audit user permissions with the [Get-PSSessionConfiguration](#) cmdlet.

PowerShell

```
Get-PSSessionConfiguration -Name 'MyJEAEndpoint' | Select-Object Permission
```

Output

```
Permission
```

```
-----  
CONTOSO\JEA_Lev1 AccessAllowed  
CONTOSO\JEA_Lev2 AccessAllowed
```

To change which users have access, run either `Set-PSSessionConfiguration -Name 'MyJEAEndpoint' -ShowSecurityDescriptorUI` for an interactive prompt or `Set-PSSessionConfiguration -Name 'MyJEAEndpoint' -SecurityDescriptorSddl <SDDL string>` to update the permissions. Users need at least *Invoke* rights to access the JEA endpoint.

It's possible to create a JEA endpoint that doesn't map a defined role to every user that has access. These users can start a JEA session, but only have access to the default cmdlets. You can audit user permissions in a JEA endpoint by running `Get-PSSessionCapability`. For more information, see [Auditing and Reporting on JEA](#).

Least privilege roles

When designing JEA roles, it's important to remember that the virtual and group-managed service accounts running behind the scenes can have unrestricted access to the local machine. JEA role capabilities help limit the commands and applications that can be run in that privileged context. Improperly designed roles can allow dangerous commands that may permit a user to break out of the JEA boundaries or obtain access to sensitive information.

For example, consider the following role capability entry:

PowerShell

```
@{  
    VisibleCmdlets = 'Microsoft.PowerShell.Management\*-Process'  
}
```

This role capability allows users to run any PowerShell cmdlet with the noun **Process** from the **Microsoft.PowerShell.Management** module. Users may need to access cmdlets like `Get-Process` to see what applications are running on the system and `Stop-Process` to kill applications that aren't responding. However, this entry also allows

`Start-Process`, which can be used to start up an arbitrary program with full administrator permissions. The program doesn't need to be installed locally on the system. A connected user could start a program from a file share that gives the user local administrator privileges, runs malware, and more.

A more secure version of this same role capability would look like:

```
PowerShell

#{@
    VisibleCmdlets = 'Microsoft.PowerShell.Management\Get-Process',
                      'Microsoft.PowerShell.Management\Stop-Process'
}
```

Avoid using wildcards in role capabilities. Be sure to regularly audit effective user permissions to see which commands are accessible to a user. For more information, see the *Check effective rights* section of the [Auditing and Reporting on JEA](#) article.

Best practice recommendations

The following are best practice recommendations to ensure the security of your JEA endpoints:

Limit the use and capabilities of PowerShell providers

Review how the allowed providers are used to ensure that you don't create vulnerabilities in your configured session.

Warning

Don't allow the **FileSystem** provider. If users can write to any part of the file system, it's possible to completely bypass security.

Don't allow the **Certificate** provider. With the provider enabled, a user could gain access to stored private keys.

Don't allow commands that can create new runspaces.

Warning

The `*-Job` cmdlets can create new runspaces without the restrictions.

Don't allow the `Trace-Command` cmdlet.

⚠ Warning

Using `Trace-Command` brings all traced commands into the session.

Don't create your own proxy implementations for the *restricted commands*.

PowerShell has a set of proxy commands for restricted command scenarios. These proxy commands ensure that input parameters can't compromise the security of the session.

The following commands have restricted proxies:

- `Exit-PSSession`
- `Get-Command`
- `Get-FormatData`
- `Get-Help`
- `Measure-Object`
- `Out-Default`
- `Select-Object`

If you create your own implementation of these commands, you may inadvertently allow users to run code prohibited by the JEA proxy commands.

JEA doesn't protect against admins

One of the core principles of JEA is that it allows nonadministrators to do some administrative tasks. JEA doesn't protect against users who already have administrator privileges. Users who belong **Domain Admins**, local **Administrators**, or other highly privileged groups can circumvent JEA's protections in other ways. For example, they could sign in with RDP, use remote MMC consoles, or connect to unconstrained PowerShell endpoints. Also, local administrator on a system can modify JEA configurations to add more users or change a role capability to extend the scope of what a user can do in their JEA session. It's important to evaluate your JEA users' extended permissions to see if there are other ways to gain privileged access to the system.

In addition to using JEA for regular day-to-day maintenance, it's common to have a just-in-time privileged access management system. These systems allow designated users to temporarily become a local administrator only after they complete a workflow that documents their use of those permissions.

Auditing and Reporting on JEA

Article • 04/01/2024

After you've deployed JEA, you need to regularly audit the JEA configuration. Auditing helps you assess that the correct people have access to the JEA endpoint and their assigned roles are still appropriate.

Find registered JEA sessions on a machine

To check which JEA sessions are registered on a machine, use the [Get-PSSessionConfiguration](#) cmdlet.

PowerShell

```
# Filter for sessions that are configured as 'RestrictedRemoteServer' to
# find JEA-like session configurations
Get-PSSessionConfiguration | Where-Object { $_.SessionType -eq
'RestrictedRemoteServer' }
```

Output

```
Name      : JEAMaintenance
PSVersion : 5.1
StartupScript :
RunAsUser  :
Permission : CONTOSO\JEA_DNS_ADMIN AccessAllowed,
CONTOSO\JEA_DNS_OPERATORS AccessAllowed,
CONTOSO\JEA_DNS_AUDITORS AccessAllowed
```

The effective rights for the endpoint are listed in the **Permission** property. These users have the right to connect to the JEA endpoint. However, the roles and commands they have access to is determined by the **RoleDefinitions** property in the [session configuration file](#) that was used to register the endpoint. Expand the **RoleDefinitions** property to evaluate the role mappings in a registered JEA endpoint.

PowerShell

```
# Get the desired session configuration
$jea = Get-PSSessionConfiguration -Name 'JEAMaintenance'

# Enumerate users/groups and which roles they have access to
$jea.RoleDefinitions.GetEnumerator() | Select-Object Name, @{
    Name = 'Role Capabilities'
```

```
Expression = { $_.Value.RoleCapabilities }  
}
```

Find available role capabilities on the machine

JEA gets role capabilities from the `.psrc` files stored in the `RoleCapabilities` folder inside a PowerShell module. The following function finds all role capabilities available on a computer.

PowerShell

```
function Find-LocalRoleCapability {  
    $results = @()  
  
    # Find modules with a "RoleCapabilities" subfolder and add any PSRC  
files to the result set  
    Get-Module -ListAvailable | ForEach-Object {  
        $psrcpath = Join-Path -Path $_.ModuleBase -ChildPath  
'RoleCapabilities'  
        if (Test-Path $psrcpath) {  
            $results += Get-ChildItem -Path $psrcpath -Filter *.psrc  
        }  
    }  
  
    # Format the results nicely to make it easier to read  
    $results | Select-Object @{ Name = 'Name'; Expression = {  
$__.Name.TrimEnd('.psrc') }}, @{  
    Name = 'Path'; Expression = { $_.FullName }  
} | Sort-Object Name  
}
```

ⓘ Note

The order of results from this function isn't necessarily the order in which the role capabilities will be selected if multiple role capabilities share the same name.

Check effective rights for a specific user

The `Get-PSSessionCapability` cmdlet enumerates all the commands available on a JEA endpoint based on a user's group memberships. The output of `Get-PSSessionCapability` is identical to that of the specified user running `Get-Command - CommandType All` in a JEA session.

PowerShell

```
Get-PSSessionCapability -ConfigurationName 'JEA Maintenance' -Username  
'CONTOSO\Alice'
```

If your users aren't permanent members of groups that would grant them additional JEA rights, this cmdlet may not reflect those extra permissions. This happens when using just-in-time privileged access management systems to allow users to temporarily belong to a security group. Carefully evaluate the mapping of users to roles and capabilities to ensure that users only get the level of access needed to do their jobs successfully.

PowerShell event logs

If you enabled module or script block logging on the system, you can see events in the Windows event logs for each command a user runs in a JEA session. To find these events, open **Microsoft-Windows-PowerShell/Operational** event log and look for events with event ID 4104.

Each event log entry includes information about the session in which the command was run. For JEA sessions, the event includes information about the **ConnectedUser** and the **RunAsUser**. The **ConnectedUser** is the actual user who created the JEA session. The **RunAsUser** is the account JEA used to execute the command.

Application event logs show changes being made by the **RunAsUser**. So having module and script logging enabled is required to trace a specific command invocation back to the **ConnectedUser**.

Application event logs

Commands run in a JEA session that interact with external applications or services may log events to their own event logs. Unlike PowerShell logs and transcripts, other logging mechanisms don't capture the connected user of the JEA session. Instead, those applications only log the virtual run-as user. To determine who ran the command, you need to consult a [session transcript](#) or correlate PowerShell event logs with the time and user shown in the application event log.

The WinRM log can also help you correlate run-as users to the connecting user in an application event log. Event ID 193 in the **Microsoft-Windows-Windows Remote Management/Operational** log records the security identifier (SID) and account name for both the connecting user and run as user for every new JEA session.

Session transcripts

If you configured JEA to create a transcript for each user session, a text copy of every user's actions are stored in the specified folder.

The following command (as an administrator) finds all transcript directories.

```
PowerShell
```

```
Get-PSSessionConfiguration |  
    Where-Object { $_.TranscriptDirectory -ne $null } |  
        Format-Table Name, TranscriptDirectory
```

Each transcript starts with information about the time the session started, which user connected to the session, and which JEA identity was assigned to them.

```
*****  
Windows PowerShell transcript start  
Start time: 20160710144736  
Username: CONTOSO\Alice  
RunAs User: WinRM Virtual Users\WinRM VA_1_CONTOSO_Alice  
Machine: SERVER01 (Microsoft Windows NT 10.0.14393.0)  
[...]
```

The body of the transcript contains information about each command the user invoked. The exact syntax of the command used is unavailable in JEA sessions because of the way commands are transformed for PowerShell remoting. However, you can still determine the effective command that was executed. Below is an example transcript snippet from a user running `Get-Service Dns` in a JEA session:

```
PS>CommandInvocation(Get-Service): "Get-Service"  
>> ParameterBinding(Get-Service): name="Name"; value="Dns"  
>> CommandInvocation(Out-Default): "Out-Default"  
>> ParameterBinding(Out-Default): name="InputObject"; value="Dns"  
  
Running   Dns           DNS Server
```

A **CommandInvocation** line is written for each command a user runs.

ParameterBindings record each parameter and value supplied with the command. In the previous example, you can see that the parameter **Name** was supplied the value **Dns** for the `Get-Service` cmdlet.

The output of each command also triggers a `CommandInvocation`, usually to `Out-Default`. The `InputObject` of `Out-Default` is the PowerShell object returned from the command. The details of that object are printed a few lines below, closely mimicking what the user would have seen.

Running Remote Commands

Article • 03/24/2025

You can run commands on one or hundreds of computers with a single PowerShell command. Windows PowerShell supports remote computing using various technologies, including WMI, RPC, and WS-Management.

PowerShell supports WMI, WS-Management, and SSH remoting. In PowerShell 7 and higher, RPC is supported only on Windows.

For more information about remoting in PowerShell, see the following articles:

- [SSH Remoting in PowerShell](#)
- [WSMan Remoting in PowerShell](#)

Windows PowerShell remoting without configuration

Many Windows PowerShell cmdlets have the **ComputerName** parameter that enables you to collect data and change settings on one or more remote computers. These cmdlets use varying communication protocols and work on all Windows operating systems without any special configuration.

These cmdlets include:

- [Restart-Computer](#)
- [Test-Connection](#)
- [Clear-EventLog](#)
- [Get-EventLog](#)
- [Get-HotFix](#)
- [Get-Process](#)
- [Get-Service](#)
- [Set-Service](#)
- [Get-WinEvent](#)
- [Get-WmiObject](#)

Typically, cmdlets that support remoting without special configuration have the **ComputerName** parameter and don't have the **Session** parameter. To find these cmdlets in your session, type:

```
PowerShell
```

```
Get-Command | Where-Object {  
    $_.Parameters.Keys -contains "ComputerName" -and  
    $_.Parameters.Keys -notcontains "Session"  
}
```

Windows PowerShell remoting

Using the WS-Management protocol, Windows PowerShell remoting lets you run any Windows PowerShell command on one or more remote computers. You can establish persistent connections, start interactive sessions, and run scripts on remote computers.

To use Windows PowerShell remoting, the remote computer must be configured for remote management. For more information, including instructions, see [About Remote Requirements](#).

Once you have configured Windows PowerShell remoting, many remoting strategies are available to you. This article lists just a few of them. For more information, see [About Remote](#).

Start an interactive session

To start an interactive session with a single remote computer, use the [Enter-PSSession](#) cmdlet. For example, to start an interactive session with the Server01 remote computer, type:

```
PowerShell  
  
Enter-PSSession Server01
```

The command prompt changes to display the name of the remote computer. Any commands that you type at the prompt run on the remote computer and the results are displayed on the local computer.

To end the interactive session, type:

```
PowerShell  
  
Exit-PSSession
```

For more information about the [Enter-PSSession](#) and [Exit-PSSession](#) cmdlets, see:

- [Enter-PSSession](#)

- [Exit-PSSession](#)

Run a Remote Command

To run a command on one or more computers, use the [Invoke-Command](#) cmdlet. For example, to run a [Get-UICulture](#) command on the Server01 and Server02 remote computers, type:

```
PowerShell
```

```
Invoke-Command -ComputerName Server01, Server02 -ScriptBlock {Get-UICulture}
```

The output is returned to your computer.

```
Output
```

LCID	Name	DisplayName	PSComputerName
1033	en-US	English (United States)	server01.corp.fabrikam.com
1033	en-US	English (United States)	server02.corp.fabrikam.com

Run a Script

To run a script on one or many remote computers, use the **FilePath** parameter of the [Invoke-Command](#) cmdlet. The script must be on or accessible to your local computer. The results are returned to your local computer.

For example, the following command runs the `DiskCollect.ps1` script on the remote computers, Server01 and Server02.

```
PowerShell
```

```
Invoke-Command -ComputerName Server01, Server02 -FilePath  
C:\Scripts\DiskCollect.ps1
```

Establish a Persistent Connection

Use the [New-PSSession](#) cmdlet to create a persistent session on a remote computer. The following example creates remote sessions on Server01 and Server02. The session objects are stored in the `$s` variable.

```
PowerShell
```

```
$s = New-PSSession -ComputerName Server01, Server02
```

Now that the sessions are established, you can run any command in them. And because the sessions are persistent, you can collect data from one command and use it in another command.

For example, the following command runs a `Get-HotFix` command in the sessions in the `$s` variable and it saves the results in the `$h` variable. The `$h` variable is created in each of the sessions in `$s`, but it doesn't exist in the local session.

PowerShell

```
Invoke-Command -Session $s {$h = Get-HotFix}
```

Now you can use the data in the `$h` variable with other commands in the same session. The results are displayed on the local computer. For example:

PowerShell

```
Invoke-Command -Session $s {$h | where {$_.InstalledBy -ne "NT AUTHORITY\SYSTEM"}}
```

Advanced Remoting

PowerShell includes cmdlets that allow you to:

- Configure and create remote sessions both from the local and remote ends
- Create customized and restricted sessions
- Import commands from a remote session that actually run implicitly on the remote session
- Configure the security of a remote session

PowerShell on Windows includes a WSMAN provider. The provider creates a `WSMan:` drive that lets you navigate through a hierarchy of configuration settings on the local computer and remote computers.

For more information about the WSMAN provider, see [WSMAN Provider](#) and [About WS-Management Cmdlets](#), or in the Windows PowerShell console, type `Get-Help WSMAN`.

For more information, see:

- [PowerShell Remoting FAQ](#)

- [Register-PSSessionConfiguration](#)
- [Import-PSSession](#)

For help with remoting errors, see [about_Remote_Troubleshooting](#).

PowerShell remoting over SSH

Article • 05/29/2025

Overview

PowerShell remoting normally uses WinRM for connection negotiation and data transport. SSH is now available for Linux and Windows platforms and allows true multiplatform PowerShell remoting.

WinRM provides a robust hosting model for PowerShell remote sessions. SSH-based remoting doesn't currently support remote endpoint configuration and Just Enough Administration (JEA).

SSH remoting lets you do basic PowerShell session remoting between Windows and Linux computers. SSH remoting creates a PowerShell host process on the target computer as an SSH subsystem. Eventually we'll implement a general hosting model, similar to WinRM, to support endpoint configuration and JEA.

The `New-PSSession`, `Enter-PSSession`, and `Invoke-Command` cmdlets now have a new parameter set to support this new remoting connection.

```
[ -HostName <string> ] [ -UserName <string> ] [ -KeyFilePath <string> ]
```

To create a remote session, you specify the target computer with the **HostName** parameter and provide the user name with **UserName**. When running the cmdlets interactively, you're prompted for a password. You can also use SSH key authentication using a private key file with the **KeyFilePath** parameter. Creating keys for SSH authentication varies by platform.

General setup information

PowerShell 6 or higher, and SSH must be installed on all computers. Install both the SSH client (`ssh.exe`) and server (`sshd.exe`) so that you can remote to and from the computers. OpenSSH for Windows is now available in Windows 10 build 1809 and Windows Server 2019. For more information, see [Manage Windows with OpenSSH](#). For Linux, install SSH, including `sshd` server, that's appropriate for your platform. You also need to install PowerShell from GitHub to get the SSH remoting feature. The SSH server must be configured to create an SSH subsystem to host a PowerShell process on the remote computer. And, you must enable **password** or **key-based** authentication.

Install the SSH service on a Windows computer

1. Install the latest version of PowerShell. For more information, see [Installing PowerShell on Windows](#).

You can confirm that PowerShell has SSH remoting support by listing the `New-PSSession` parameter sets. You'll notice there are parameter set names that begin with `SSH`. Those parameter sets include `SSH` parameters.

```
PowerShell
```

```
(Get-Command New-PSSession).ParameterSets.Name
```

```
Output
```

```
Name
```

```
----
```

```
SSHHost
```

```
SSHHostHashParam
```

2. Install the latest Win32 OpenSSH. For installation instructions, see [Getting started with OpenSSH](#).

 **Note**

If you want to set PowerShell as the default shell for OpenSSH, see [Configuring Windows for OpenSSH](#).

3. Edit the `sshd_config` file located at `$Env:ProgramData\ssh`.

- Make sure password authentication is enabled:

```
PasswordAuthentication yes
```

- Create the SSH subsystem that hosts a PowerShell process on the remote computer:

```
Subsystem powershell C:/program~1/powershell/7/pwsh.exe -sshs
```

Note

There is a bug in OpenSSH for Windows that prevents you from using a path with spaces for the subsystem executable. There are two ways to work around this issue:

- Use the Windows *8.3-style* short name for the PowerShell executable path
- Create a symbolic link to the PowerShell executable that results in a path without spaces

For more information, see [issue #784](#) in the PowerShell/Win32-OpenSSH repository.

You only need to get the 8.3-style name for the segment of the path that contains the space. By default PowerShell 7 is installed in `C:\Program Files\PowerShell\7\`. The 8.3-style name for `Program Files` should be `program~1`. You can use the following command to verify the name:

```
PowerShell
```

```
Get-CimInstance Win32_Directory -Filter 'Name="C:\\Program Files"' |  
    Select-Object EightDotThreeFileName
```

The 8.3 name is a legacy feature of the NTFS file system that can be disabled. This feature must be enabled for the volume on which PowerShell is installed.

Alternatively, you can create a symbolic link to the PowerShell executable that results in a path without spaces. This method is preferred because it allows you to update the link if the path to the PowerShell executable ever changes, without also needing to update your `sshd_config` file.

Use the following command to create a symbolic link to the executable:

```
PowerShell
```

```
$newItemSplat = @{  
    ItemType = 'SymbolicLink'  
    Path = 'C:\ProgramData\ssh\'  
    Name = 'pwsh.exe'  
    Value = (Get-Command pwsh.exe).Source  
}  
New-Item @newItemSplat
```

This command creates the symbolic link in the same directory used by the OpenSSH server to store the host keys and other configuration.

- Optionally, enable key authentication:

```
PubkeyAuthentication yes
```

For more information, see [Managing OpenSSH Keys](#).

4. Restart the `sshd` service.

```
PowerShell
```

```
Restart-Service sshd
```

5. Add the path where OpenSSH is installed to your PATH environment variable. For example, `C:\Program Files\OpenSSH\`. This entry allows for the `ssh.exe` to be found.

Install the SSH service on an Ubuntu Linux computer

1. Install the latest version of PowerShell, see [Installing PowerShell on Ubuntu](#).

2. Install [Ubuntu OpenSSH Server ↗](#).

```
Bash
```

```
sudo apt install openssh-client  
sudo apt install openssh-server
```

3. Edit the `sshd_config` file at location `/etc/ssh`.

- Make sure password authentication is enabled:

```
PasswordAuthentication yes
```

- Optionally, enable key authentication:

```
PubkeyAuthentication yes
```

For more information about creating SSH keys on Ubuntu, see the manpage for [ssh-keygen](#).

- Add a PowerShell subsystem entry:

```
Subsystem powershell /usr/bin/pwsh -sshs -NoLogo
```

! Note

The default location of the PowerShell executable is `/usr/bin/pwsh`. The location can vary depending on how you installed PowerShell.

4. Restart the ssh service.

Bash

```
sudo systemctl restart sshd.service
```

Install the SSH service on a macOS computer

1. Install the latest version of PowerShell. For more information, [Installing PowerShell on macOS](#).

Make sure SSH Remoting is enabled by following these steps:

- Open `System Settings`.
- Click on `General`.
- Click on `Sharing`.
- Check `Remote Login` to set `Remote Login: On`.
- Allow access to the appropriate users.

2. Edit the `sshd_config` file at location `/private/etc/ssh/sshd_config`.

Use a text editor such as `nano`:

Bash

```
sudo nano /private/etc/ssh/sshd_config
```

- Make sure password authentication is enabled:

```
PasswordAuthentication yes
```

- Add a PowerShell subsystem entry:

```
Subsystem powershell /usr/local/bin/pwsh -sshs -NoLogo
```

 **Note**

The default location of the PowerShell executable is `/usr/local/bin/pwsh`. The location can vary depending on how you installed PowerShell.

- Optionally, enable key authentication:

```
PubkeyAuthentication yes
```

3. Restart the `sshd` service.

Bash

```
sudo launchctl stop com.openssh.sshd
sudo launchctl start com.openssh.sshd
```

 **Note**

When you upgrade your operating system, the SSH configuration file might be overwritten. Make sure you check the configuration file after an upgrade.

Authentication

PowerShell remoting over SSH relies on the authentication exchange between the SSH client and SSH service and doesn't implement any authentication schemes itself. The result is that any configured authentication schemes including multi-factor authentication are handled by SSH and independent of PowerShell. For example, you can configure the SSH service to require public key authentication and a one-time password for added security. Configuration of multi-factor authentication is outside the scope of this documentation. Refer to documentation for SSH on how to correctly configure multi-factor authentication and validate it works outside of PowerShell before attempting to use it with PowerShell remoting.

! Note

Users retain the same privileges in remote sessions. Meaning, Administrators have access to an elevated shell, and normal users do not.

PowerShell remoting example

The easiest way to test remoting is to try it on a single computer. In this example, we create a remote session back to the same Linux computer. We're using PowerShell cmdlets interactively so we see prompts from SSH asking to verify the host computer and prompting for a password. You can do the same thing on a Windows computer to ensure remoting is working. Then, remote between computers by changing the host name.

Linux to Linux

PowerShell

```
$session = New-PSSession -HostName UbuntuVM1 -UserName TestUser
```

Output

```
The authenticity of host 'UbuntuVM1 (9.129.17.107)' can't be established.  
ECDSA key fingerprint is SHA256:2kCbnhT2dUE6WCggVJ8Hyfu1z2wE4lifaJXL07QJy0Y.  
Are you sure you want to continue connecting (yes/no)?  
TestUser@UbuntuVM1's password:
```

PowerShell

```
$session
```

Output

Id	Name	ComputerName	ComputerType	State	ConfigurationName
Availability					
--	--	--	--	--	--
1	SSH1	UbuntuVM1	RemoteMachine	Opened	DefaultShell
Available					

PowerShell

```
Enter-PSSession $session
```

Output

```
[UbuntuVM1]: PS /home/TestUser> uname -a
Linux TestUser-UbuntuVM1 4.2.0-42-generic 49~16.04.1-Ubuntu SMP Wed Jun 29
20:22:11 UTC 2016 x86_64 x86_64 x86_64 GNU/Linux
```

```
[UbuntuVM1]: PS /home/TestUser> Exit-PSSession
```

PowerShell

```
Invoke-Command $session -ScriptBlock { Get-Process pwsh }
```

Output

Handles	NPM(K)	PM(K)	WS(K)	CPU(s)	Id	SI	ProcessName
PSComputerName							
--	--	--	--	--	--	--	--
0	0	0	19	3.23	10635	635	pwsh
0	0	0	21	4.92	11033	017	pwsh
0	0	0	20	3.07	11076	076	pwsh

Linux to Windows

PowerShell

```
Enter-PSSession -HostName WinVM1 -UserName PTestName
```

PTestName@WinVM1's password:

PowerShell

```
[WinVM1]: PS C:\Users\PTestName\Documents> cmd /c ver
```

Output

```

```
[WinVM2]: PS C:\Users\PSRemoteUser\Documents>
```

Limitations

- The `sudo` command doesn't work in a remote session to a Linux computer.
- PSRemoting over SSH doesn't support Profiles and doesn't have access to `$PROFILE`. Once in a session, you can load a profile by dot sourcing the profile with the full filepath. This isn't related to SSH profiles. You can configure the SSH server to use PowerShell as the default shell and to load a profile through SSH. See the SSH documentation for more information.
- Prior to PowerShell 7.1, remoting over SSH didn't support second-hop remote sessions. This capability was limited to sessions using WinRM. PowerShell 7.1 allows `Enter-PSSession` and `Enter-PSHostProcess` to work from within any interactive remote session.

Using WS-Management (WSMan) Remoting in PowerShell

Article • 01/27/2025

Enabling PowerShell remoting

To enable PowerShell remoting run the `Enable-PSRemoting` cmdlet in an elevated PowerShell session. Running `Enable-PSRemoting` configures a remoting endpoint for the specific installation version that you are running the cmdlet in. For example, when you run `Enable-PSRemoting` while running PowerShell 7.4, PowerShell creates a remoting endpoint runs PowerShell 7.4. If you run `Enable-PSRemoting` while running PowerShell 7-preview, PowerShell creates a remoting endpoint that runs PowerShell 7-preview. You can create multiple remoting endpoints for different versions of that run side-by-side.

Running `Enable-PSRemoting` creates two endpoints for that version.

- One has a simple name corresponding to the PowerShell major version. that hosts the session. For example, **PowerShell.7.4**.
- The other configuration name contains the full version number. For example, **PowerShell.7.4.7**.

You can connect to the latest version of PowerShell 7 host version using the simple name, **PowerShell.7.4**. You can connect to a specific version of PowerShell using the longer, version-specific name.

Use the **ConfigurationName** parameter with the `New-PSSession` and `Enter-PSSession` cmdlets to connect to a named configuration.

Remoting to older versions of Windows

The following prerequisites must be met to enable PowerShell remoting over WSMan on older versions of Windows.

- Install the Windows Management Framework (WMF) 5.1 (as necessary). For more information about WMF, see [WMF Overview](#).
- Install the [Universal C Runtime](#) on Windows versions predating Windows 10. It's available via direct download or Windows Update. Fully patched systems already have this package installed.

WSMan remoting isn't supported on non-Windows platforms

Since the release of PowerShell 6, support for remoting over WS-Management (WSMan) on non-Windows platforms has only been available to a limited set of Linux distributions. All versions of those distributions that supported WSMan are no longer supported by the Linux vendors that created them.

On non-Windows, WSMan relied on the [Open Management Infrastructure \(OMI\)](#) project, which no longer supports PowerShell remoting. The OMI WSMan client is dependent on [OpenSSL 1.0](#). Most Linux distributions have moved to [OpenSSL 2.0](#), which isn't backward-compatible. At this time, there is no supported distribution that has the dependencies needed for the OMI WSMan client to work.

The outdated libraries and supporting code have been removed for non-Windows platforms. WSMan-based remoting is still supported between Windows systems. Remoting over SSH is supported for all platforms. For more information, see [PowerShell remoting over SSH](#).

ⓘ Note

Users may be able to get WSMan remoting to work using the [PSWSMan](#) module. This module isn't supported or maintained by Microsoft.

Security Considerations for PowerShell Remoting using WinRM

Article • 03/24/2025

PowerShell Remoting is the recommended way to manage Windows systems. PowerShell Remoting is enabled by default in Windows Server 2012 R2 and higher. This document covers security concerns, recommendations, and best practices when using PowerShell Remoting.

What is PowerShell Remoting?

PowerShell Remoting uses [Windows Remote Management \(WinRM\)](#) to allow users to run PowerShell commands on remote computers. WinRM is the Microsoft implementation of the [Web Services for Management \(WS-Management\)](#) ↗ protocol. You can find more information about using PowerShell Remoting at [Running Remote Commands](#).

PowerShell Remoting isn't the same as using the `ComputerName` parameter of a cmdlet to run it on a remote computer, which uses Remote Procedure Call (RPC) as its underlying protocol.

PowerShell Remoting default settings

PowerShell Remoting with WinRM listens on the following ports:

- HTTP: 5985
- HTTPS: 5986

By default, PowerShell Remoting only allows connections from members of the Administrators group. Sessions are launched under the user's context, so all operating system access controls applied to individual users and groups continue to apply to them while connected over PowerShell Remoting.

On private networks, the default Windows Firewall rule for PowerShell Remoting accepts all connections. On public networks, the default Windows Firewall rule allows PowerShell Remoting connections only from within the same subnet. You have to explicitly change that rule to open PowerShell Remoting to all connections on a public network.

Warning

The firewall rule for public networks is meant to protect the computer from potentially malicious external connection attempts. Use caution when removing this rule.

Process isolation

PowerShell Remoting uses WinRM for communication between computers. WinRM runs as a service under the Network Service account, and spawns isolated processes running as user accounts to host PowerShell instances. An instance of PowerShell running as one user has no access to a process running an instance of PowerShell as another user.

Event logs generated by PowerShell Remoting

Researchers from Mandiant presented a session at the BlackHat conference that provides a good summary of the event logs and other security evidence generated by PowerShell Remoting sessions. For more information, see [Investigating PowerShell Attacks ↗](#).

Encryption and transport protocols

It's helpful to consider the security of a PowerShell Remoting connection from two perspectives: initial authentication, and ongoing communication.

Regardless of the transport protocol used (HTTP or HTTPS), WinRM always encrypts all PowerShell remoting communication after initial authentication.

Initial authentication

Authentication confirms the identity of the client to the server - and ideally - the server to the client.

When a client connects to a domain server using its computer name, the default authentication protocol is [Kerberos](#). Kerberos guarantees both the user identity and server identity without sending any sort of reusable credential.

When a client connects to a domain server using its IP address, or connects to a workgroup server, Kerberos authentication isn't possible. In that case, PowerShell Remoting relies on the [NTLM authentication protocol](#). The NTLM authentication protocol guarantees the user identity without sending any sort of delegable credential. To prove user identity, the NTLM protocol requires that both the client and server

compute a session key from the user's password without ever exchanging the password itself. The server typically doesn't know the user's password, so it communicates with the domain controller, which does know the user's password and calculates the session key for the server.

The NTLM protocol doesn't, however, guarantee server identity. As with all protocols that use NTLM for authentication, an attacker with access to a domain-joined computer's machine account could invoke the domain controller to compute an NTLM session-key and impersonate the server.

NTLM-based authentication is disabled by default. You can enable NTLM by either configuring SSL on the target server, or by configuring the WinRM TrustedHosts setting on the client.

Using SSL certificates to validate server identity during NTLM-based connections

Since the NTLM authentication protocol can't ensure the identity of the target server (only that it already knows your password), you can configure target servers to use SSL for PowerShell Remoting. Assigning an SSL certificate to the target server (if issued by a Certificate Authority that the client also trusts) enables NTLM-based authentication that guarantees both the user identity and server identity.

Ignoring NTLM-based server identity errors

If deploying an SSL certificate to a server for NTLM connections is infeasible, you can suppress the resulting identity errors by adding the server to the WinRM **TrustedHosts** list. Adding a server name to the **TrustedHosts** list shouldn't be considered as any form of statement of the trustworthiness of the hosts themselves - as the NTLM authentication protocol can't guarantee that you are in fact connecting to the host you're intending to connect to. Instead, you should consider the **TrustedHosts** setting to be the list of hosts for which you wish to suppress the error generated by being unable to verify the server's identity.

Ongoing Communication

Once initial authentication is complete, the WinRM encrypts the ongoing communication. When you connect over HTTPS, WinRM uses the TLS protocol to negotiate the encryption used to transport data. When you connect over HTTP, WinRM uses the message-level encryption negotiated by the initial authentication protocol.

- Basic authentication provides no encryption.
- NTLM authentication uses an RC4 cipher with a 128-bit key.
- The `etype` in the TGS ticket determines Kerberos authentication encryption. This is AES-256 on modern systems.
- CredSSP encryption uses the TLS cipher suite negotiated in the handshake.

Making the second hop

By default, PowerShell Remoting uses Kerberos (if available) or NTLM for authentication. Both of these protocols authenticate to the remote machine without sending credentials to it. This is the most secure way to authenticate, but because the remote machine doesn't have the user's credentials, it can't access other computers and services on the user's behalf. This is known as the *second hop problem*.

There are several ways to avoid this problem. For descriptions of these methods, and the pros and cons of each, see [Making the second hop in PowerShell Remoting](#).

Making the second hop in PowerShell Remoting

Article • 04/01/2024

The "second hop problem" refers to a situation like the following:

1. You are logged in to *ServerA*.
2. From *ServerA*, you start a remote PowerShell session to connect to *ServerB*.
3. A command you run on *ServerB* via your PowerShell Remoting session attempts to access a resource on *ServerC*.
4. Access to the resource on *ServerC* is denied, because the credentials you used to create the PowerShell Remoting session aren't passed from *ServerB* to *ServerC*.

There are several ways to address this problem. The following table lists the methods in order of preference.

[+] Expand table

Configuration	Note
CredSSP	Balances ease of use and security
Resource-based Kerberos constrained delegation	Higher security with simpler configuration
Kerberos constrained delegation	High security but requires Domain Administrator
Kerberos delegation (unconstrained)	Not recommended
Just Enough Administration (JEA)	Can provide the best security but requires more detailed configuration
PSSessionConfiguration using RunAs	Simpler to configure but requires credential management
Pass credentials inside an <code>Invoke-Command</code> script block	Simplest to use but you must provide credentials

CredSSP

You can use the [Credential Security Support Provider \(CredSSP\)](#) for authentication.

CredSSP caches credentials on the remote server (*ServerB*), so using it opens you up to credential theft attacks. If the remote computer is compromised, the attacker has access to the user's credentials. CredSSP is disabled by default on both client and server

computers. You should enable CredSSP only in the most trusted environments. For example, a domain administrator connecting to a domain controller because the domain controller is highly trusted.

For more information about security concerns when using CredSSP for PowerShell Remoting, see [Accidental Sabotage: Beware of CredSSP ↴](#).

For more information about credential theft attacks, see [Mitigating Pass-the-Hash \(PtH\) Attacks and Other Credential Theft ↴](#).

For an example of how to enable and use CredSSP for PowerShell remoting, see [Enable PowerShell "Second-Hop" Functionality with CredSSP ↴](#).

Pros

- It works for all servers with Windows Server 2008 or later.

Cons

- Has security vulnerabilities.
- Requires configuration of both client and server roles.
- doesn't work with the Protected Users group. For more information, see [Protected Users Security Group](#).

Kerberos constrained delegation

You can use legacy constrained delegation (not resource-based) to make the second hop. Configure Kerberos constrained delegation with the option "Use any authentication protocol" to allow protocol transition.

Pros

- Requires no special coding
- Credentials aren't stored.

Cons

- Doesn't support the second hop for WinRM.
- Requires Domain Administrator access to configure.
- Must be configured on the Active Directory object of the remote server (*ServerB*).
- Limited to one domain. Can't cross domains or forests.

- Requires rights to update objects and Service Principal Names (SPNs).
- *ServerB* can acquire a Kerberos ticket to *ServerC* on behalf of the user without user intervention.

 Note

Active Directory accounts that have the **Account is sensitive and can't be delegated** property set can't be delegated. For more information, see [Security Focus: Analysing 'Account is sensitive and can't be delegated' for Privileged Accounts](#) and [Kerberos Authentication Tools and Settings](#).

Resource-based Kerberos constrained delegation

Using resource-based Kerberos constrained delegation (introduced in Windows Server 2012), you configure credential delegation on the server object where resources reside. In the second hop scenario described above, you configure *ServerC* to specify from where it accepts delegated credentials.

Pros

- Credentials aren't stored.
- Configured using PowerShell cmdlets. No special coding required.
- Doesn't require Domain Administrator access to configure.
- Works across domains and forests.

Cons

- Requires Windows Server 2012 or later.
- Doesn't support the second hop for WinRM.
- Requires rights to update objects and Service Principal Names (SPNs).

 Note

Active Directory accounts that have the **Account is sensitive and can't be delegated** property set can't be delegated. For more information, see [Security Focus: Analysing 'Account is sensitive and can't be delegated' for Privileged Accounts](#) and [Kerberos Authentication Tools and Settings](#).

Example

Let's look at a PowerShell example that configures resource-based constrained delegation on *ServerC* to allow delegated credentials from a *ServerB*. This example assumes that all servers are running supported versions of Windows Server, and that there is at least one Windows domain controller for each trusted domain.

Before you can configure constrained delegation, you must add the `RSAT-AD-PowerShell` feature to install the Active Directory PowerShell module, and then import that module into your session:

```
PowerShell

Add-WindowsFeature RSAT-AD-PowerShell
Import-Module ActiveDirectory
Get-Command -ParameterName PrincipalsAllowedToDelegateToAccount
```

Several available cmdlets now have a `PrincipalsAllowedToDelegateToAccount` parameter:

Output		
CommandType	Name	ModuleName
Cmdlet	New-ADComputer	ActiveDirectory
Cmdlet	New-ADServiceAccount	ActiveDirectory
Cmdlet	New-ADUser	ActiveDirectory
Cmdlet	Set-ADComputer	ActiveDirectory
Cmdlet	Set-ADServiceAccount	ActiveDirectory
Cmdlet	Set-ADUser	ActiveDirectory

The `PrincipalsAllowedToDelegateToAccount` parameter sets the Active Directory object attribute `msDS-AllowedToActOnBehalfOfOtherIdentity`, which contains an access control list (ACL) that specifies which accounts have permission to delegate credentials to the associated account (in our example, it will be the machine account for *ServerA*).

Now let's set up the variables we'll use to represent the servers:

```
PowerShell

# Set up variables for reuse
$ServerA = $Env:COMPUTERNAME
$ServerB = Get-ADComputer -Identity ServerB
$ServerC = Get-ADComputer -Identity ServerC
```

WinRM (and therefore PowerShell remoting) runs as the computer account by default. You can see this by looking at the **StartName** property of the `winrm` service:

PowerShell

```
Get-CimInstance Win32_Service -Filter 'Name="winrm"' | Select-Object StartName
```

Output

```
StartName  
-----  
NT AUTHORITY\NetworkService
```

For *ServerC* to allow delegation from a PowerShell remoting session on *ServerB*, we must set the **PrincipalsAllowedToDelegateToAccount** parameter on *ServerC* to the computer object of *ServerB*:

PowerShell

```
# Grant resource-based Kerberos constrained delegation
Set-ADComputer -Identity $ServerC -PrincipalsAllowedToDelegateToAccount
$ServerB

# Check the value of the attribute directly
$x = Get-ADComputer -Identity $ServerC -Properties msDS-
AllowedToActOnBehalfOfOtherIdentity
$x.'msDS-AllowedToActOnBehalfOfOtherIdentity'.Access

# Check the value of the attribute indirectly
Get-ADComputer -Identity $ServerC -Properties
PrincipalsAllowedToDelegateToAccount
```

The Kerberos [Key Distribution Center \(KDC\)](#) caches denied-access attempts (negative cache) for 15 minutes. If *ServerB* has previously attempted to access *ServerC*, you need to clear the cache on *ServerB* by invoking the following command:

PowerShell

```
Invoke-Command -ComputerName $ServerB.Name -Credential $cred -ScriptBlock {
    klist purge -li 0x3e7
}
```

You could also restart the computer, or wait at least 15 minutes to clear the cache.

After clearing the cache, you can successfully run code from *ServerA* through *ServerB* to *ServerC*:

```
PowerShell

# Capture a credential
$cred = Get-Credential Contoso\Alice

# Test kerberos double hop
Invoke-Command -ComputerName $ServerB.Name -Credential $cred -ScriptBlock {
    Test-Path \\$($Using:ServerC.Name)\C$
    Get-Process lsass -ComputerName $($Using:ServerC.Name)
    Get-EventLog -LogName System -Newest 3 -ComputerName
    $($Using:ServerC.Name)
}
```

In this example, the `Using:` scope modifier is used to make the `$ServerC` variable visible to *ServerB*. For more information about the `Using:` scope modifier, see [about_Remote_Variables](#).

To allow multiple servers to delegate credentials to *ServerC*, set the value of the `PrincipalsAllowedToDelegateToAccount` parameter on *ServerC* to an array:

```
PowerShell

# Set up variables for each server
$ServerB1 = Get-ADComputer -Identity ServerB1
$ServerB2 = Get-ADComputer -Identity ServerB2
$ServerB3 = Get-ADComputer -Identity ServerB3
$ServerC = Get-ADComputer -Identity ServerC

$servers = @(
    $ServerB1,
    $ServerB2,
    $ServerB3
)

# Grant resource-based Kerberos constrained delegation
Set-ADComputer -Identity $ServerC -PrincipalsAllowedToDelegateToAccount
$servers
```

If you want to make the second hop across domains, use the `Server` parameter to specify fully-qualified domain name (FQDN) of the domain controller of the domain to which *ServerB* belongs:

```
PowerShell
```

```
# For ServerC in Contoso domain and ServerB in other domain
$ServerB = Get-ADComputer -Identity ServerB -Server dc1.alpineskihouse.com
$ServerC = Get-ADComputer -Identity ServerC
Set-ADComputer -Identity $ServerC -PrincipalsAllowedToDelegateToAccount
$ServerB
```

To remove the ability to delegate credentials to ServerC, set the value of the **PrincipalsAllowedToDelegateToAccount** parameter on *ServerC* to `$null`:

PowerShell

```
Set-ADComputer -Identity $ServerC -PrincipalsAllowedToDelegateToAccount
$null
```

Information on resource-based Kerberos constrained delegation

- [What's New in Kerberos Authentication](#)
- [How Windows Server 2012 Eases the Pain of Kerberos Constrained Delegation, Part 1 ↗](#)
- [How Windows Server 2012 Eases the Pain of Kerberos Constrained Delegation, Part 2 ↗](#)
- [Understanding Kerberos Constrained Delegation for Microsoft Entra application proxy deployments with Integrated Windows Authentication ↗](#)
- [\[MS-ADA2\] Active Directory Schema Attributes M2.210 Attribute msDS-AllowedToActOnBehalfOfOtherIdentity\]MS-ADA2](#)
- [\[MS-SFU\] Kerberos Protocol Extensions: Service for User and Constrained Delegation Protocol 1.3.2 S4U2proxy\]MS-SFU](#)
- [Remote Administration Without Constrained Delegation Using PrincipalsAllowedToDelegateToAccount](#)

Kerberos delegation (unconstrained)

You can also use Kerberos unconstrained delegation to make the second hop. Like all Kerberos scenarios, credentials aren't stored. This method doesn't support the second hop for WinRM.

 **Warning**

This method provides no control of where delegated credentials are used. It's less secure than CredSSP. This method should only be used for testing scenarios.

Just Enough Administration (JEA)

JEA allows you to restrict what commands an administrator can run during a PowerShell session. It can be used to solve the second hop problem.

For information about JEA, see [Just Enough Administration](#).

Pros

- No password maintenance when using a virtual account.

Cons

- Requires WMF 5.0 or later.
- Requires configuration on every intermediate server (*ServerB*).

PSSessionConfiguration using RunAs

You can create a session configuration on *ServerB* and set its **RunAsCredential** parameter.

For information about using **PSSessionConfiguration** and **RunAs** to solve the second hop problem, see [Another solution to multi-hop PowerShell remoting](#).

Pros

- Works with any server with WMF 3.0 or later.

Cons

- Requires configuration of **PSSessionConfiguration** and **RunAs** on every intermediate server (*ServerB*).
- Requires password maintenance when using a domain **RunAs** account

Pass credentials inside an Invoke-Command script block

You can pass credentials inside the `ScriptBlock` parameter of a call to the [Invoke-Command](#) cmdlet.

Pros

- Doesn't require special server configuration.
- Works on any server running WMF 2.0 or later.

Cons

- Requires an awkward code technique.
- If running WMF 2.0, requires different syntax for passing arguments to a remote session.

Example

The following example shows how to pass credentials in a script block:

PowerShell

```
# This works without delegation, passing fresh creds
# Note $Using:Cred in nested request
$cred = Get-Credential Contoso\Administrator
Invoke-Command -ComputerName ServerB -Credential $cred -ScriptBlock {
    hostname
    Invoke-Command -ComputerName ServerC -Credential $Using:cred -
    ScriptBlock {hostname}
}
```

[PowerShell Remoting Security Considerations](#)

Securing a restricted PowerShell remoting session

Article • 04/01/2024

There are scenarios where you want to host a PowerShell session that, for security reasons, has been limited to a subset of PowerShell commands.

By definition, a restricted session is one where `Import-Module` isn't allowed to be used. There may be other limitations, but this is the primary requirement. If the user can import a module, then they can run anything they want.

Examples of restricted sessions include:

- Just-Enough-Administration (JEA)
- Custom restricted remoting implementations such as the Exchange and Teams modules

For most system administrators, JEA provides the best experience for creating restricted sessions and should be your first choice. For more information about JEA, see the [JEA Overview](#).

Recommendations for custom session implementations

If your scenario requires a custom implementation, then you should follow these recommendations.

Limit the use and capabilities of PowerShell providers

Review how the allowed providers are used to ensure that you don't create vulnerabilities in your restricted session implementation.

Warning

Don't allow the `FileSystem` provider. If users can write to any part of the file system, it's possible to completely bypass security.

Don't allow the `Certificate` provider. With the provider enabled, a user could gain access to stored private keys.

Don't allow commands that can create new runspaces

⚠ Warning

The `*-Job` cmdlets can create new runspaces without the restrictions.

Don't allow the `Trace-Command` cmdlet.

⚠ Warning

Using `Trace-Command` brings all traced commands into the session.

Don't create your own proxy implementations for the restricted commands

PowerShell has a set of proxy commands for restricted command scenarios. These proxy commands ensure that input parameters can't compromise the security of the session.

The following commands have restricted proxies:

- `Exit-PSSession`
- `Get-Command`
- `Get-FormatData`
- `Get-Help`
- `Measure-Object`
- `Out-Default`
- `Select-Object`

If you create your own implementation of these commands, you may inadvertently allow users to run code prohibited by the JEA proxy commands.

You can run the following command to get a list of restricted commands:

PowerShell

```
$commands =
[System.Management.Automation.CommandMetadata]::GetRestrictedCommands(
    [System.Management.Automation.SessionCapabilities]::RemoteServer
)
```

You can examine the restricted proxy commands by using the following command:

PowerShell

```
$commands =  
[System.Management.Automation.CommandMetadata]::GetRestrictedCommands(  
    [System.Management.Automation.SessionCapabilities]::RemoteServer  
)  
$getHelpProxyBlock =  
[System.Management.Automation.ProxyCommand]::Create($commands['Get-Help'])
```

Configure the session to use NoLanguage mode

PowerShell `NoLanguage` mode disables the PowerShell scripting language completely. You can't run scripts or use variables. You can only run native commands and cmdlets.

For more information about language modes, see [about_Language_Modes](#).

Don't allow the debugger to be used in the session

By default, the PowerShell debugger runs code in `FullLanguage` mode. Set the `UseFullLanguageModeInDebugger` property in the `SessionState` to false.

For more information, see [UseFullLanguageModeInDebugger](#).

PowerShell Remoting FAQ

FAQ

When you work remotely, you type commands in PowerShell on one computer (known as the "local computer"), but the commands run on another computer (known as the "remote computer"). The experience of working remotely should be as much like working directly at the remote computer as possible.

Note

To use PowerShell remoting, the remote computer must be configured for remoting. For more information, see [about_Remote_Requirements](#).

Must both computers have PowerShell installed?

Yes. To work remotely, the local and remote computers must have PowerShell, the Microsoft .NET Framework, and the Web Services for Management (WS-Management) protocol. Any files and other resources that are needed to execute a particular command must be on the remote computer.

Computers running Windows PowerShell 3.0 and computers running Windows PowerShell 2.0 can connect to each other remotely and run remote commands. However, some features, such as the ability to disconnect from a session and reconnect to it, work only when both computers are running Windows PowerShell 3.0.

You must have permission to connect to the remote computer, permission to run PowerShell, and permission to access data stores (such as files and folders), and the registry on the remote computer.

For more information, see [about_Remote_Requirements](#).

How does remoting work?

When you submit a remote command, the command is transmitted across the network to the PowerShell engine on the remote computer, and it runs in the PowerShell client on the remote computer. The command results are sent back to the local computer and appear in the PowerShell session on the local computer.

To transmit the commands and receive the output, PowerShell uses the WS-Management protocol. For information about the WS-Management protocol, see [WS-Management Protocol](#) in the Windows documentation.

Beginning in Windows PowerShell 3.0, remote sessions are stored on the remote computer. This enables you to disconnect from the session and reconnect from a different session or a different computer without interrupting the commands or losing state.

Is PowerShell remoting secure?

When you connect to a remote computer, the system uses the username and password credentials on the local computer or the credentials that you supply in the command to log you in to the remote computer. The credentials and the rest of the transmission are encrypted.

To add additional protection, you can configure the remote computer to use Secure Sockets Layer (SSL) instead of HTTP to listen for Windows Remote Management (WinRM) requests. Then, users can use the `UseSSL` parameter of the `Invoke-Command`, `New-PSSession`, and `Enter-PSSession` cmdlets when establishing a connection. This option uses the more secure HTTPS channel instead of HTTP.

Do all remote commands require PowerShell remoting?

No. Some cmdlets have a `ComputerName` parameter that lets you get objects from the remote computer.

These cmdlets do not use PowerShell remoting. So, you can use them on any computer that is running PowerShell, even if the computer is not configured for PowerShell remoting or if the computer does not meet the requirements for PowerShell remoting.

These cmdlets include the following:

- `Get-HotFix`
- `Rename-Computer`
- `Restart-Computer`
- `Stop-Computer`

To find all the cmdlets with a `ComputerName` parameter, type:

```
PowerShell
```

```
Get-Help * -Parameter ComputerName  
# or  
Get-Command -ParameterName ComputerName
```

To determine whether the **ComputerName** parameter of a particular cmdlet requires PowerShell remoting, see the parameter description. To display the parameter description, type:

```
PowerShell
```

```
Get-Help <cmdlet-name> -Parameter ComputerName
```

For example:

```
PowerShell
```

```
Get-Help Get-HotFix -Parameter ComputerName
```

For all other commands, use the `Invoke-Command` cmdlet.

How do I run a command on a remote computer?

To run a command on a remote computer, use the `Invoke-Command` cmdlet.

Enclose your command in braces (`{}`) to make it a script block. Use the **ScriptBlock** parameter of `Invoke-Command` to specify the command.

You can use the **ComputerName** parameter of `Invoke-Command` to specify a remote computer. Or, you can create a persistent connection to a remote computer (a session) and then use the **Session** parameter of `Invoke-Command` to run the command in the session.

For example, the following commands run a `Get-Process` command remotely.

```
PowerShell
```

```
Invoke-Command -ComputerName Server01, Server02 -ScriptBlock {Get-Process}  
# - OR -
```

```
Invoke-Command -Session $s -ScriptBlock {Get-Process}
```

To interrupt a remote command, type `CTRL + C`. The interruption request is passed to the remote computer, where it terminates the remote command.

For more information about remote commands, see [about_Remote](#) and the Help topics for the cmdlets that support remoting.

Can I just telnet into a remote computer?

You can use the `Enter-PSSession` cmdlet to start an interactive session with a remote computer.

At the PowerShell prompt, type:

```
PowerShell  
Enter-PSSession <ComputerName>
```

The command prompt changes to show that you are connected to the remote computer.

```
<ComputerName>\C:>
```

Now, the commands that you type run on the remote computer just as though you typed them directly on the remote computer.

To end the interactive session, type:

```
PowerShell  
Exit-PSSession
```

An interactive session is a persistent session that uses the WS-Management protocol. It is not the same as using Telnet, but it provides a similar experience.

For more information, see [Enter-PSSession](#).

Can I create a persistent connection?

Yes. You can run remote commands by specifying the name of the remote computer, its NetBIOS name, or its IP address. Or, you can run remote commands by specifying a PowerShell session (PSSession) that is connected to the remote computer.

When you use the **ComputerName** parameter of `Invoke-Command` or `Enter-PSSession`, PowerShell establishes a temporary connection. PowerShell uses the connection to run only the current command, and then it closes the connection. This is a very efficient method for running a single command or several unrelated commands, even on many remote computers.

When you use the `New-PSSession` cmdlet to create a PSSession, PowerShell establishes a persistent connection for the PSSession. Then, you can run multiple commands in the PSSession, including commands that share data.

Typically, you create a PSSession to run a series of related commands that share data. Otherwise, the temporary connection created by the **ComputerName** parameter is sufficient for most commands.

For more information about sessions, see [about_PSSessions](#).

Can I run commands on more than one computer at a time?

Yes. The **ComputerName** parameter of the `Invoke-Command` cmdlet accepts multiple computer names, and the **Session** parameter accepts multiple PSSessions.

When you run an `Invoke-Command` command, PowerShell runs the commands on all of the specified computers or in all of the specified PSSessions.

PowerShell can manage hundreds of concurrent remote connections. However, the number of remote commands that you can send might be limited by the resources of your computer and its capacity to establish and maintain multiple network connections.

For more information, see the example in the `Invoke-Command` Help topic.

Where are my profiles?

PowerShell profiles are not run automatically in remote sessions, so the commands that the profile adds are not present in the session. In addition, the `$PROFILE` automatic

variable is not populated in remote sessions.

To run a profile in a session, use the `Invoke-Command` cmdlet.

For example, the following command runs the `CurrentUserCurrentHost` profile from the local computer in the session in `$s`.

```
Invoke-Command -Session $s -FilePath $PROFILE
```

The following command runs the `CurrentUserCurrentHost` profile from the remote computer in the session in `$s`. Because the `$PROFILE` variable is not populated, the command uses the explicit path to the profile.

PowerShell

```
Invoke-Command -Session $s {  
    . "$HOME\Documents\WindowsPowerShell\Microsoft.PowerShell_profile.ps1"  
}
```

After running this command, the commands that the profile adds to the session are available in `$s`.

You can also use a startup script in a session configuration to run a profile in every remote session that uses the session configuration.

For more information about PowerShell profiles, see [about_Profiles](#). For more information about session configurations, see [Register-PSSessionConfiguration](#).

How does throttling work on remote commands?

To help you manage the resources on your local computer, PowerShell includes a per-command throttling feature that lets you limit the number of concurrent remote connections that are established for each command.

The default is 32 concurrent connections, but you can use the `ThrottleLimit` parameter of the cmdlets to set a custom throttle limit for particular commands.

When you use the throttling feature, remember that it is applied to each command, not to the entire session or to the computer. If you are running commands concurrently in

several sessions or PSSessions, the number of concurrent connections is the sum of the concurrent connections in all the sessions.

To find cmdlets with a **ThrottleLimit** parameter, type:

```
Get-Help * -Parameter ThrottleLimit  
-or-  
Get-Command -ParameterName ThrottleLimit
```

Is the output of remote commands different from local output?

When you use PowerShell locally, you send and receive "live" .NET Framework objects; "live" objects are objects that are associated with actual programs or system components. When you invoke the methods or change the properties of live objects, the changes affect the actual program or component. And, when the properties of a program or component change, the properties of the object that represent them also change.

However, because most live objects cannot be transmitted over the network, PowerShell "serializes" most of the objects sent in remote commands, that is, it converts each object into a series of XML (Constraint Language in XML [CLiXML]) data elements for transmission.

When PowerShell receives a serialized object, it converts the XML into a deserialized object type. The deserialized object is an accurate record of the properties of the program or component at a previous time, but it is no longer "live", that is, it is no longer directly associated with the component. And, the methods are removed because they are no longer effective.

Typically, you can use deserialized objects just as you would use live objects, but you must be aware of their limitations. Also, the objects that are returned by the `Invoke-Command` cmdlet have additional properties that help you to determine the origin of the command.

Some object types, such as DirectoryInfo objects and GUIDs, are converted back into live objects when they are received. These objects do not need any special handling or formatting.

For information about interpreting and formatting remote output, see [about_Remote_Output](#).

Can I run background jobs remotely?

Yes. A PowerShell background job is a PowerShell command that runs asynchronously without interacting with the session. When you start a background job, the command prompt returns immediately, and you can continue to work in the session while the job runs even if it runs for an extended period of time.

You can start a background job even while other commands are running because background jobs always run asynchronously in a temporary session.

You can run background jobs on a local or remote computer. By default, a background job runs on the local computer. However, you can use the **AsJob** parameter of the `Invoke-Command` cmdlet to run any remote command as a background job. And, you can use `Invoke-Command` to run a `Start-Job` command remotely.

For more information about background jobs in PowerShell , see [about_Jobs](#) and [about_Remote_Jobs](#).

Can I run Windows programs on a remote computer?

You can use PowerShell remote commands to run Windows-based programs on remote computers. For example, you can run `Shutdown.exe` or `Ipconfig.exe` on a remote computer.

However, you cannot use PowerShell commands to open the user interface for any program on a remote computer.

When you start a Windows program on a remote computer, the command is not completed, and the PowerShell command prompt does not return, until the program is finished or until you press `CTRL + C` to interrupt the command. For example, if you run the `Ipconfig.exe` program on a remote computer, the command prompt does not return until `Ipconfig.exe` is completed.

If you use remote commands to start a program that has a user interface, the program process starts, but the user interface does not appear. The PowerShell command is not completed, and the command prompt does not return until you stop the program

process or until you press `CTRL + C`, which interrupts the command and stops the process.

For example, if you use a PowerShell command to run `Notepad` on a remote computer, the Notepad process starts on the remote computer, but the Notepad user interface does not appear. To interrupt the command and restore the command prompt, press `CTRL + C`.

Can I limit the commands that users can run remotely on my computer?

Yes. Every remote session must use one of the session configurations on the remote computer. You can manage the session configurations on your computer (and the permissions to those session configurations) to determine who can run commands remotely on your computer and which commands they can run.

A session configuration configures the environment for the session. You can define the configuration by using an assembly that implements a new configuration class or by using a script that runs in the session. The configuration can determine the commands that are available in the session. And, the configuration can include settings that protect the computer, such as settings that limit the amount of data that the session can receive remotely in a single object or command. You can also specify a security descriptor that determines the permissions that are required to use the configuration.

The `Enable-PSRemoting` cmdlet creates the default session configurations on your computer: `Microsoft.PowerShell`, `Microsoft.PowerShell.Workflow`, and `Microsoft.PowerShell32` (64-bit operating systems only). `Enable-PSRemoting` sets the security descriptor for the configuration to allow only members of the Administrators group on your computer to use them.

You can use the session configuration cmdlets to edit the default session configurations, to create new session configurations, and to change the security descriptors of all the session configurations.

Beginning in Windows PowerShell 3.0, the `New-PSSessionConfigurationFile` cmdlet lets you create custom session configurations by using a text file. The file includes options for setting the language mode and for specifying the cmdlets and modules that are available in sessions that use the session configuration.

When users use the `Invoke-Command`, `New-PSSession`, or `Enter-PSSession` cmdlets, they can use the `ConfigurationName` parameter to indicate the session configuration that is

used for the session. And, they can change the default configuration that their sessions use by changing the value of the `$PSSessionConfigurationName` preference variable in the session.

For more information about session configurations, see the Help for the session configuration cmdlets. To find the session configuration cmdlets, type:

```
PowerShell
```

```
Get-Command *PSSessionConfiguration
```

What are fan in and fan out configurations?

The most common PowerShell remoting scenario involving multiple computers is the one-to-many configuration, in which one local computer (the administrator's computer) runs PowerShell commands on numerous remote computers. This is known as the "fan-out" scenario.

However, in some enterprises, the configuration is many-to-one, where many client computers connect to a single remote computer that is running PowerShell, such as a file server or a kiosk. This is known as the "fan-in" configuration.

PowerShell remoting supports both fan-out and fan-in configurations.

For the fan-out configuration, PowerShell uses the Web Services for Management (WS-Management) protocol and the WinRM service that supports the Microsoft implementation of WS-Management. When a local computer connects to a remote computer, WS-Management establishes a connection and uses a plug-in for PowerShell to start the PowerShell host process (`Wsmprovhost.exe`) on the remote computer. The user can specify an alternate port, an alternate session configuration, and other features to customize the remote connection.

To support the "fan-in" configuration, PowerShell uses internet Information Services (IIS) to host WS-Management, to load the PowerShell plug-in, and to start PowerShell. In this scenario, instead of starting each PowerShell session in a separate process, all PowerShell sessions run in the same host process.

IIS hosting and fan-in remote management is not supported in Windows XP or in Windows Server 2003.

In a fan-in configuration, the user can specify a connection URI and an HTTP endpoint, including the transport, computer name, port, and application name. IIS forwards all the requests with a specified application name to the application. The default is WS-Management, which can host PowerShell.

You can also specify an authentication mechanism and prohibit or allow redirection from HTTP and HTTPS endpoints.

Can I test remoting on a single computer not in a domain?

Yes. PowerShell remoting is available even when the local computer is not in a domain. You can use the remoting features to connect to sessions and to create sessions on the same computer. The features work the same as they do when you connect to a remote computer.

To run remote commands on a computer in a workgroup, change the following Windows settings on the computer.

Caution: These settings affect all users on the system and they can make the system more vulnerable to a malicious attack. Use caution when making these changes.

- Windows Vista, Windows 7, Windows 8:

Create the following registry entry, and then set its value to 1:

LocalAccountTokenFilterPolicy in

`HKLM\SOFTWARE\Microsoft\Windows\CurrentVersion\Policies\System`

You can use the following PowerShell command to add this entry:

```
PowerShell

$parameters = @{

    Path='HKLM:\SOFTWARE\Microsoft\Windows\CurrentVersion\Policies\System'
    Name='LocalAccountTokenFilterPolicy'
    propertyType='DWord'
    Value=1
}

New-ItemProperty @parameters
```

- Windows Server 2003, Windows Server 2008, Windows Server 2012, Windows Server 2012 R2:

No changes are needed because the default setting of the "Network Access: Sharing and security model for local accounts" policy is "Classic". Verify the setting in case it has changed.

Can I run remote commands on a computer in another domain?

Yes. Typically, the commands run without error, although you might need to use the **Credential** parameter of the `Invoke-Command`, `New-PSSession`, or `Enter-PSSession` cmdlets to provide the credentials of a member of the Administrators group on the remote computer. This is sometimes required even when the current user is a member of the Administrators group on the local and remote computers.

However, if the remote computer is not in a domain that the local computer trusts, the remote computer might not be able to authenticate the user's credentials.

To enable authentication, use the following command to add the remote computer to the list of trusted hosts for the local computer in WinRM. Type the command at the PowerShell prompt.

```
PowerShell
```

```
Set-Item WSMAN:\localhost\Client\TrustedHosts -Value <Remote-computer-name>
```

For example, to add the Server01 computer to the list of trusted hosts on the local computer, type the following command at the PowerShell prompt:

```
PowerShell
```

```
Set-Item WSMAN:\localhost\Client\TrustedHosts -Value Server01
```

Does PowerShell support remoting over SSH?

Yes. For more information, see [PowerShell remoting over SSH](#).

Desired State Configuration (DSC) Overview

Article • 03/19/2025

DSC is a management platform that enables you to manage your IT and development infrastructure with configuration as code.

There are four versions of DSC available:

- **Microsoft DSC 3.0** is the new version of DSC. This version provides true cross-platform support. It is a standalone product that's not dependent on PowerShell, however, you can still use your existing PowerShell DSC resources.
- **PowerShell DSC 3.0 (preview)** is the version of DSC supported by the [Azure Machine Configuration](#) on Linux.
- **PowerShell DSC 2.0** is the version of DSC that shipped in PowerShell 7.

With the release of PowerShell 7.2, the **PSDesiredStateConfiguration** module is no longer included in the PowerShell package. Separating DSC into its own module allows us to invest and develop DSC independent of PowerShell and reduces the size of the PowerShell package. Users of DSC will enjoy the benefit of upgrading DSC without the need to upgrade PowerShell, accelerating the time to deployment of new DSC features. Users that want to continue using DSC v2 can download **PSDesiredStateConfiguration** 2.0.5 from the PowerShell Gallery.

- **PowerShell DSC 1.1** is the legacy version of DSC that originally shipped in Windows PowerShell 5.1.

For more information, see the [Desired State Configuration](#) overview article.

The PowerShell Gallery

Article • 04/13/2023

The [PowerShell Gallery](#) is the central repository for PowerShell content. In it, you can find PowerShell scripts, modules containing PowerShell cmdlets and Desired State Configuration (DSC) resources. Some of these packages are authored by Microsoft, and others are authored by the PowerShell community.

The **PowerShellGet** module contains cmdlets for discovering, installing, updating, and publishing PowerShell packages from the PowerShell Gallery. These packages can contain artifacts such as Modules, DSC Resources, Role Capabilities, and Scripts. Make sure you have the latest version of **PowerShellGet** installed.

The documentation for **PowerShellGet** and the PowerShell Gallery has been moved to a new location so that we can manage the version-specific information separate from the versions of PowerShell.

See the new documentation in [PowerShellGet and the PowerShell Gallery](#).

2022-May

New content

- Create a Crescendo configuration using the Crescendo cmdlets
- Overview of the SecretManagement and SecretStore modules
- Get started with the SecretStore module
- Understanding the SecretManagement module
- Managing a SecretStore vault

Content updates

- Renamed the `staging` branch to `main`
- Updated the Table of Contents for easier discovery
 - Moved Support Lifecycle to the top level
 - Moved Contributor Guide to the top level
- 7.3-preview.4 release notes
- Bulk formatting cleanup for many docs
 - PowerShell-Docs content - 272 files
 - Secrets management - 17 files
- Updated the PSScriptAnalyzer README and deleted docs that were migrated to Microsoft Learn
- Removed CentOS and Fedora from docs - no longer supported
- Retired 7.1 content - no longer supported
 - Collapse release notes into diff article
 - Delete or move content to archive repo

2022-March

New Content

- New PowerShell docs
 - [about_Member-Access_Enumeration](#)
 - [about_Module_Manifests](#)
 - [How to create a command-line predictor](#)
- Utility modules updates
 - New docs for Crescendo release
 - [Install Crescendo](#)
 - [Choose a command-line tool](#)
 - [Decide which features to amplify](#)
 - [Create a Crescendo cmdlet](#)
 - [Generate and test a Crescendo module](#)
 - Moved PlatyPS article from PowerShell docs to the PlatyPS documentation
 - [Moved PlatyPS article](#)
 - Migrated more PSScriptAnalyzer documentation from the source code repository
 - [Using PSScriptAnalyzer](#)
 - [Rules and recommendations](#)
 - [Creating custom rules](#)

Content updates

- Bulk cleanup of related links in About_ topics
- Added issue and PR templates to all docs repos
- Updates for 7.3 preview content
 - New tab completions
 - Support for SSH options on remoting cmdlets
 - New experimental feature `PSAMSIMethodInvocationLogging`

Other projects

- Created a prototype cmdlet `Get-WhatsNew` based on the [draft RFC ↗](#)
 - Check out the RFC and provide feedback

New team member

- Welcome [Mikey Lombardi ↗](#) to the docs team

What's new in PowerShell Docs for 2021

Article • 03/30/2025

This article lists notable changes made to docs each month and celebrates the contributions from the community.

Help us make the documentation better for you. Read the [Contributor's Guide](#) to learn how to get started.

2021-December

New Content

- Added PowerShell 7.3-preview.1 [preview content]
- New DSC 3.0 content
 - [PowerShell Desired State Configuration overview](#)
 - [Manage configuration using PowerShell DSC](#)
 - [DSC Configurations](#)
 - [DSC Resources](#)

Content updates

- Moved Desired State Configuration [content](#) to new docset and repository
 - DSC is now being developed outside of the PowerShell product.
 - The move allows for better versioning of documentation for DSC.

2021-September

New Content

- SDK documentation
 - [How to validate an argument using a script](#)
 - [ValidateScript Attribute Declaration](#)
- Learning content
 - [PowerShell security features](#)

Content updates

- Install documentation - Did a complete rewrite of the setup documentation. There is now a separate article for each supported OS.
 - [Install on Windows](#)
 - [Install on macOS](#)
 - [Install on Linux](#)
 - [Alpine](#)
 - [CentOS](#)
 - [Debian](#)
 - [Fedora](#)
 - [Raspberry Pi OS](#)
 - [Red Hat Enterprise Linux](#)
 - [Ubuntu](#)
 - [Alternate install methods](#)
 - [Community supported Linux](#)
- Supporting documentation
 - [Using PowerShell in Docker](#)
 - [Arm Processor support](#)
 - [Microsoft Update for PowerShell FAQ](#)
 - [PowerShell Support Lifecycle](#)

- Reformatted and updated the PSScriptAnalyzer rules documentation. Next month we plan to publish these docs to Microsoft Learn.
 - [Rules documentation on GitHub ↗](#)
- Lots of general editorial updates across 4500 files
- PowerShell 7.2-preview.10 documentation updates

2021-June

New content

- [about_Intrinsic_Members](#)
- [about_Booleans](#)

Content updates

- Converted [about_Remote_FAQ](#) to new YAML format and moved to conceptual TOC
- Moved **PSDesiredStateConfiguration** out of 7.2 docs and into PowerShell-Docs-Modules
 - DSC is being removed from PowerShell to become an optional module that is loaded from the PowerShell Gallery
 - Long-term plan is to move all DSC documentation out of PowerShell-Docs into a new repository for DSC content
- Totally rewrote the PowerShell release notes to summarize the current state, making it easier for users to find the information without having to read every release note.
 - [Differences between Windows PowerShell 5.1 and PowerShell \(core\) 7.x](#)
 - [PowerShell differences on non-Windows platforms](#)
- PowerShell 7.2-preview.7 documentation updates

Microsoft PowerShell Logo and Digital Art Guidelines

As a general rule, third parties may not use Microsoft logos and artwork without permission. The following are the limited circumstances under which third parties may use the Microsoft PowerShell logo and artwork.

- For non-commercial purposes (documentation or on a website) that reference your connection with Microsoft PowerShell.

Any uses outside of these guidelines as determined by Microsoft is strictly prohibited.

Do not use the Microsoft PowerShell logo or artwork in products, product packaging, or other business services for which a formal license is required.

Microsoft reserves the right in its sole discretion to terminate or modify permission to display the logo or artwork, and may request that third parties modify or delete any use of the logo or artwork that, in Microsoft's sole judgment, does not comply with these guidelines or might otherwise impair Microsoft's rights in the logo.

Using Visual Studio Code for PowerShell Development

Article • 04/28/2023

[Visual Studio Code](#) (VS Code) is a cross-platform script editor by Microsoft. Together with the [PowerShell extension](#), it provides a rich and interactive script editing experience, making it easier to write reliable PowerShell scripts. Visual Studio Code with the PowerShell extension is the recommended editor for writing PowerShell scripts.

It supports the following PowerShell versions:

- PowerShell 7.2 and higher (Windows, macOS, and Linux)
- Windows PowerShell 5.1 (Windows-only) with .NET Framework 4.8

ⓘ Note

Visual Studio Code isn't the same as [Visual Studio](#).

Getting started

Before you begin, make sure PowerShell exists on your system. For modern workloads on Windows, macOS, and Linux, see the following links:

- [Installing PowerShell on Linux](#)
- [Installing PowerShell on macOS](#)
- [Installing PowerShell on Windows](#)

For traditional Windows PowerShell workloads, see [Installing Windows PowerShell](#).

ⓘ Important

The [Windows PowerShell ISE](#) is still available for Windows. However, it's no longer in active feature development. The ISE only works with PowerShell 5.1 and older. As a component of Windows, it continues to be officially supported for security and high-priority servicing fixes. we've no plans to remove the ISE from Windows.

Install VS Code and the PowerShell Extension

1. Install Visual Studio Code. For more information, see the overview [Setting up Visual Studio Code](#).

There are installation instructions for each platform:

- [Running Visual Studio Code on Windows](#)
- [Running Visual Studio Code on macOS](#)
- [Running Visual Studio Code on Linux](#)

2. Install the PowerShell Extension.

- a. Launch the VS Code app by typing `code` in a console or `code-insiders` if you installed Visual Studio Code Insiders.
- b. Launch **Quick Open** on Windows or Linux by pressing `Ctrl + P`. On macOS, press `Cmd + P`.
- c. In Quick Open, type `ext install powershell` and press **Enter**.
- d. The **Extensions** view opens on the Side Bar. Select the PowerShell extension from Microsoft.
- e. Click the **Install** button on the PowerShell extension from Microsoft.
- f. After the install, if you see the **Install** button turn into **Reload**, Click on **Reload**.
- g. After VS Code has reloaded, you're ready for editing.

For example, to create a new file, click **File > New**. To save it, click **File > Save** and then provide a filename, such as `HelloWorld.ps1`. To close the file, click the `X` next to the filename. To exit VS Code, **File > Exit**.

Installing the PowerShell Extension on Restricted Systems

Some systems are set up to require validation of all code signatures. You may receive the following error:

```
Language server startup failed.
```

This problem can occur when PowerShell's execution policy is set by Windows Group Policy. To manually approve PowerShell Editor Services and the PowerShell extension for VS Code, open a PowerShell prompt and run the following command:

```
PowerShell
```

```
Import-Module $HOME\.vscode\extensions\ms-
vscode.powershell*\modules\PowerShellEditorServices\PowerShellEditorServices
.psd1
```

You're prompted with **Do you want to run software from this untrusted publisher?** Type **A** to run the file. Then, open VS Code and verify that the PowerShell extension is functioning properly. If you still have problems getting started, let us know in a [GitHub issue](#).

Choosing a version of PowerShell to use with the extension

With PowerShell installing side-by-side with Windows PowerShell, it's now possible to use a specific version of PowerShell with the PowerShell extension. This feature looks at a few well-known paths on different operating systems to discover installations of PowerShell.

Use the following steps to choose the version:

1. Open the **Command Palette** on Windows or Linux with **ctrl + Shift + P**. On macOS, use **Cmd + Shift + P**.
2. Search for **Session**.
3. Click on **PowerShell: Show Session Menu**.
4. Choose the version of PowerShell you want to use from the list.

If you installed PowerShell to a non-typical location, it might not show up initially in the Session Menu. You can extend the session menu by [adding your own custom paths](#) as described below.

The PowerShell session menu can also be accessed from the **{}** icon in the bottom right corner of status bar. Hovering on or selecting this icon displays a shortcut to the session menu and a small pin icon. If you select the pin icon, the version number is added to the status bar. The version number is a shortcut to the session menu requiring fewer clicks.

Note

Pinning the version number replicates the behavior of the extension in versions of VS Code before 1.65. The 1.65 release of VS Code changed the APIs the PowerShell extension uses and standardized the status bar for language extensions.

Configuration settings for Visual Studio Code

First, if you're not familiar with how to change settings in VS Code, we recommend reading [Visual Studio Code's settings](#) documentation.

After reading the documentation, you can add configuration settings in `settings.json`.

JSON

```
{  
    "editor.renderWhitespace": "all",  
    "editor.renderControlCharacters": true,  
    "files.trimTrailingWhitespace": true,  
    "files.encoding": "utf8bom",  
    "files.autoGuessEncoding": true  
}
```

If you don't want these settings to affect all file types, VS Code also allows per-language configurations. Create a language-specific setting by putting settings in a `[<language-name>]` field. For example:

JSON

```
{  
    "[powershell)": {  
        "files.encoding": "utf8bom",  
        "files.autoGuessEncoding": true  
    }  
}
```

Tip

For more information about file encoding in VS Code, see [Understanding file encoding](#). Also, check out [How to replicate the ISE experience in VS Code](#) for other tips on how to configure VS Code for PowerShell editing.

Adding your own PowerShell paths to the session menu

You can add other PowerShell executable paths to the session menu through the [Visual Studio Code setting](#) `powershell.powerShellAdditionalExePaths`.

You can do this using the GUI:

1. From the **Command Palette** search for and select **Open User Settings**. Or use the keyboard shortcut on Windows or Linux `Ctrl + ,`. On macOS, use `Cmd + ,`.
2. In the **Settings** editor, search for **PowerShell Additional Exe Paths**.
3. Click **Add Item**.
4. For the **Key** (under **Item**), provide your choice of name for this additional PowerShell installation.

5. For the **Value** (under **Value**), provide the absolute path to the executable itself.

You can add as many additional paths as you like. The added items show up in the session menu with the given key as the name.

Alternatively you can add key-value pairs to the object

`powershell.powerShellAdditionalExePaths` in your `settings.json`:

JSON

```
{  
  "powershell.powerShellAdditionalExePaths": {  
    "Downloaded PowerShell":  
      "C:/Users/username/Downloads/PowerShell/pwsh.exe",  
    "Built PowerShell":  
      "C:/Users/username/src/PowerShell/src/powershell-win-  
      core/bin/Debug/net6.0/win7-x64/publish/pwsh.exe"  
  },  
}
```

ⓘ Note

Prior to version 2022.5.0 of the extension, this setting was a list of objects with the required keys `exePath` and `versionName`. A breaking change was introduced to support configuration via GUI. If you had previously configured this setting, please convert it the new format. The value given for `versionName` is now the **Key**, and the value given for `exePath` is now the **Value**. You can do this more easily by resetting the value and using the Settings interface.

To set the default PowerShell version, set the value

`powershell.powerShellDefaultVersion` to the text displayed in the session menu (the text used for the key):

JSON

```
{  
  "powershell.powerShellAdditionalExePaths": {  
    "Downloaded PowerShell":  
      "C:/Users/username/Downloads/PowerShell/pwsh.exe",  
  },  
  "powershell.powerShellDefaultVersion": "Downloaded PowerShell",  
}
```

After you've configured this setting, restart VS Code or to reload the current VS Code window from the **Command Palette**, type `Developer: Reload Window`.

If you open the session menu, you now see your additional PowerShell installations.

💡 Tip

If you build PowerShell from source, this is a great way to test out your local build of PowerShell.

Debugging with Visual Studio Code

No-workspace debugging

In VS Code version 1.9 (or higher), you can debug PowerShell scripts without opening the folder that contains the PowerShell script.

1. Open the PowerShell script file with **File > Open File...**
2. Set a breakpoint - select a line then press **F9**
3. Press **F5** to start debugging

You should see the Debug actions pane appear that allows you to break into the debugger, step, resume, and stop debugging.

Workspace debugging

Workspace debugging refers to debugging in the context of a folder that you've opened from the **File** menu using **Open Folder...**. The folder you open is typically your PowerShell project folder or the root of your Git repository. Workspace debugging allows you to define multiple debug configurations other than just debugging the currently open file.

Follow these steps to create a debug configuration file:

1. Open the **Debug** view on Windows or Linux by pressing **Ctrl + Shift + D**. On macOS, press **Cmd + Shift + D**.
2. Click the **create a launch.json file** link.
3. From the **Select Environment** prompt, choose **PowerShell**.
4. Choose the type of debugging you'd like to use:
 - **Launch Current File** - Launch and debug the file in the currently active editor window

- **Launch Script** - Launch and debug the specified file or command
- **Interactive Session** - Debug commands executed from the Integrated Console
- **Attach** - Attach the debugger to a running PowerShell Host Process

VS Code creates a directory and a file `.vscode\launch.json` in the root of your workspace folder to store the debug configuration. If your files are in a Git repository, you typically want to commit the `launch.json` file. The contents of the `launch.json` file are:

```
JSON

{
  "version": "0.2.0",
  "configurations": [
    {
      "type": "PowerShell",
      "request": "launch",
      "name": "PowerShell Launch (current file)",
      "script": "${file}",
      "args": [],
      "cwd": "${file}"
    },
    {
      "type": "PowerShell",
      "request": "attach",
      "name": "PowerShell Attach to Host Process",
      "processId": "${command.PickPSPHostProcess}",
      "runspaceId": 1
    },
    {
      "type": "PowerShell",
      "request": "launch",
      "name": "PowerShell Interactive Session",
      "cwd": "${workspaceRoot}"
    }
  ]
}
```

This file represents the common debug scenarios. When you open this file in the editor, you see an **Add Configuration...** button. You can click this button to add more PowerShell debug configurations. One useful configuration to add is **PowerShell: Launch Script**. With this configuration, you can specify a file containing optional arguments that are used whenever you press `F5` no matter which file is active in the editor.

After the debug configuration is established, you can select the configuration you want to use during a debug session. Select a configuration from the debug configuration

drop-down in the **Debug** view's toolbar.

Troubleshooting the PowerShell extension

If you experience any issues using VS Code for PowerShell script development, see the [troubleshooting guide ↗](#) on GitHub.

Useful resources

How to replicate the ISE experience in Visual Studio Code

Article • 07/10/2023

While the PowerShell extension for VS Code doesn't seek complete feature parity with the PowerShell ISE, there are features in place to make the VS Code experience more natural for users of the ISE.

This document tries to list settings you can configure in VS Code to make the user experience a bit more familiar compared to the ISE.

ISE Mode

Note

This feature is available in the PowerShell Preview extension since version 2019.12.0 and in the PowerShell extension since version 2020.3.0.

The easiest way to replicate the ISE experience in Visual Studio Code is by turning on "ISE Mode". To do this, open the command palette (`F1` OR `Ctrl + Shift + P` OR `Cmd + Shift + P` on macOS) and type in "ISE Mode". Select "PowerShell: Enable ISE Mode" from the list.

This command automatically applies the settings described below. The result looks like this:

(PREVIEW) POWERSHELL COMMAND EXPLORER:... Untitled-1

```
Add-AzADGroupMember
Add-AzContainerServiceAgentPoolProfile
Add-AzEnvironment
Add-AzImageDataDisk
Add-AzKeyVaultCertificate
Add-AzKeyVaultCertificateContact
Add-AzKeyVaultKey
Add-AzKeyVaultManagedStorageAccount
Add-AzKeyVaultNetworkRule
Add-AzRmStorageContainerLegalHold
Add-AzStorageAccountManagementPolicyAct...
Add-AzStorageAccountNetworkRule
Add-AzVhd
Add-AzVMAdditionalUnattendContent
Add-AzVMDataDisk
Add-AzVMNetworkInterface
Add-AzVMSecret
Add-AzVmssAdditionalUnattendContent
Add-AzVmssDataDisk
Add-AzVmssDiagnosticsExtension
Add-AzVmssExtension
Add-AzVmssPublickey
Add-AzVmssNetworkInterfaceConfiguration
Add-AzVmssSecret
Add-AzVmssSshPublicKey
Add-AzVmssVMDataDisk
Add-AzVmssWinRMListener
Add-Content
Add-History
Add-Member
Add-PoshGitToProfile
Add-RoleMember
Add-Secret
Add-SqlAvailabilityDatabase
Add-SqlAvailabilityGroupListenerStaticIp
Add-SqlAzureAuthenticationContext
```

PROBLEMS OUTPUT DEBUG CONSOLE TERMINAL

1: PowerShell Integrated Cor

```
===== PowerShell Integrated Console =====
tyler ~
>>> [ ]
```

ISE Mode configuration settings

ISE Mode makes the following changes to VS Code settings.

- Key bindings

Function	ISE Binding	VS Code Binding
Interrupt and break debugger	<code>Ctrl + B</code>	<code>F6</code>
Execute current line/highlighted text	<code>F8</code>	<code>F8</code>
List available snippets	<code>Ctrl + J</code>	<code>Ctrl + Alt + J</code>

! Note

You can **configure** your own key bindings in VS Code as well.

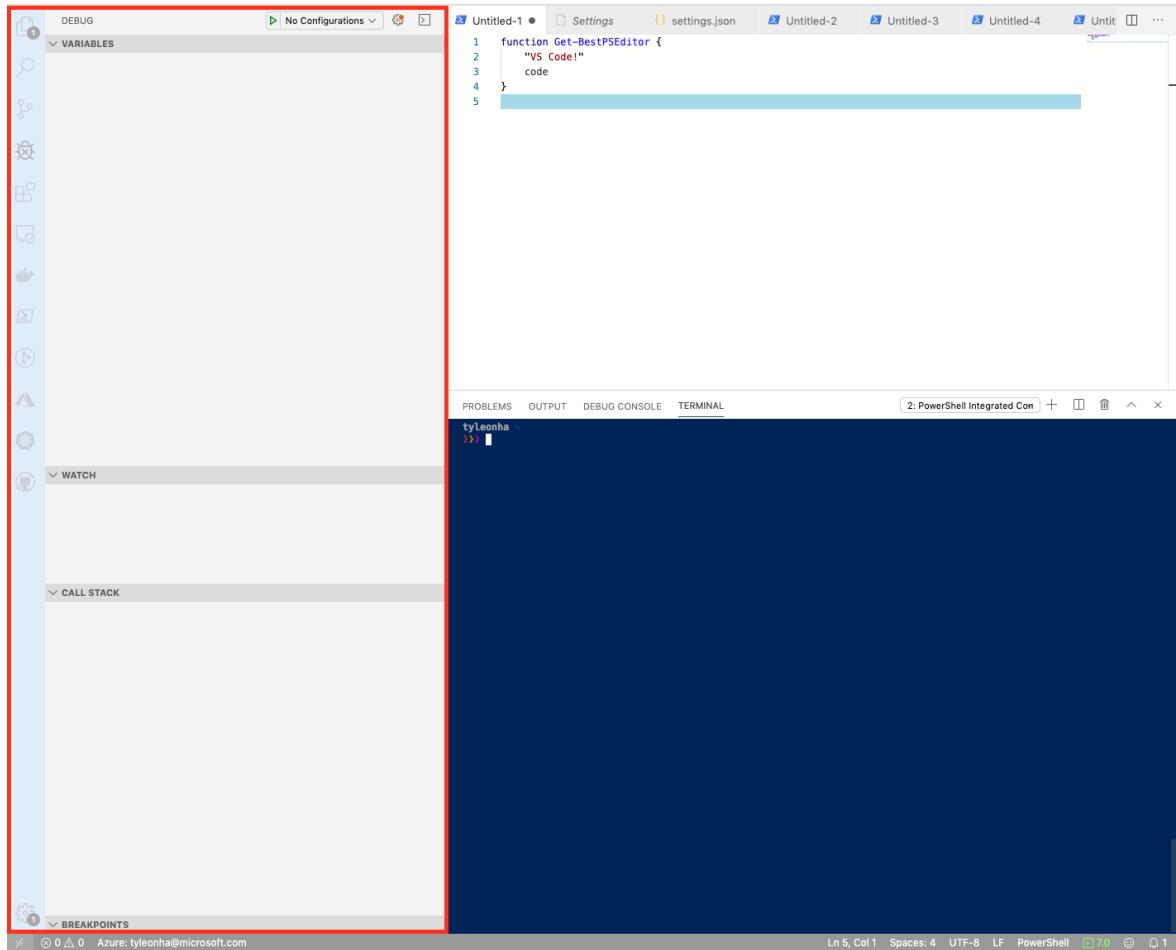

- Simplified ISE-like UI

If you're looking to simplify the Visual Studio Code UI to look more closely to the UI of the ISE, apply these two settings:

JSON

```
"workbench.activityBar.visible": false,  
"debug.openDebug": "neverOpen",
```

These settings hide the "Activity Bar" and the "Debug Side Bar" sections shown inside the red box below:

The end result looks like this:

A screenshot of the Microsoft Visual Studio Code interface. The top menu bar includes 'File', 'Edit', 'Selection', 'View', 'Go', 'Debug', 'Terminal', 'Window', and 'Help'. The title bar shows 'Code - Insiders' and the file 'Install-VSCode.ps1'. The main editor area displays a PowerShell script with code for installing VS Code. Below the editor are tabs for 'PROBLEMS', 'OUTPUT', 'DEBUG CONSOLE', and 'TERMINAL'. The terminal tab is active, showing a dark blue background with white text. At the bottom of the screen, there are status indicators: 'tyleonha ~', '2: PowerShell Integrated Con', and various system status icons.

- Tab completion

To enable more ISE-like tab completion, add this setting:

JSON

```
"editor.tabCompletion": "on",
```

- No focus on console when executing

To keep the focus in the editor when you execute with **F8**:

JSON

```
"powershell.integratedConsole.focusConsoleOnExecute": false
```

The default is `true` for accessibility purposes.

- Don't start integrated console on startup

To stop the integrated console on startup, set:

JSON

```
"powershell.integratedConsole.showOnStartup": false
```

ⓘ Note

The background PowerShell process still starts to provide IntelliSense, script analysis, symbol navigation, etc., but the console won't be shown.

- Assume files are PowerShell by default

To make new/untitled files, register as PowerShell by default:

JSON

```
"files.defaultLanguage": "powershell",
```

- Color scheme

There are a number of ISE themes available for VS Code to make the editor look much more like the ISE.

In the [Command Palette](#) type `theme` to get [Preferences: Color Theme](#) and press `Enter`. In the drop-down list, select `PowerShell ISE`.

You can set this theme in the settings with:

JSON

```
"workbench.colorTheme": "PowerShell ISE",
```

- PowerShell Command Explorer

Thanks to the work of [@corbob](#), the PowerShell extension has the beginnings of its own command explorer.

In the [Command Palette](#), enter `PowerShell Command Explorer` and press `Enter`.

- Open in the ISE

If you want to open a file in the Windows PowerShell ISE anyway, open the [Command Palette](#), search for "open in ise", then select [PowerShell: Open Current](#)

Other resources

- 4sysops has [a great article ↗](#) on configuring VS Code to be more like the ISE.
- Mike F Robbins has [a great post ↗](#) on setting up VS Code.

VS Code Tips

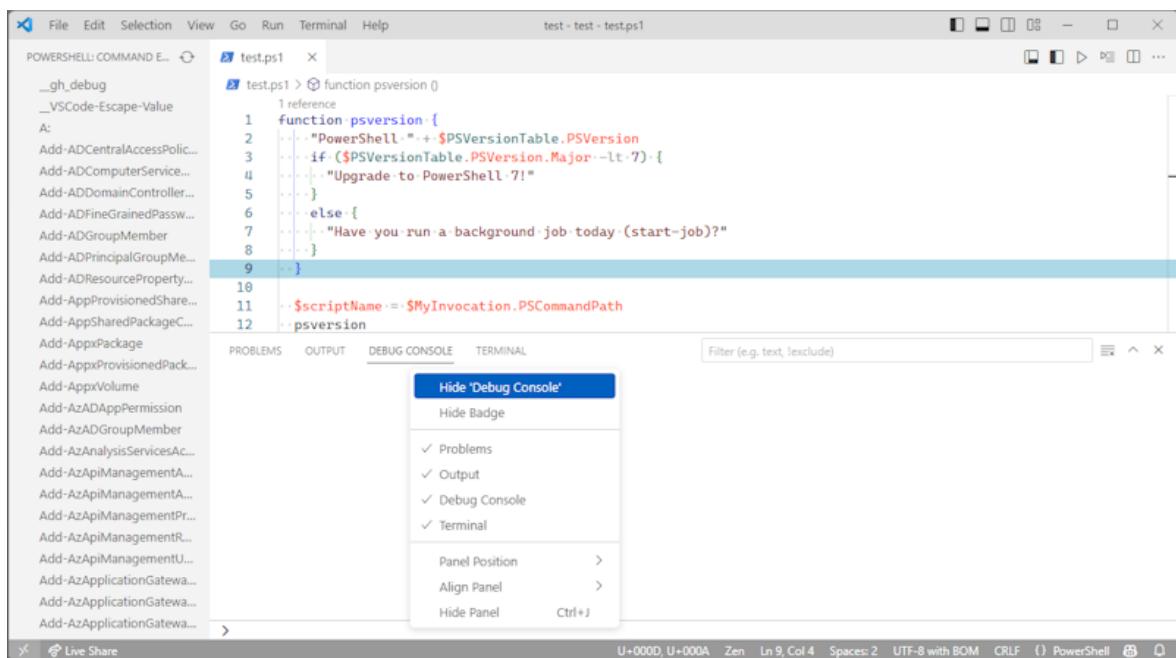

- Command Palette

The Command Palette is handy way of executing commands in VS Code. Open the command palette using **F1** OR **Ctrl + Shift + P** OR **Cmd + Shift + P** on macOS.

For more information, see [the VS Code documentation ↗](#).

- Hide the Debug Console panel

The PowerShell extension uses the built-in debugging interface of VS Code to allow for debugging of PowerShell scripts and modules. However, the extension does not use the Debug Console panel. To hide the Debug Console, right-click on **Debug Console** and select **Hide 'Debug Console'**.

For more information about debugging PowerShell with Visual Studio Code, see [Using VS Code](#).

More settings

If you know of more ways to make VS Code feel more familiar for ISE users, contribute to this doc. If there's a compatibility configuration you're looking for, but you can't find any way to enable it, [open an issue ↗](#) and ask away!

We're always happy to accept PRs and contributions as well!

 **Collaborate with us on GitHub**

The source for this content can be found on GitHub, where you can also create and review issues and pull requests. For more information, see [our contributor guide](#).

Using Visual Studio Code for remote editing and debugging

Article • 04/16/2025

For those of you that are familiar with the ISE, you may recall that you could run `psedit file.ps1` from the integrated console to open files - local or remote - right in the ISE.

This feature is also available in the PowerShell extension for VS Code. This guide shows you how to do it.

Prerequisites

This guide assumes that you have:

- A remote resource (ex: a VM, a container) that you have access to
- PowerShell running on it and the host machine
- VS Code and the PowerShell extension for VS Code

This feature works on PowerShell and Windows PowerShell.

This feature also works when connecting to a remote machine via WinRM, PowerShell Direct, or SSH. If you want to use SSH, but are using Windows, check out the [Win32 version of SSH](#)!

Important

The `Open-EditorFile` and `psedit` commands only work in the **PowerShell Integrated Console** created by the PowerShell extension for VS Code.

Usage examples

These examples show remote editing and debugging from a MacBook Pro to an Ubuntu VM running in Azure. The process is identical on Windows.

Local file editing with Open-EditorFile

With the PowerShell extension for VS Code started and the PowerShell Integrated Console opened, we can type `open-EditorFile foo.ps1` or `psedit foo.ps1` to open the local `foo.ps1` file right in the editor.

The screenshot shows a dark-themed instance of Visual Studio Code. In the top left, there are icons for file operations like Open, Save, and Close. The title bar shows the file name 'foo.ps1'. The main editor area contains the following PowerShell script:

```
1 Write-Host "psedit foo.ps1"
2
3 Write-Host "then you can edit this file"
4
5 Write-Host "and debug it too"
```

Below the editor, the bottom navigation bar includes tabs for PROBLEMS, OUTPUT, DEBUG CONSOLE, and TERMINAL. The TERMINAL tab is selected, showing the output of the command:

```
/Users/tylerleonhardt/Desktop> psedit ./foo.ps1
/Users/tylerleonhardt/Desktop> [ ]
```

The status bar at the bottom displays the file path, line count (Ln 5), column count (Col 30), space usage (Spaces: 4), encoding (UTF-8), line separator (LF), the current language mode (PowerShell), the commit hash (6.0), and a smiley face icon.

ⓘ Note

The file `foo.ps1` must already exist.

From there, we can:

- Add breakpoints to the gutter

The screenshot shows a dark-themed instance of Visual Studio Code. In the top-left corner, there are three window control buttons (red, yellow, green). The title bar displays "foo.ps1". On the left side, there's a vertical toolbar with icons for file operations, search, and other tools. The main editor area contains a PowerShell script named "foo.ps1" with the following content:

```
1 Write-Host "psedit foo.ps1"
2
3 Write-Host "then you can edit this file"
4
5 Write-Host "and debug it too"
```

Below the editor is a tab bar with "PROBLEMS", "OUTPUT", "DEBUG CONSOLE", and "TERMINAL". The "TERMINAL" tab is selected, showing the command "/Users/tylerleonhardt/Desktop> psedit ./foo.ps1" followed by a blank line. At the bottom of the screen, there's a purple status bar displaying "Ln 5, Col 30 Spaces: 4 UTF-8 LF PowerShell" and some other icons.

- Hit F5 to debug the PowerShell script.

The screenshot shows the PowerShell Integrated Terminal in Visual Studio Code. A breakpoint has been hit on line 3 of the script 'foo.ps1'. The terminal output shows the command 'psedit foo.ps1' being run, followed by the hit breakpoint message. The code editor on the left displays the script content:

```
1 Write-Host "psedit foo.ps1"
2
3 Write-Host "then you can edit this file"
4
5 Write-Host "and debug it too"
```

The terminal tab bar indicates the session is 1: PowerShell Int. The status bar at the bottom shows the current line (Ln 3, Col 41), spaces (Spaces: 4), encoding (UTF-8 LF), and PowerShell version (6.0).

While debugging, you can interact with the debug console, check out the variables in the scope on the left, and all the other standard debugging tools.

Remote file editing with Open-EditorFile

Now let's get into remote file editing and debugging. The steps are nearly the same, there's just one thing we need to do first - enter our PowerShell session to the remote server.

There's a cmdlet for to do so. It's called `Enter-PSSession`.

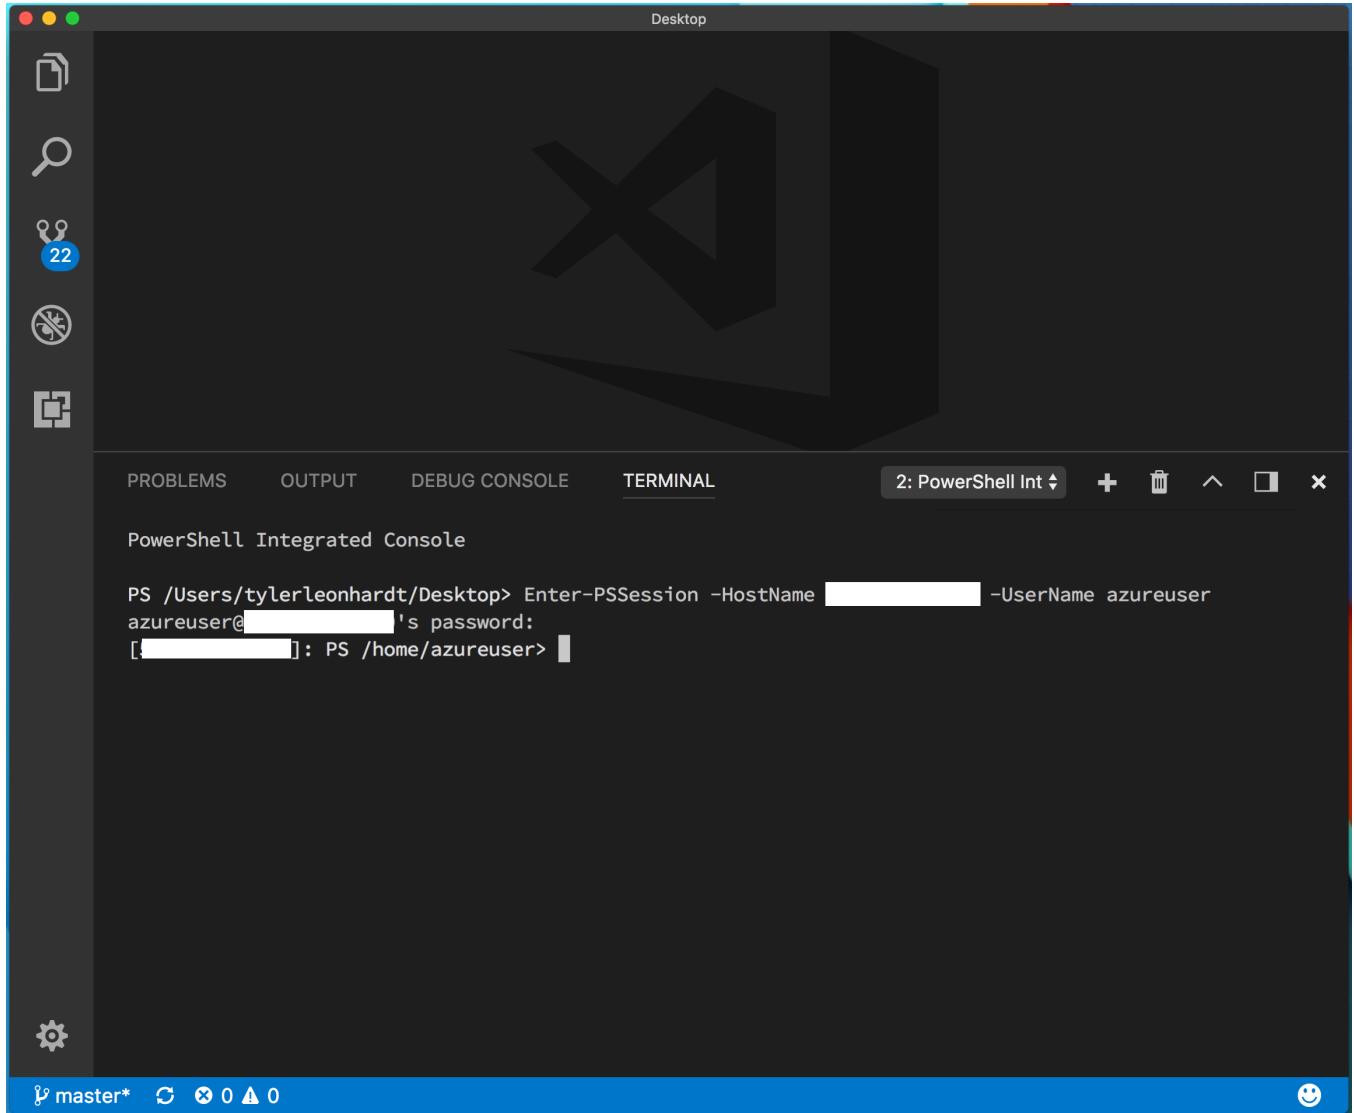

In short:

- `Enter-PSSession -ComputerName foo` starts a session via WinRM
- `Enter-PSSession -ContainerId foo` and `Enter-PSSession -VmId foo` start a session via PowerShell Direct
- `Enter-PSSession -HostName foo` starts a session via SSH

For more information, see the documentation for `Enter-PSSession`.

Since we're remoting to an Ubuntu VM in Azure, we're using SSH.

First, in the Integrated Console, run `Enter-PSSession`. You're connected to the remote session when [`<hostname>`] shows up to the left of your prompt.

The screenshot shows the Visual Studio Code desktop application window. The title bar says "Desktop". The left sidebar has icons for File, Search, Issues (22), and Snippets. The main area is a dark-themed terminal window titled "PowerShell Integrated Console". It displays the command `PS /Users/tylerleonhardt/Desktop> Enter-PSSession -HostName [REDACTED] -UserName azureuser`, followed by a password prompt: `azureuser@[REDACTED]'s password:`. Below the terminal, the status bar shows "Y master*" and "0 0 ▲ 0".

```
PowerShell Integrated Console

PS /Users/tylerleonhardt/Desktop> Enter-PSSession -HostName [REDACTED] -UserName azureuser
azureuser@[REDACTED]'s password:
[REDACTED]: PS /home/azureuser> 
```

Now, we can do the same steps as if we're editing a local script.

1. Run `Open-EditorFile test.ps1` or `psedit test.ps1` to open the remote `test.ps1` file

The screenshot shows the Visual Studio Code interface with the following details:

- Title Bar:** [Extension Development Host] - test.ps1 — Polaris
- Sidebar:** Includes icons for File, Find, Search, Diff, and Settings.
- Code Editor:** A file named "test.ps1" containing the following PowerShell code:

```
1 Write-Host "this file is on an Ubuntu VM in Azure"
2
3 Write-Host "It's running PowerShell Core"
4
5 Write-Host "Hello World!"
```
- Terminal:** An integrated PowerShell console titled "PowerShell Integrated Console". It shows the following session:

```
PS /Users/tylerleonhardt/Desktop/Polaris> Enter-PSSession -HostName [REDACTED] -UserName azureuser

azureuser@[REDACTED]'s password:
[REDACTED]: PS /home/azureuser> ls
test.ps1
[REDACTED]: PS /home/azureuser> PSEdit ./test.ps1
[REDACTED]: PS /home/azureuser> [REDACTED]
```
- Status Bar:** Shows the current branch as "master*", file count as "0 ▲ 0", line 5, column 25, spaces: 4, encoding as UTF-8, line feed as LF, and the language as PowerShell.

2. Edit the file/set breakpoints

The screenshot shows the Visual Studio Code interface with the following details:

- Title Bar:** [Extension Development Host] - test.ps1 — Polaris
- Code Editor:** A file named "test.ps1" is open, containing the following PowerShell script:

```
1 Write-Host "this file is on an Ubuntu VM in Azure"
2
3 Write-Host "It's running PowerShell Core"
4
5 Write-Host "Hello World!"
```
- Sidebar:** Includes icons for File, Search, Find in Current File, and a Taskbar with 22 items.
- Bottom Navigation:** PROBLEMS, OUTPUT, DEBUG CONSOLE, TERMINAL (selected).
- Terminal:** PowerShell Integrated Console showing session activity:

```
PS /Users/tylerleonhardt/Desktop/Polaris> Enter-PSSession -HostName [REDACTED] -UserName azureuser
azureuser@[REDACTED]'s password:
[REDACTED]: PS /home/azureuser> ls
test.ps1
[REDACTED]: PS /home/azureuser> PSEdit ./test.ps1
[REDACTED]: PS /home/azureuser> [REDACTED]
```
- Bottom Status Bar:** master*, 0 errors, 0 warnings, Line 5, Column 25, Spaces: 4, UTF-8, LF, PowerShell, 6.0, [REDACTED], Smiley icon.

3. Start debugging (F5) the remote file

The screenshot shows the Polaris PowerShell IDE interface. On the left, there's a sidebar with icons for file operations, search, and debugging. The main area has tabs for 'DEBUG' and 'test.ps1'. The 'test.ps1' tab contains the following PowerShell script:

```
1 Write-Host "this file is on an Ubuntu VM in Azure"
2
3 Write-Host "It's running PowerShell Core"
4
5 Write-Host "Hello World!"
```

The line 'Write-Host "It's running PowerShell Core"' is highlighted in yellow, indicating it is the current line of execution. Below the code editor is a terminal window titled 'PowerShell Integrated Console' showing the command 'Enter-PSSession -HostName' followed by a redacted host name. The session is connected to an Ubuntu VM in Azure, as indicated by the password prompt and directory listing. The bottom status bar shows the file is in 'master*' branch, has 0 changes, and is using PowerShell 6.0.

If you have any problems, you can open issues in the [GitHub repo](#).

Understanding file encoding in VS Code and PowerShell

Article • 11/30/2023

When using VS Code to create and edit PowerShell scripts, it's important that your files are saved using the correct character encoding format.

What is file encoding and why is it important?

VS Code manages the interface between a human entering strings of characters into a buffer and reading/writing blocks of bytes to the filesystem. When VS Code saves a file, it uses a text encoding to decide what bytes each character becomes. For more information, see [about_Character_Encoding](#).

Similarly, when PowerShell runs a script it must convert the bytes in a file to characters to reconstruct the file into a PowerShell program. Since VS Code writes the file and PowerShell reads the file, they need to use the same encoding system. This process of parsing a PowerShell script goes: *bytes -> characters -> tokens -> abstract syntax tree -> execution*.

Both VS Code and PowerShell are installed with a sensible default encoding configuration. However, the default encoding used by PowerShell has changed with the release of PowerShell 6. To ensure you have no problems using PowerShell or the PowerShell extension in VS Code, you need to configure your VS Code and PowerShell settings properly.

Common causes of encoding issues

Encoding problems occur when the encoding of VS Code or your script file doesn't match the expected encoding of PowerShell. There is no way for PowerShell to automatically determine the file encoding.

You're more likely to have encoding problems when you're using characters not in the [7-bit ASCII character set](#). For example:

- Extended non-letter characters like em-dash (–), non-breaking space („) or left double quotation mark („)
- Accented latin characters (É, ü)
- Non-latin characters like Cyrillic (д, ц)

- CJK characters (本, 화, ガ)

Common reasons for encoding issues are:

- The encodings of VS Code and PowerShell haven't been changed from their defaults. For PowerShell 5.1 and below, the default encoding is different from VS Code's.
- Another editor has opened and overwritten the file in a new encoding. This often happens with the ISE.
- The file is checked into source control in an encoding that's different from what VS Code or PowerShell expects. This can happen when collaborators use editors with different encoding configurations.

How to tell when you have encoding issues

Often encoding errors present themselves as parse errors in scripts. If you find strange character sequences in your script, this can be the problem. In the example below, an en-dash (-) appears as the characters â€" :

```
Output

Send-MailMessage : A positional parameter cannot be found that accepts
argument 'Testing FuseMail SMTP...'.
At C:\Users\<User>\<OneDrive>\Development\PowerShell\Scripts\Send-
EmailUsingSmtpRelay.ps1:6 char:1
+ Send-MailMessage â&euro;"From $from â&euro;"To $recipient1 â&euro;"Subject
$subject ...
+ ~~~~~
+ CategoryInfo          : InvalidArgument: (:) [Send-MailMessage],
ParameterBindingException
+ FullyQualifiedErrorId :
PositionalParameterNotFound,Microsoft.PowerShell.Commands.SendMailMessage
```

This problem occurs because VS Code encodes the character – in UTF-8 as the bytes `0xE2 0x80 0x93`. When these bytes are decoded as Windows-1252, they're interpreted as the characters â€" .

Some strange character sequences that you might see include:

- â€" instead of – (an en-dash)
- â€" instead of — (an em-dash)
- Ä,,2 instead of Å
- Â instead of ® (a non-breaking space)
- Æ© instead of é

This handy [reference](#) lists the common patterns that indicate a UTF-8/Windows-1252 encoding problem.

How the PowerShell extension in VS Code interacts with encodings

The PowerShell extension interacts with scripts in a number of ways:

1. When scripts are edited in VS Code, the contents are sent by VS Code to the extension. The [Language Server Protocol](#) mandates that this content is transferred in UTF-8. Therefore, it isn't possible for the extension to get the wrong encoding.
2. When scripts are executed directly in the Integrated Console, they're read from the file by PowerShell directly. If PowerShell's encoding differs from VS Code's, something can go wrong here.
3. When a script that's open in VS Code references another script that isn't open in VS Code, the extension falls back to loading that script's content from the file system. The PowerShell extension defaults to UTF-8 encoding, but uses [byte-order mark](#), or BOM, detection to select the correct encoding.

The problem occurs when assuming the encoding of BOM-less formats (like [UTF-8](#) with no BOM and [Windows-1252](#)). The PowerShell extension defaults to UTF-8. The extension can't change VS Code's encoding settings. For more information, see [issue #824](#).

Choosing the right encoding

Different systems and applications can use different encodings:

- In .NET Standard, on the web, and in the Linux world, UTF-8 is now the dominant encoding.
- Many .NET Framework applications use [UTF-16](#). For historical reasons, this is sometimes called "Unicode", a term that now refers to a broad [standard](#) that includes both UTF-8 and UTF-16.
- On Windows, many native applications that predate Unicode continue to use Windows-1252 by default.

Unicode encodings also have the concept of a byte-order mark (BOM). BOMs occur at the beginning of text to tell a decoder which encoding the text is using. For multi-byte encodings, the BOM also indicates [endianness](#) of the encoding. BOMs are designed to

be bytes that rarely occur in non-Unicode text, allowing a reasonable guess that text is Unicode when a BOM is present.

BOMs are optional and their adoption isn't as popular in the Linux world because a dependable convention of UTF-8 is used everywhere. Most Linux applications presume that text input is encoded in UTF-8. While many Linux applications will recognize and correctly handle a BOM, a number don't, leading to artifacts in text manipulated with those applications.

Therefore:

- If you work primarily with Windows applications and Windows PowerShell, you should prefer an encoding like UTF-8 with BOM or UTF-16.
- If you work across platforms, you should prefer UTF-8 with BOM.
- If you work mainly in Linux-associated contexts, you should prefer UTF-8 without BOM.
- Windows-1252 and latin-1 are essentially legacy encodings that you should avoid if possible. However, some older Windows applications may depend on them.
- It's also worth noting that script signing is [encoding-dependent](#), meaning a change of encoding on a signed script will require resigning.

Configuring VS Code

VS Code's default encoding is UTF-8 without BOM.

To set [VS Code's encoding](#), go to the VS Code settings (`ctrl + ,`) and set the `"files.encoding"` setting:

JSON

```
"files.encoding": "utf8bom"
```

Some possible values are:

- `utf8`: [UTF-8] without BOM
- `utf8bom`: [UTF-8] with BOM
- `utf16le`: Little endian [UTF-16]
- `utf16be`: Big endian [UTF-16]
- `windows1252`: [Windows-1252]

You should get a dropdown for this in the GUI view, or completions for it in the JSON view.

You can also add the following to autodetect encoding when possible:

JSON

```
"files.autoGuessEncoding": true
```

If you don't want these settings to affect all file types, VS Code also allows per-language configurations. Create a language-specific setting by putting settings in a [`<language-name>`] field. For example:

JSON

```
[powershell]: {
  "files.encoding": "utf8bom",
  "files.autoGuessEncoding": true
}
```

You may also want to consider installing the [Gremlins tracker](#) for Visual Studio Code. This extension reveals certain Unicode characters that easily corrupted because they're invisible or look like other normal characters.

Configuring PowerShell

PowerShell's default encoding varies depending on version:

- In PowerShell 6+, the default encoding is UTF-8 without BOM on all platforms.
- In Windows PowerShell, the default encoding is usually Windows-1252, which is an extension of [latin-1](#) (also known as ISO 8859-1).

In PowerShell 5+ you can find your default encoding with this:

PowerShell

```
[psobject].Assembly.GetTypes() | Where-Object { $_.Name -eq 'ClrFacade' } |
  ForEach-Object {
    $_.GetMethod('GetDefaultEncoding',
    [System.Reflection.BindingFlags]'nonpublic,static').Invoke($null, @()) }
```

The following [script](#) can be used to determine what encoding your PowerShell session infers for a script without a BOM.

PowerShell

```

$badBytes = [byte[]]@(0xC3, 0x80)
$utf8Str = [System.Text.Encoding]::UTF8.GetString($badBytes)
$bytes = [System.Text.Encoding]::ASCII.GetBytes('Write-Output '') +
[byte[]]@(0xC3, 0x80) + [byte[]]@(0x22)
$path = Join-Path ([System.IO.Path]::GetTempPath()) 'encodingtest.ps1'

try
{
    [System.IO.File]::WriteAllBytes($path, $bytes)

    switch (& $path)
    {
        $utf8Str
        {
            return 'UTF-8'
            break
        }

        default
        {
            return 'Windows-1252'
            break
        }
    }
}
finally
{
    Remove-Item $path
}

```

It's possible to configure PowerShell to use a given encoding more generally using profile settings. See the following articles:

- @mklement0's [answer about PowerShell encoding on Stack Overflow ↗](#).
- @rkeithhill's [blog post about dealing with BOM-less UTF-8 input in PowerShell ↗](#).

It's not possible to force PowerShell to use a specific input encoding. PowerShell 5.1 and below, running on Windows with the locale set to en-US, defaults to Windows-1252 encoding when there's no BOM. Other locale settings may use a different encoding. To ensure interoperability, it's best to save scripts in a Unicode format with a BOM.

Important

Any other tools you have that touch PowerShell scripts may be affected by your encoding choices or re-encode your scripts to another encoding.

Existing scripts

Scripts already on the file system may need to be re-encoded to your new chosen encoding. In the bottom bar of VS Code, you'll see the label UTF-8. Click it to open the action bar and select **Save with encoding**. You can now pick a new encoding for that file. See [VS Code's encoding ↗](#) for full instructions.

If you need to re-encode multiple files, you can use the following script:

PowerShell

```
Get-ChildItem *.ps1 -Recurse | ForEach-Object {
    $content = Get-Content -Path $_
    Set-Content -Path $_.FullName -Value $content -Encoding UTF8 -PassThru -
    Force
}
```

The PowerShell Integrated Scripting Environment (ISE)

If you also edit scripts using the PowerShell ISE, you need to synchronize your encoding settings there.

The ISE should honor a BOM, but it's also possible to use reflection to [set the encoding ↗](#). Note that this wouldn't be persisted between startups.

Source control software

Some source control tools, such as git, ignore encodings; git just tracks the bytes. Others, like Azure DevOps or Mercurial, may not. Even some git-based tools rely on decoding text.

When this is the case, make sure you:

- Configure the text encoding in your source control to match your VS Code configuration.
- Ensure all your files are checked into source control in the relevant encoding.
- Be wary of changes to the encoding received through source control. A key sign of this is a diff indicating changes but where nothing seems to have changed (because bytes have but characters have not).

Collaborators' environments

On top of configuring source control, ensure that your collaborators on any files you share don't have settings that override your encoding by re-encoding PowerShell files.

Other programs

Any other program that reads or writes a PowerShell script may re-encode it.

Some examples are:

- Using the clipboard to copy and paste a script. This is common in scenarios like:
 - Copying a script into a VM
 - Copying a script out of an email or webpage
 - Copying a script into or out of a Microsoft Word or PowerPoint document
- Other text editors, such as:
 - Notepad
 - vim
 - Any other PowerShell script editor
- Text editing utilities, like:
 - `Get-Content` / `Set-Content` / `Out-File`
 - PowerShell redirection operators like `>` and `>>`
 - `sed` / `awk`
- File transfer programs, like:
 - A web browser, when downloading scripts
 - A file share

Some of these tools deal in bytes rather than text, but others offer encoding configurations. In those cases where you need to configure an encoding, you need to make it the same as your editor encoding to prevent problems.

Other resources on encoding in PowerShell

There are a few other nice posts on encoding and configuring encoding in PowerShell that are worth a read:

Using Visual Studio Code to debug compiled cmdlets

Article • 02/08/2023

This guide shows you how to interactively debug C# source code for a compiled PowerShell module using Visual Studio Code (VS Code) and the C# extension.

Some familiarity with the Visual Studio Code debugger is assumed.

- For a general introduction to the VS Code debugger, see [Debugging in Visual Studio Code ↗](#).
- For examples of debugging PowerShell script files and modules, see [Using Visual Studio Code for remote editing and debugging](#).

This guide assumes you have read and followed the instructions in the [Writing Portable Modules](#) guide.

Creating a build task

Build your project automatically before launching a debugging session. Rebuilding ensures that you debug the latest version of your code.

Configure a build task:

1. In the **Command Palette**, run the **Configure Default Build Task** command.
[Run Configure Default Build Task](#)
2. In the **Select a task to configure** dialog, choose **Create tasks.json file from template**.
3. In the **Select a Task Template** dialog, choose **.NET Core**.

A new `tasks.json` file is created if one doesn't exist yet.

To test your build task:

1. In the **Command Palette**, run the **Run Build Task** command.
2. In the **Select the build task to run** dialog, choose **build**.

Information about DLL files being locked

By default, a successful build doesn't show output in the terminal pane. If you see output that contains the text **Project file doesn't exist**, you should edit the `tasks.json` file. Include the explicit path to the C# project expressed as `"${workspaceFolder}/myModule"`. In this example, `myModule` is the name of the project folder. This entry must go after the `build` entry in the `args` list as follows:

```
JSON

{
  "label": "build",
  "command": "dotnet",
  "type": "shell",
  "args": [
    "build",
    "${workspaceFolder}/myModule",
    // Ask dotnet build to generate full paths for file names.
    "/property:GenerateFullPaths=true",
    // Do not generate summary otherwise it leads to duplicate
errors in Problems panel
    "/consoleloggerparameters:NoSummary",
  ],
  "group": "build",
  "presentation": {
    "reveal": "silent"
  },
  "problemMatcher": "$msCompile"
}
```

When debugging, your module DLL is imported into the PowerShell session in the VS Code terminal. The DLL becomes locked. The following message is displayed when you run the build task without closing the terminal session:

```
Output

Could not copy "obj\Debug\netstandard2.0\myModule.dll" to
"bin\Debug\netstandard2.0\myModule.dll"`.
```

Terminal sessions must be closed before you rebuild.

Setting up the debugger

To debug the PowerShell cmdlet, you need to set up a custom launch configuration. This configuration is used to:

- Build your source code
- Start PowerShell with your module loaded

- Leave PowerShell open in the terminal pane

When you invoke your cmdlet in the terminal session, the debugger stops at any breakpoints set in your source code.

Configuring launch.json for PowerShell

1. Install the [C# for Visual Studio Code](#) extension
2. In the Debug pane, add a debug configuration
3. In the `Select environment` dialog, choose `.NET Core`
4. The `launch.json` file is opened in the editor. With your cursor inside the `configurations` array, you see the `configuration` picker. If you don't see this list, select **Add Configuration**.
5. To create a default debug configuration, select **Launch .NET Core Console App**:
[Launch .NET Core Console App](#)

6. Edit the `name`, `program`, `args`, and `console` fields as follows:

```
JSON

{
    "name": "PowerShell cmdlets: pwsh",
    "type": "coreclr",
    "request": "launch",
    "preLaunchTask": "build",
    "program": "pwsh",
    "args": [
        "-NoExit",
        "-NoProfile",
        "-Command",
        "Import-Module ${workspaceFolder}/myModule/bin/Debug/netstandard2.0/myModule.dll",
    ],
    "cwd": "${workspaceFolder}",
    "stopAtEntry": false,
    "console": "integratedTerminal"
}
```

The `program` field is used to launch `pwsh` so that the cmdlet being debugged can be run. The `-NoExit` argument prevents the PowerShell session from exiting as soon as the module is imported. The path in the `Import-Module` argument is the default build output path when you've followed the [Writing Portable Modules](#) guide. If you've created a

module manifest (.psd1 file), you should use the path to that instead. The / path separator works on Windows, Linux, and macOS. You must use the integrated terminal to run the PowerShell commands you want to debug.

ⓘ Note

If the debugger doesn't stop at any breakpoints, look in the Visual Studio Code Debug Console for a line that says:

```
Loaded '/path/to/myModule.dll'. Skipped loading symbols. Module is optimized and the debugger option 'Just My Code' is enabled.
```

If you see this, add "justMyCode": false to your launch config (at the same level as "console": "integratedTerminal".

Configuring launch.json for Windows PowerShell

This launch configuration works for testing your cmdlets in Windows PowerShell (powershell.exe). Create a second launch configuration with the following changes:

1. name should be PowerShell cmdlets: powershell
2. type should be clr
3. program should be powershell

It should look like this:

JSON

```
{
  "name": "PowerShell cmdlets: powershell",
  "type": "clr",
  "request": "launch",
  "preLaunchTask": "build",
  "program": "powershell",
  "args": [
    "-NoExit",
    "-NoProfile",
    "-Command",
    "Import-Module ${workspaceFolder}/myModule/bin/Debug/netstandard2.0/myModule.dll",
  ],
  "cwd": "${workspaceFolder}",
```

```
        "stopAtEntry": false,  
        "console": "integratedTerminal"  
    }  
}
```

Launching a debugging session

Now everything is ready to begin debugging.

- Place a breakpoint in the source code for the cmdlet you want to debug:
[A breakpoint shows as a red dot in the gutter](#)
- Ensure that the relevant **PowerShell cmdlets** configuration is selected in the configuration drop-down menu in the **Debug** view:
[Select the launch configuration](#)
- Press **F5** or click on the **Start Debugging** button
- Switch to the terminal pane and invoke your cmdlet:

[Invoke the cmdlet](#)

- Execution stops at the breakpoint:

[Execution halts at breakpoint](#)

You can step through the source code, inspect variables, and inspect the call stack.

To end debugging, click **Stop** in the debug toolbar or press **Shift** + **F5**. The shell used for debugging exits and releases the lock on the compiled DLL file.

PowerShell scripting performance considerations

Article • 05/26/2025

PowerShell scripts that leverage .NET directly and avoid the pipeline tend to be faster than idiomatic PowerShell. Idiomatic PowerShell uses cmdlets and PowerShell functions, often leveraging the pipeline, and resorting to .NET only when necessary.

! Note

Many of the techniques described here aren't idiomatic PowerShell and may reduce the readability of a PowerShell script. Script authors are advised to use idiomatic PowerShell unless performance dictates otherwise.

Suppressing output

There are many ways to avoid writing objects to the pipeline.

- Assignment or file redirection to `$null`
- Casting to `[void]`
- Pipe to `out-Null`

The speeds of assigning to `$null`, casting to `[void]`, and file redirection to `$null` are almost identical. However, calling `out-Null` in a large loop can be significantly slower, especially in PowerShell 5.1.

PowerShell

```
$tests = @{
    'Assign to $null' = {
        $arrayList = [System.Collections.ArrayList]::new()
        foreach ($i in 0..$args[0]) {
            $null = $arraylist.Add($i)
        }
    }
    'Cast to [void]' = {
        $arrayList = [System.Collections.ArrayList]::new()
        foreach ($i in 0..$args[0]) {
            [void] $arraylist.Add($i)
        }
    }
    'Redirect to $null' = {
        $arrayList = [System.Collections.ArrayList]::new()
        foreach ($i in 0..$args[0]) {
```

```

        $arraylist.Add($i) > $null
    }
}
'Pipe to Out-Null' = {
    $arrayList = [System.Collections.ArrayList]::new()
    foreach ($i in 0..$args[0]) {
        $arraylist.Add($i) | Out-Null
    }
}
}

10kb, 50kb, 100kb | ForEach-Object {
    $groupResult = foreach ($test in $tests.GetEnumerator()) {
        $ms = (Measure-Command { & $test.Value $_ }).TotalMilliseconds

        [pscustomobject]@{
            Iterations      = $_
            Test           = $test.Key
            TotalMilliseconds = [Math]::Round($ms, 2)
        }

        [GC]::Collect()
        [GC]::WaitForPendingFinalizers()
    }

    $groupResult = $groupResult | Sort-Object TotalMilliseconds
    $groupResult | Select-Object *, @{
        Name      = 'RelativeSpeed'
        Expression = {
            $relativeSpeed = $_.TotalMilliseconds /
                $groupResult[0].TotalMilliseconds
            [Math]::Round($relativeSpeed, 2).ToString() + 'x'
        }
    }
}

```

These tests were run on a Windows 11 machine in PowerShell 7.3.4. The results are shown below:

Output

Iterations	Test	TotalMilliseconds	RelativeSpeed
10240	Assign to \$null	36.74	1x
10240	Redirect to \$null	55.84	1.52x
10240	Cast to [void]	62.96	1.71x
10240	Pipe to Out-Null	81.65	2.22x
51200	Assign to \$null	193.92	1x
51200	Cast to [void]	200.77	1.04x
51200	Redirect to \$null	219.69	1.13x
51200	Pipe to Out-Null	329.62	1.7x
102400	Redirect to \$null	386.08	1x
102400	Assign to \$null	392.13	1.02x

```
102400 Cast to [void]  
102400 Pipe to Out-Null
```

```
405.24 1.05x  
572.94 1.48x
```

The times and relative speeds can vary depending on the hardware, the version of PowerShell, and the current workload on the system.

Array addition

Generating a list of items is often done using an array with the addition operator:

```
PowerShell
```

```
$results = @()  
$results += Get-Something  
$results += Get-SomethingElse  
$results
```

ⓘ Note

In PowerShell 7.5, array addition was optimized and no longer creates a new array for each operation. The performance considerations described here still apply to PowerShell versions prior to 7.5. For more information, see [What's New in PowerShell 7.5](#).

Array addition is inefficient because arrays have a fixed size. Each addition to the array creates a new array big enough to hold all elements of both the left and right operands. The elements of both operands are copied into the new array. For small collections, this overhead may not matter. Performance can suffer for large collections.

There are a couple of alternatives. If you don't actually require an array, instead consider using a typed generic list (`[List<T>]`):

```
PowerShell
```

```
$results = [System.Collections.Generic.List[Object]]::new()  
$results.AddRange((Get-Something))  
$results.AddRange((Get-SomethingElse))  
$results
```

The performance impact of using array addition grows exponentially with the size of the collection and the number additions. This code compares explicitly assigning values to an array with using array addition and using the `Add(T)` method on a `[List<T>]` object. It defines explicit assignment as the baseline for performance.

PowerShell

```
$tests = @{
    'PowerShell Explicit Assignment' = {
        param($Count)

        $result = foreach($i in 1..$Count) {
            $i
        }
    }
    '.Add(T) to List<T>' = {
        param($Count)

        $result = [Collections.Generic.List[int]]::new()
        foreach($i in 1..$Count) {
            $result.Add($i)
        }
    }
    '+= Operator to Array' = {
        param($Count)

        $result = @()
        foreach($i in 1..$Count) {
            $result += $i
        }
    }
}

5kb, 10kb, 100kb | ForEach-Object {
    $groupResult = foreach($test in $tests.GetEnumerator()) {
        $ms = (Measure-Command { & $test.Value -Count $_ }).TotalMilliseconds

        [pscustomobject]@{
            CollectionSize      = $_
            Test                = $test.Key
            TotalMilliseconds = [Math]::Round($ms, 2)
        }
    }

    [GC]::Collect()
    [GC]::WaitForPendingFinalizers()
}

$groupResult = $groupResult | Sort-Object TotalMilliseconds
$groupResult | Select-Object *, @{
    Name      = 'RelativeSpeed'
    Expression = {
        $relativeSpeed = $_.TotalMilliseconds /
        $groupResult[0].TotalMilliseconds
        [Math]::Round($relativeSpeed, 2).ToString() + 'x'
    }
}
```

These tests were run on a Windows 11 machine in PowerShell 7.3.4.

Output

CollectionSize Test	TotalMilliseconds	RelativeSpeed
5120 PowerShell Explicit Assignment	26.65	1x
5120 .Add(T) to List<T>	110.98	4.16x
5120 += Operator to Array	402.91	15.12x
10240 PowerShell Explicit Assignment	0.49	1x
10240 .Add(T) to List<T>	137.67	280.96x
10240 += Operator to Array	1678.13	3424.76x
102400 PowerShell Explicit Assignment	11.18	1x
102400 .Add(T) to List<T>	1384.03	123.8x
102400 += Operator to Array	201991.06	18067.18x

When you're working with large collections, array addition is dramatically slower than adding to a `List<T>`.

When using a `[List<T>]` object, you need to create the list with a specific type, like `[string]` or `[int]`. When you add objects of a different type to the list, they are cast to the specified type. If they can't be cast to the specified type, the method raises an exception.

PowerShell

```
$intList = [System.Collections.Generic.List[int]]::new()
[int]$intList.Add(1)
[int]$intList.Add('2')
[int]$intList.Add(3.0)
[int]$intList.Add('Four')
[int]$intList
```

Output

```
MethodException:
Line |
 5 |     $intList.Add('Four')
   | ~~~~~
   | Cannot convert argument "item", with value: "Four", for "Add" to type
   | "System.Int32": "Cannot convert value "Four" to type "System.Int32".
   | Error: "The input string 'Four' was not in a correct format.""
```

```
1
2
3
```

When you need the list to be a collection of different types of objects, create it with `[Object]` as the list type. You can enumerate the collection inspect the types of the objects in it.

PowerShell

```
$objectList = [System.Collections.Generic.List[Object]]::new()
)objectList.Add(1)
)objectList.Add('2')
)objectList.Add(3.0)
)objectList | ForEach-Object { "$_ is $($_.GetType())" }
```

Output

```
1 is int
2 is string
3 is double
```

If you do require an array, you can call the `ToArray()` method on the list or you can let PowerShell create the array for you:

PowerShell

```
$results = @(
    Get-Something
    Get-SomethingElse
)
```

In this example, PowerShell creates an `[ArrayList]` to hold the results written to the pipeline inside the array expression. Just before assigning to `$results`, PowerShell converts the `[ArrayList]` to an `[Object[]]`.

String addition

Strings are immutable. Each addition to the string actually creates a new string big enough to hold the contents of both the left and right operands, then copies the elements of both operands into the new string. For small strings, this overhead may not matter. For large strings, this can affect performance and memory consumption.

There are at least two alternatives:

- The `-join` operator concatenates strings
- The .NET `[StringBuilder]` class provides a mutable string

The following example compares the performance of these three methods of building a string.

PowerShell

```

$tests = @{
    'StringBuilder' = {
        $sb = [System.Text.StringBuilder]::new()
        foreach ($i in 0..$args[0]) {
            $sb = $sb.AppendLine("Iteration $i")
        }
        $sb.ToString()
    }
    'Join operator' = {
        $string = @(
            foreach ($i in 0..$args[0]) {
                "Iteration $i"
            }
        ) -join "`n"
        $string
    }
    'Addition Assignment +=' = {
        $string = ''
        foreach ($i in 0..$args[0]) {
            $string += "Iteration $i`n"
        }
        $string
    }
}

10kb, 50kb, 100kb | ForEach-Object {
    $groupResult = foreach ($test in $tests.GetEnumerator()) {
        $ms = (Measure-Command { & $test.Value $_ }).TotalMilliseconds

        [pscustomobject]@{
            Iterations      = $_
            Test           = $test.Key
            TotalMilliseconds = [Math]::Round($ms, 2)
        }

        [GC]::Collect()
        [GC]::WaitForPendingFinalizers()
    }

    $groupResult = $groupResult | Sort-Object TotalMilliseconds
    $groupResult | Select-Object *, @{
        Name      = 'RelativeSpeed'
        Expression = {
            $relativeSpeed = $_.TotalMilliseconds /
                $groupResult[0].TotalMilliseconds
            [Math]::Round($relativeSpeed, 2).ToString() + 'x'
        }
    }
}

```

These tests were run on a Windows 11 machine in PowerShell 7.4.2. The output shows that the `-join` operator is the fastest, followed by the `[StringBuilder]` class.

Output

Iterations	Test	TotalMilliseconds	RelativeSpeed
10240	Join operator	14.75	1x
10240	StringBuilder	62.44	4.23x
10240	Addition Assignment +=	619.64	42.01x
51200	Join operator	43.15	1x
51200	StringBuilder	304.32	7.05x
51200	Addition Assignment +=	14225.13	329.67x
102400	Join operator	85.62	1x
102400	StringBuilder	499.12	5.83x
102400	Addition Assignment +=	67640.79	790.01x

The times and relative speeds can vary depending on the hardware, the version of PowerShell, and the current workload on the system.

Processing large files

The idiomatic way to process a file in PowerShell might look something like:

```
PowerShell
```

```
Get-Content $path | Where-Object Length -GT 10
```

This can be an order of magnitude slower than using .NET APIs directly. For example, you can use the .NET `[StreamReader]` class:

```
PowerShell
```

```
try {
    $reader = [System.IO.StreamReader]::new($path)
    while (-not $reader.EndOfStream) {
        $line = $reader.ReadLine()
        if ($line.Length -gt 10) {
            $line
        }
    }
}
finally {
    if ($reader) {
        $reader.Dispose()
    }
}
```

You could also use the `ReadLines` method of `[System.IO.File]`, which wraps `StreamReader`, simplifies the reading process:

```
PowerShell
```

```
foreach ($line in [System.IO.File]::ReadLines($path)) {  
    if ($line.Length -gt 10) {  
        $line  
    }  
}
```

Looking up entries by property in large collections

It's common to need to use a shared property to identify the same record in different collections, like using a name to retrieve an ID from one list and an email from another. Iterating over the first list to find the matching record in the second collection is slow. In particular, the repeated filtering of the second collection has a large overhead.

Given two collections, one with an **Id** and **Name**, the other with **Name** and **Email**:

```
PowerShell
```

```
$Employees = 1..10000 | ForEach-Object {  
    [pscustomobject]@{  
        Id    = $_  
        Name = "Name$_"  
    }  
}  
  
$Accounts = 2500..7500 | ForEach-Object {  
    [pscustomobject]@{  
        Name  = "Name$_"  
        Email = "Name$_@fabrikam.com"  
    }  
}
```

The usual way to reconcile these collections to return a list of objects with the **Id**, **Name**, and **Email** properties might look like this:

```
PowerShell
```

```
$Results = $Employees | ForEach-Object -Process {  
    $Employee = $_  
  
    $Account = $Accounts | Where-Object -FilterScript {  
        $_.Name -eq $Employee.Name  
    }  
  
    [pscustomobject]@{  
        Id    = $Employee.Id  
        Name = $Employee.Name  
    }
```

```
        Email = $Account.Email  
    }  
}
```

However, that implementation has to filter all 5000 items in the `$Accounts` collection once for every item in the `$Employee` collection. That can take minutes, even for this single-value lookup.

Instead, you can make a [Hash Table](#) that uses the shared **Name** property as a key and the matching account as the value.

PowerShell

```
$LookupHash = @{}  
foreach ($Account in $Accounts) {  
    $LookupHash[$Account.Name] = $Account  
}
```

Looking up keys in a hash table is much faster than filtering a collection by property values. Instead of checking every item in the collection, PowerShell can check if the key is defined and use its value.

PowerShell

```
$Results = $Employees | ForEach-Object -Process {  
    $Email = $LookupHash[$_.Name].Email  
    [pscustomobject]@{  
        Id      = $_.Id  
        Name   = $_.Name  
        Email  = $Email  
    }  
}
```

This is much faster. While the looping filter took minutes to complete, the hash lookup takes less than a second.

Use Write-Host carefully

The `Write-Host` command should only be used when you need to write formatted text to the host console, rather than writing objects to the `Success` pipeline.

`Write-Host` can be an order of magnitude slower than `[Console]::WriteLine()` for specific hosts like `pwsh.exe`, `powershell.exe`, or `powershell_ise.exe`. However, `[Console]::WriteLine()` isn't guaranteed to work in all hosts. Also, output written using `[Console]::WriteLine()` doesn't get written to transcripts started by `Start-Transcript`.

JIT compilation

PowerShell compiles the script code to bytecode that's interpreted. Beginning in PowerShell 3, for code that's repeatedly executed in a loop, PowerShell can improve performance by Just-in-time (JIT) compiling the code into native code.

Loops that have fewer than 300 instructions are eligible for JIT-compilation. Loops larger than that are too costly to compile. When the loop has executed 16 times, the script is JIT-compiled in the background. When the JIT-compilation completes, execution is transferred to the compiled code.

Avoid repeated calls to a function

Calling a function can be an expensive operation. If you're calling a function in a long running tight loop, consider moving the loop inside the function.

Consider the following examples:

```
PowerShell

$tests = @{
    'Simple for-loop'      = {
        param([int] $RepeatCount, [random] $RanGen)

        for ($i = 0; $i -lt $RepeatCount; $i++) {
            $null = $RanGen.Next()
        }
    }
    'Wrapped in a function' = {
        param([int] $RepeatCount, [random] $RanGen)

        function Get-RandomNumberCore {
            param ($Rng)

            $Rng.Next()
        }

        for ($i = 0; $i -lt $RepeatCount; $i++) {
            $null = Get-RandomNumberCore -Rng $RanGen
        }
    }
    'for-loop in a function' = {
        param([int] $RepeatCount, [random] $RanGen)

        function Get-RandomNumberAll {
            param ($Rng, $Count)

            for ($i = 0; $i -lt $Count; $i++) {
                $null = $Rng.Next()
            }
        }
    }
}
```

```

        }

    }

    Get-RandomNumberAll -Rng $RanGen -Count $RepeatCount
}

}

5kb, 10kb, 100kb | ForEach-Object {
    $Rng = [random]::new()
    $groupResult = foreach ($test in $tests.GetEnumerator()) {
        $ms = Measure-Command { & $test.Value -RepeatCount $_ -RanGen $Rng }

        [pscustomobject]@{
            CollectionSize      = $_
            Test                = $test.Key
            TotalMilliseconds = [Math]::Round($ms.TotalMilliseconds,2)
        }
    }

    [GC]::Collect()
    [GC]::WaitForPendingFinalizers()
}

$groupResult = $groupResult | Sort-Object TotalMilliseconds
$groupResult | Select-Object *, @{
    Name      = 'RelativeSpeed'
    Expression = {
        $relativeSpeed = $_.TotalMilliseconds /
$groupResult[0].TotalMilliseconds
        [Math]::Round($relativeSpeed, 2).ToString() + 'x'
    }
}
}
}

```

The **Basic for-loop** example is the base line for performance. The second example wraps the random number generator in a function that's called in a tight loop. The third example moves the loop inside the function. The function is only called once but the code still generates the same amount of random numbers. Notice the difference in execution times for each example.

Output

CollectionSize	Test	TotalMilliseconds	RelativeSpeed
5120	for-loop in a function	9.62	1x
5120	Simple for-loop	10.55	1.1x
5120	Wrapped in a function	62.39	6.49x
10240	Simple for-loop	17.79	1x
10240	for-loop in a function	18.48	1.04x
10240	Wrapped in a function	127.39	7.16x
102400	for-loop in a function	179.19	1x
102400	Simple for-loop	181.58	1.01x
102400	Wrapped in a function	1155.57	6.45x

Avoid wrapping cmdlet pipelines

Most cmdlets are implemented for the pipeline, which is a sequential syntax and process. For example:

```
PowerShell  
cmdlet1 | cmdlet2 | cmdlet3
```

Initializing a new pipeline can be expensive, therefore you should avoid wrapping a cmdlet pipeline into another existing pipeline.

Consider the following example. The `Input.csv` file contains 2100 lines. The `Export-Csv` command is wrapped inside the `ForEach-Object` pipeline. The `Export-Csv` cmdlet is invoked for every iteration of the `ForEach-Object` loop.

```
PowerShell  
  
$measure = Measure-Command -Expression {  
    Import-Csv .\Input.csv | ForEach-Object -Begin { $Id = 1 } -Process {  
        [pscustomobject]@{  
            Id      = $Id  
            Name   = $_.opened_by  
        } | Export-Csv .\Output1.csv -Append  
    }  
}  
  
'Wrapped = {0:N2} ms' -f $measure.TotalMilliseconds
```

```
Output  
  
Wrapped = 15,968.78 ms
```

For the next example, the `Export-Csv` command was moved outside of the `ForEach-Object` pipeline. In this case, `Export-Csv` is invoked only once, but still processes all objects passed out of `ForEach-Object`.

```
PowerShell  
  
$measure = Measure-Command -Expression {  
    Import-Csv .\Input.csv | ForEach-Object -Begin { $Id = 2 } -Process {  
        [pscustomobject]@{  
            Id      = $Id  
            Name   = $_.opened_by  
        }  
    } | Export-Csv .\Output2.csv
```

```
}
```

```
'Unwrapped = {0:N2} ms' -f $measure.TotalMilliseconds
```

Output

```
Unwrapped = 42.92 ms
```

The unwrapped example is **372 times faster**. Also, notice that the first implementation requires the **Append** parameter, which isn't required for the later implementation.

Object creation

Creating objects using the `New-Object` cmdlet can be slow. The following code compares the performance of creating objects using the `New-Object` cmdlet to the `[pscustomobject]` type accelerator.

PowerShell

```
Measure-Command {
    $test = 'PSCustomObject'
    for ($i = 0; $i -lt 100000; $i++) {
        $resultObject = [pscustomobject]@{
            Name = 'Name'
            Path = 'FullName'
        }
    }
} | Select-Object @{n='Test';e={$test}},TotalSeconds

Measure-Command {
    $test = 'New-Object'
    for ($i = 0; $i -lt 100000; $i++) {
        $resultObject = New-Object -TypeName psobject -Property @{
            Name = 'Name'
            Path = 'FullName'
        }
    }
} | Select-Object @{n='Test';e={$test}},TotalSeconds
```

Output

Test	TotalSeconds
---	-----
PSCustomObject	0.48
New-Object	3.37

PowerShell 5.0 added the `new()` static method for all .NET types. The following code compares the performance of creating objects using the `New-Object` cmdlet to the `new()` method.

```
PowerShell

Measure-Command {
    $test = 'new() method'
    for ($i = 0; $i -lt 100000; $i++) {
        $sb = [System.Text.StringBuilder]::new(1000)
    }
} | Select-Object @{n='Test';e={$test}},TotalSeconds

Measure-Command {
    $test = 'New-Object'
    for ($i = 0; $i -lt 100000; $i++) {
        $sb = New-Object -TypeName System.Text.StringBuilder -ArgumentList 1000
    }
} | Select-Object @{n='Test';e={$test}},TotalSeconds
```

Output

Test	TotalSeconds
new() method	0.59
New-Object	3.17

Use `OrderedDictionary` to dynamically create new objects

There are situations where we may need to dynamically create objects based on some input, the perhaps most commonly used way to create a new `PSObject` and then add new properties using the `Add-Member` cmdlet. The performance cost for small collections using this technique may be negligible however it can become very noticeable for big collections. In that case, the recommended approach is to use an `[OrderedDictionary]` and then convert it to a `PSObject` using the `[pscustomobject]` type accelerator. For more information, see the *Creating ordered dictionaries* section of [about_Hash_Tables](#).

Assume you have the following API response stored in the variable `$json`.

```
JSON

{
  "tables": [
    {
      "name": "PrimaryResult",
```

```

    "columns": [
        { "name": "Type", "type": "string" },
        { "name": "TenantId", "type": "string" },
        { "name": "count_", "type": "long" }
    ],
    "rows": [
        [ "Usage", "63613592-b6f7-4c3d-a390-22ba13102111", "1" ],
        [ "Usage", "d436f322-a9f4-4aad-9a7d-271fb66001c", "1" ],
        [ "BillingFact", "63613592-b6f7-4c3d-a390-22ba13102111", "1" ],
        [ "BillingFact", "d436f322-a9f4-4aad-9a7d-271fb66001c", "1" ],
        [ "Operation", "63613592-b6f7-4c3d-a390-22ba13102111", "7" ],
        [ "Operation", "d436f322-a9f4-4aad-9a7d-271fb66001c", "5" ]
    ]
}
]
}

```

Now, suppose you want to export this data to a CSV. First you need to create new objects and add the properties and values using the `Add-Member` cmdlet.

PowerShell

```

$data = $json | ConvertFrom-Json
$columns = $data.tables.columns
$result = foreach ($row in $data.tables.rows) {
    $obj = [psobject]::new()
    $index = 0

    foreach ($column in $columns) {
        $obj | Add-Member -MemberType NoteProperty -Name $column.name -Value
$row[$index++]
    }

    $obj
}

```

Using an `OrderedDictionary`, the code can be translated to:

PowerShell

```

$data = $json | ConvertFrom-Json
$columns = $data.tables.columns
$result = foreach ($row in $data.tables.rows) {
    $obj = [ordered]@{}
    $index = 0

    foreach ($column in $columns) {
        $obj[$column.name] = $row[$index++]
    }
}

```

```
[pscustomobject] $obj  
}
```

In both cases the `$result` output would be same:

Output

Type	TenantId	count_
Usage	63613592-b6f7-4c3d-a390-22ba13102111	1
Usage	d436f322-a9f4-4aad-9a7d-271fbf66001c	1
BillingFact	63613592-b6f7-4c3d-a390-22ba13102111	1
BillingFact	d436f322-a9f4-4aad-9a7d-271fbf66001c	1
Operation	63613592-b6f7-4c3d-a390-22ba13102111	7
Operation	d436f322-a9f4-4aad-9a7d-271fbf66001c	5

The latter approach becomes exponentially more efficient as the number of objects and member properties increases.

Here is a performance comparison of three techniques for creating objects with 5 properties:

PowerShell

```
$tests = @{  
    '[ordered] into [pscustomobject] cast' = {  
        param([int] $Iterations, [string[]] $Props)  
  
        foreach ($i in 1..$Iterations) {  
            $obj = [ordered]@{}  
            foreach ($prop in $Props) {  
                $obj[$prop] = $i  
            }  
            [pscustomobject] $obj  
        }  
    }  
    'Add-Member' = {  
        param([int] $Iterations, [string[]] $Props)  
  
        foreach ($i in 1..$Iterations) {  
            $obj = [psobject]::new()  
            foreach ($prop in $Props) {  
                $obj | Add-Member -MemberType NoteProperty -Name $prop -Value $i  
            }  
            $obj  
        }  
    }  
    'PSObject.Properties.Add' = {  
        param([int] $Iterations, [string[]] $Props)  
  
        # this is how, behind the scenes, `Add-Member` attaches  
        # new properties to our PSObject.  
    }  
}
```

```

# Worth having it here for performance comparison

foreach ($i in 1..$Iterations) {
    $obj = [psobject]::new()
    foreach ($prop in $Props) {
        $obj.psobject.Properties.Add(
            [psnoteproperty]::new($prop, $i))
    }
    $obj
}

$properties = 'Prop1', 'Prop2', 'Prop3', 'Prop4', 'Prop5'

1kb, 10kb, 100kb | ForEach-Object {
    $groupResult = foreach ($test in $tests.GetEnumerator()) {
        $ms = Measure-Command { & $test.Value -Iterations $_ -Props $properties }

        [pscustomobject]@{
            Iterations      = $_
            Test           = $test.Key
            TotalMilliseconds = [Math]::Round($ms.TotalMilliseconds, 2)
        }

        [GC]::Collect()
        [GC]::WaitForPendingFinalizers()
    }

    $groupResult = $groupResult | Sort-Object TotalMilliseconds
    $groupResult | Select-Object *, @{
        Name      = 'RelativeSpeed'
        Expression = {
            $relativeSpeed = $_.TotalMilliseconds /
                $groupResult[0].TotalMilliseconds
            [Math]::Round($relativeSpeed, 2).ToString() + 'x'
        }
    }
}

```

And these are the results:

Output

Iterations	Test	TotalMilliseconds	RelativeSpeed
1024	[ordered] into [pscustomobject] cast	22.00	1x
1024	PSObject.Properties.Add	153.17	6.96x
1024	Add-Member	261.96	11.91x
10240	[ordered] into [pscustomobject] cast	65.24	1x
10240	PSObject.Properties.Add	1293.07	19.82x
10240	Add-Member	2203.03	33.77x
102400	[ordered] into [pscustomobject] cast	639.83	1x

102400 PSObject.Properties.Add
102400 Add-Member

13914.67 21.75x
23496.08 36.72x

PowerShell module authoring considerations

Article • 11/17/2022

This document includes some guidelines related to how a module is authored for best performance.

Module Manifest Authoring

A module manifest that doesn't use the following guidelines can have a noticeable impact on general PowerShell performance even if the module isn't used in a session.

Command auto-discovery analyzes each module to determine which commands the module exports and this analysis can be expensive. The results of module analysis are cached per user, but the cache isn't available on first run, which is a typical scenario with containers. During module analysis, if the exported commands can be fully determined from the manifest, more expensive analysis of the module can be avoided.

Guidelines

- In the module manifest, don't use wildcards in the `AliasesToExport`, `CmdletsToExport`, and `FunctionsToExport` entries.
- If the module doesn't export commands of a particular type, specify this explicitly in the manifest by specifying `@()`. A missing or `$null` entry is equivalent to specifying the wildcard `*`.

The following should be avoided where possible:

```
PowerShell

@{
    FunctionsToExport = '*'

    # Also avoid omitting an entry, it's equivalent to using a wildcard
    # CmdletsToExport = '*'
    # AliasesToExport = '*'
}
```

Instead, use:

PowerShell

```
@{
    FunctionsToExport = 'Format-Hex', 'Format-Octal'
    CmdletsToExport = @() # Specify an empty array, not $null
    AliasesToExport = @() # Also ensure all three entries are present
}
```

Avoid CDXML

When deciding how to implement your module, there are three primary choices:

- Binary (usually C#)
- Script (PowerShell)
- CDXML (an XML file wrapping CIM)

If the speed of loading your module is important, CDXML is roughly an order of magnitude slower than a binary module.

A binary module loads the fastest because it's compiled ahead of time and can use NGen to JIT compile once per machine.

A script module typically loads a bit more slowly than a binary module because PowerShell must parse the script before compiling and executing it.

A CDXML module is typically much slower than a script module because it must first parse an XML file which then generates quite a bit of PowerShell script that's then parsed and compiled.

Optimize performance using parallel execution

Article • 05/19/2025

PowerShell provides several options for the creation of parallel invocations.

- `Start-Job` runs each job in a separate process, each with a new instance of PowerShell. In many cases, a linear loop is faster. Also, serialization and deserialization can limit the usefulness of the objects returned. This command is built in to all versions of PowerShell.
- `Start-ThreadJob` is a cmdlet found in the **ThreadJob** module. This command uses PowerShell runspaces to create and manage thread-based jobs. These jobs are lighter-weight than the jobs created by `Start-Job` and avoid potential loss of type fidelity required by cross-process serialization and deserialization. The **ThreadJob** module comes with PowerShell 7 and higher. For Windows PowerShell 5.1, you can install this module from the PowerShell Gallery.
- Use the **System.Management.Automation.Runspaces** namespace from the PowerShell SDK to create your own parallel logic. Both `ForEach-Object -Parallel` and `Start-ThreadJob` use PowerShell runspaces to execute the code in parallel.
- Workflows are a feature of Windows PowerShell 5.1. Workflows aren't available in PowerShell 7.0 and higher. Workflows are a special type of PowerShell script that can run in parallel. They're designed for long-running tasks and can be paused and resumed. Workflows aren't recommended for new development. For more information, see [about_Workflows](#).
- `ForEach-Object -Parallel` is a feature of PowerShell 7.0 and higher. Like `Start-ThreadJob`, it uses PowerShell runspaces to create and manage thread-based jobs. This command is designed for use in a pipeline.

Limit execution concurrency

Running scripts in parallel doesn't guarantee improved performance. For example, the following scenarios can benefit from parallel execution:

- Compute intensive scripts on multi-threaded multi-core processors
- Scripts that spend time waiting for results or doing file operations, as long as those operations don't block each other.

It's important to balance the overhead of parallel execution with the type of work done. Also, there are limits to the number of invocations that can run in parallel.

The `Start-ThreadJob` and `ForEach-Object -Parallel` commands have a `ThrottleLimit` parameter to limit the number of jobs running at one time. As more jobs are started, they're queued and wait until the current number of jobs drops below the throttle limit. As of PowerShell 7.1, `ForEach-Object -Parallel` reuses runspaces from a runspace pool by default. The `ThrottleLimit` parameter sets the runspace pool size. The default runspace pool size is 5. You can still create a new runspace for each iteration using the `UseNewRunspace` switch.

The `Start-Job` command doesn't have a `ThrottleLimit` parameter. You have to manage the number of jobs running at one time.

Measure performance

The following function, `Measure-Parallel`, compares the speed of the following parallel execution approaches:

- `Start-Job` - creates a child PowerShell process behind the scenes
- `Start-ThreadJob` - runs each job in a separate thread
- `ForEach-Object -Parallel` - runs each job in a separate thread
- `Start-Process` - invokes an external program asynchronously

ⓘ Note

This approach only makes sense if your parallel tasks only consist of a single call to an external program, as opposed to running a block of PowerShell code. Also, the only way to capture output with this approach is by redirecting to a file.

PowerShell

```
function Measure-Parallel {
    [CmdletBinding()]
    param(
        [ValidateRange(2, 2147483647)]
        [int] $BatchSize = 5,
        [ValidateSet('Job', 'ThreadJob', 'Process', 'ForEachParallel', 'All')]
        [string[]] $Approach,
        # pass a higher count to run multiple batches
        [ValidateRange(2, 2147483647)]
        [int] $JobCount = $BatchSize
    )
```

```

$noForEachParallel = $PSVersionTable.PSVersion.Major -lt 7
$noStartThreadJob = -not (Get-Command -ErrorAction Ignore Start-ThreadJob)

# Translate the approach arguments into their corresponding hashtable keys
# (see below).
if ('All' -eq $Approach) { $Approach = 'Job', 'ThreadJob', 'Process',
'ForEachParallel' }
$approaches = $Approach.ForEach({
    if ($_. -eq 'ForEachParallel') { 'ForEach-Object -Parallel' }
    else { $_ -replace '^', 'Start-' }
})

if ($noStartThreadJob) {
    if ($interactive -or $approaches -contains 'Start-ThreadJob') {
        Write-Warning "Start-ThreadJob is not installed, omitting its test."
        $approaches = $approaches.Where({ $_ -ne 'Start-ThreadJob' })
    }
}
if ($noForEachParallel) {
    if ($interactive -or $approaches -contains 'ForEach-Object -Parallel') {
        Write-Warning 'ForEach-Object -Parallel require PowerShell v7+, omitting its test.'
        $approaches = $approaches.Where({ $_ -ne 'ForEach-Object -Parallel' })
    }
}

# Simulated input: Create 'f0.zip', 'f1.zip', ... file names.
$zipFiles = 0..($JobCount - 1) -replace '^', 'f' -replace '$', '.zip'

# Sample executables to run - here, the native shell is called to simply
# echo the argument given.
$exe = if ($env:OS -eq 'Windows_NT') { 'cmd.exe' } else { 'sh' }

# The list of its arguments *as a single string* - use '{0}' as the
placeholder
# for where the input object should go.
$exeArgList = if ($env:OS -eq 'Windows_NT') {
    '/c "echo {0} > NUL"'
} else {
    '-c "echo {0} > /dev/null"'
}

# A hashtable with script blocks that implement the 3 approaches to
parallelism.
$approachImpl = [ordered] @{

    # child-process-based job
    $approachImpl['Start-Job'] = {
        param([array] $batch)
        $batch |
            ForEach-Object {
                Start-Job {
                    Invoke-Expression ($using:exe + ' ' + ($using:exeArgList -f
$args[0]))
                } -ArgumentList $_
            }
    }
}

```

```

    } |
    Receive-Job -Wait -AutoRemoveJob | Out-Null
}

# thread-based job - requires the ThreadJob module
if (-not $noStartThreadJob) {
    # If Start-ThreadJob is available, add an approach for it.
    $approachImpl['Start-ThreadJob'] = {
        param([array] $batch)
        $batch |
        ForEach-Object {
            Start-ThreadJob -ThrottleLimit $BatchSize {
                Invoke-Expression ($using:exe + ' ' + ($using:exeArgList -
f $args[0]))
            } -ArgumentList $_
        } |
        Receive-Job -Wait -AutoRemoveJob | Out-Null
    }
}

# ForEach-Object -Parallel job
if (-not $noForEachParallel) {
    $approachImpl['ForEach-Object -Parallel'] = {
        param([array] $batch)
        $batch | ForEach-Object -ThrottleLimit $BatchSize -Parallel {
            Invoke-Expression ($using:exe + ' ' + ($using:exeArgList -f $_))
        }
    }
}

# direct execution of an external program
$approachImpl['Start-Process'] = {
    param([array] $batch)
    $batch |
    ForEach-Object {
        Start-Process -NoNewWindow -PassThru $exe -ArgumentList
($exeArgList -f $_)
    } |
    Wait-Process
}

# Partition the array of all indices into subarrays (batches)
$batches = @(
    0..([math]::Ceiling($zipFiles.Count / $batchSize) - 1) | ForEach-Object {
        , $zipFiles[( $_ * $batchSize)..($_ * $batchSize + $batchSize - 1)]
    }
)

$tsTotals = foreach ($appr in $approaches) {
    $i = 0
    $tsTotal = [timespan] 0
    $batches | ForEach-Object {
        Write-Verbose "$batchSize-element '$appr' batch"
        $ts = Measure-Command { & $approachImpl[$appr] $_ | Out-Null }
        $tsTotal += $ts
    }
}

```

```

        if (++$i -eq $batches.Count) {
            # last batch processed.
            if ($batches.Count -gt 1) {
                Write-Verbose ("'$app' processing $JobCount items finished in
" +
                            "$($tsTotal.TotalSeconds.ToString('N2')) secs.")
            }
            $tsTotal # output the overall timing for this approach
        }
    }

# Output a result object with the overall timings.
$oht = [ordered] @{}
$oht['JobCount'] = $JobCount
$oht['BatchSize'] = $BatchSize
$oht['BatchCount'] = $batches.Count
$i = 0
foreach ($app in $approaches) {
    $oht[($app + ' (secs.)')] = $tsTotals[$i++].ToString('N2')
}
[pscustomobject] $oht
}

```

The following example uses `Measure-Parallel` to run 20 jobs in parallel, 5 at a time, using all available approaches.

PowerShell

```
Measure-Parallel -Approach All -BatchSize 5 -JobCount 20 -Verbose
```

The following output comes from a Windows computer running PowerShell 7.5.1. Your timing can vary based on many factors, but the ratios should provide a sense of relative performance.

Output

```

VERBOSE: 5-element 'Start-Job' batch
VERBOSE: 5-element 'Start-Job' batch
VERBOSE: 5-element 'Start-Job' batch
VERBOSE: 5-element 'Start-Job' batch
VERBOSE: 'Start-Job' processing 20 items finished in 7.58 secs.
VERBOSE: 5-element 'Start-ThreadJob' batch
VERBOSE: 5-element 'Start-ThreadJob' batch
VERBOSE: 5-element 'Start-ThreadJob' batch
VERBOSE: 5-element 'Start-ThreadJob' batch
VERBOSE: 'Start-ThreadJob' processing 20 items finished in 2.37 secs.
VERBOSE: 5-element 'Start-Process' batch
VERBOSE: 5-element 'Start-Process' batch
VERBOSE: 5-element 'Start-Process' batch
VERBOSE: 5-element 'Start-Process' batch
VERBOSE: 'Start-Process' processing 20 items finished in 0.26 secs.

```

```
VERBOSE: 5-element 'ForEach-Object -Parallel' batch
VERBOSE: 'ForEach-Object -Parallel' processing 20 items finished in 0.79 secs.
```

```
JobCount : 20
BatchSize : 5
BatchCount : 4
Start-Job (secs.) : 7.58
Start-ThreadJob (secs.) : 2.37
Start-Process (secs.) : 0.26
ForEach-Object -Parallel (secs.) : 0.79
```

Conclusions

- The `Start-Process` approach performs best because it doesn't have the overhead of job management. However, as previously noted, this approach has fundamental limitations.
- The `ForEach-Object -Parallel` adds the least overhead, followed by `Start-ThreadJob`.
- `Start-Job` has the most overhead because of the hidden PowerShell instances it creates for each job.

Portable Modules

Article • 06/29/2023

Windows PowerShell is written for [.NET Framework](#) while PowerShell Core is written for [.NET Core](#). Portable modules are modules that work in both Windows PowerShell and PowerShell Core. While .NET Framework and .NET Core are highly compatible, there are differences in the available APIs between the two. There are also differences in the APIs available in Windows PowerShell and PowerShell Core. Modules intended to be used in both environments need to be aware of these differences.

Porting an existing module

Porting a PSSnapIn

PowerShell [SnapIns](#) aren't supported in PowerShell Core. However, it's trivial to convert a PSSnapIn to a PowerShell module. Typically, the PSSnapIn registration code is in a single source file of a class that derives from [PSSnapIn](#). Remove this source file from the build; it's no longer needed.

Use [New-ModuleManifest](#) to create a new module manifest that replaces the need for the PSSnapIn registration code. Some values from the [PSSnapIn](#) (such as [Description](#)) can be reused within the module manifest.

The [RootModule](#) property in the module manifest should be set to the name of the assembly (`.dll`) implementing the cmdlets.

The .NET Portability Analyzer (aka APIPort)

To port modules written for Windows PowerShell to work with PowerShell Core, start with the [.NET Portability Analyzer](#). Run this tool against your compiled assembly to determine if the .NET APIs used in the module are compatible with .NET Framework, .NET Core, and other .NET runtimes. The tool suggests alternate APIs if they exist. Otherwise, you may need to add [runtime checks](#) and restrict capabilities not available in specific runtimes.

Creating a new module

If creating a new module, the recommendation is to use the [.NET CLI](#).

Installing the PowerShell Standard module template

Once the .NET CLI is installed, install a template library to generate a simple PowerShell module. The module will be compatible with Windows PowerShell, PowerShell Core, Windows, Linux, and macOS.

The following example shows how to install the template:

PowerShell

```
dotnet new install Microsoft.PowerShell.Standard.Module.Template
```

Output

```
The following template packages will be installed:  
  Microsoft.PowerShell.Standard.Module.Template
```

```
Success: Microsoft.PowerShell.Standard.Module.Template::0.1.3 installed the  
following templates:
```

Template Name	Short Name	Language	Tags
PowerShell Standard Module	psmodule	[C#]	Library/PowerShell/Module

Creating a new module project

After the template is installed, you can create a new PowerShell module project using that template. In this example, the sample module is called 'myModule'.

```
PS> mkdir myModule
```

```
Directory: C:\Users\Steve
```

Mode	LastWriteTime	Length	Name
d----	8/3/2018 2:41 PM		myModule

```
PS> cd myModule
```

```
PS C:\Users\Steve\myModule> dotnet new psmodule
```

```
The template "PowerShell Standard Module" was created successfully.
```

```
Processing post-creation actions...
```

```
Restoring C:\Users\Steve\myModule\myModule.csproj:
```

```
  Determining projects to restore...
```

```
  Restored C:\Users\Steve\myModule\myModule.csproj (in 184 ms).
```

```
Restore succeeded.
```

Building the module

Use standard .NET CLI commands to build the project.

PowerShell

```
dotnet build
```

Output

```
PS C:\Users\Steve\myModule> dotnet build
MSBuild version 17.6.3+07e294721 for .NET
  Determining projects to restore...
  All projects are up-to-date for restore.
  PowerShellPG ->
C:\Users\Steve\myModule\bin\Debug\netstandard2.0\myModule.dll

Build succeeded.
  0 Warning(s)
  0 Error(s)

Time Elapsed 00:00:02.36
```

Testing the module

After building the module, you can import it and execute the sample cmdlet.

PowerShell

```
Import-Module .\bin\Debug\netstandard2.0\myModule.dll
Test-SampleCmdlet -?
Test-SampleCmdlet -FavoriteNumber 7 -FavoritePet Cat
```

Output

NAME

Test-SampleCmdlet

SYNTAX

```
Test-SampleCmdlet [-FavoriteNumber] <int> [[-FavoritePet] {Cat | Dog | Horse}] [<CommonParameters>]
```

ALIASES

None

REMARKS

None

```
FavoriteNumber FavoritePet
-----
7 Cat
```

Debugging the module

For a guide on setting up Visual Studio Code to debug the module, see [Using Visual Studio Code for debugging compiled cmdlets](#).

Supporting technologies

The following sections describe in detail some of the technologies used by this template.

.NET Standard Library

[.NET Standard](#) is a formal specification of .NET APIs that are available in all .NET implementations. Managed code targeting .NET Standard works with the .NET Framework and .NET Core versions that are compatible with that version of the .NET Standard.

Note

Although an API may exist in .NET Standard, the API implementation in .NET Core may throw a `PlatformNotSupportedException` at runtime, so to verify compatibility with Windows PowerShell and PowerShell Core, the best practice is to run tests for your module within both environments. Also run tests on Linux and macOS if your module is intended to be cross-platform.

Targeting .NET Standard helps ensure that, as the module evolves, incompatible APIs don't accidentally get introduced into the module. Incompatibilities are discovered at compile time instead of runtime.

However, it isn't required to target .NET Standard for a module to work with both Windows PowerShell and PowerShell Core, as long as you use compatible APIs. The Intermediate Language (IL) is compatible between the two runtimes. You can target .NET Framework 4.6.1, which is compatible with .NET Standard 2.0. If you don't use APIs

outside of .NET Standard 2.0, then your module works with PowerShell Core 6 without recompilation.

PowerShell Standard Library

The [PowerShell Standard](#) library is a formal specification of PowerShell APIs available in all PowerShell versions greater than or equal to the version of that standard.

For example, [PowerShell Standard 5.1](#) is compatible with both Windows PowerShell 5.1 and PowerShell Core 6.0 or newer.

We recommend you compile your module using PowerShell Standard Library. The library ensures the APIs are available and implemented in both Windows PowerShell and PowerShell Core 6. PowerShell Standard is intended to always be forwards-compatible. A module built using PowerShell Standard Library 5.1 will always be compatible with future versions of PowerShell.

Module Manifest

Indicating Compatibility With Windows PowerShell and PowerShell Core

After validating that your module works with both Windows PowerShell and PowerShell Core, the module manifest should explicitly indicate compatibility by using the [CompatiblePSEditions](#) property. A value of `Desktop` means that the module is compatible with Windows PowerShell, while a value of `Core` means that the module is compatible with PowerShell Core. Including both `Desktop` and `Core` means that the module is compatible with both Windows PowerShell and PowerShell Core.

ⓘ Note

`Core` doesn't automatically mean that the module is compatible with Windows, Linux, and macOS. The [CompatiblePSEditions](#) property was introduced in PowerShell v5. Module manifests that use the [CompatiblePSEditions](#) property fail to load in versions prior to PowerShell v5.

Indicating OS Compatibility

First, validate that your module works on Linux and macOS. Next, indicate compatibility with those operating systems in the module manifest. This makes it easier for users to

find your module for their operating system when published to the [PowerShell Gallery](#).

Within the module manifest, the `PrivateData` property has a `PSData` sub-property. The optional `Tags` property of `PSData` takes an array of values that show up in PowerShell Gallery. The PowerShell Gallery supports the following compatibility values:

    }
}
}

```

Dependency on Native Libraries

Modules intended for use across different operating systems or processor architectures may depend on a managed library that itself depends on some native libraries.

Prior to PowerShell 7, one would have to have custom code to load the appropriate native dll so that the managed library can find it correctly.

With PowerShell 7, native binaries to load are searched in sub-folders within the managed library's location following a subset of the [.NET RID Catalog](#) notation.

```

managed.dll folder
|
|--- 'win-x64' folder
|     |--- native.dll
|
|--- 'win-x86' folder
|     |--- native.dll
|
|--- 'win-arm' folder
|     |--- native.dll
|
|--- 'win-arm64' folder
|     |--- native.dll
|

```

```
|--- 'linux-x64' folder
|     |--- native.so

|--- 'linux-x86' folder
|     |--- native.so

|--- 'linux-arm' folder
|     |--- native.so

|--- 'linux-arm64' folder
|     |--- native.so

|--- 'osx-x64' folder
|     |--- native.dylib
```

How to create a Standard Library binary module

Article • 02/02/2023

I recently had an idea for module that I wanted to implement as a binary module. I have yet to create one using the [PowerShell Standard Library](#) so this felt like a good opportunity. I used the [Creating a cross-platform binary module](#) guide to create this module without any roadblocks. We're going to walk that same process and I'll add a little extra commentary along the way.

ⓘ Note

The [original version](#) of this article appeared on the blog written by [@KevinMarquette](#). The PowerShell team thanks Kevin for sharing this content with us. Please check out his blog at [PowerShellExplained.com](#).

What's the PowerShell Standard Library?

The PowerShell Standard Library allows us to create cross platform modules that work in both PowerShell and Windows PowerShell 5.1.

Why binary modules?

When you are writing a module in C# you give up easy access to PowerShell cmdlets and functions. But if you are creating a module that doesn't depend on a lot of other PowerShell commands, the performance benefit can be significant. PowerShell was optimized for the administrator, not the computer. By switching to C#, you get to shed the overhead added by PowerShell.

For example, we have a critical process that does a lot of work with JSON and hashtables. We optimized the PowerShell as much as we could but the process still takes 12 minutes to complete. The module already contained a lot of C# style PowerShell. This makes conversion to a binary module clean and simple. By converting to a binary module, we reduced the process time from over 12 minutes to under four minutes.

Hybrid modules

You can mix binary cmdlets with PowerShell advanced functions. Everything you know about script modules applies the same way. The empty `psm1` file is included so you can add other PowerShell functions later.

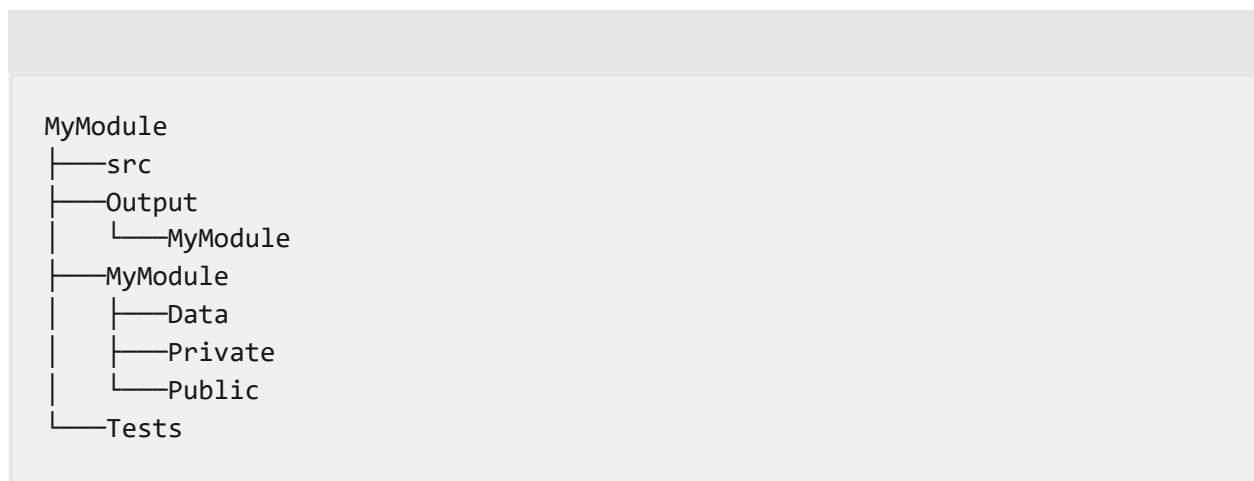

Almost all of the compiled cmdlets that I have created started out as PowerShell functions first. All of our binary modules are really hybrid modules.

Build scripts

I kept the build script simple here. I generally use a large `Invoke-Build` script as part of my CI/CD pipeline. It does more magic like running Pester tests, running `PSScriptAnalyzer`, managing versioning, and publishing to the PSGallery. Once I started using a build script for my modules, I was able to find lots of things to add to it.

Planning the module

The plan for this module is to create a `src` folder for the C# code and structure the rest like I would for a script module. This includes using a build script to compile everything into an `Output` folder. The folder structure looks like this:

Getting Started

First I need to create the folder and create the git repo. I'm using `$module` as a placeholder for the module name. This should make it easier for you to reuse these examples if needed.

```
PowerShell

$module = 'MyModule'
New-Item -Path $module -Type Directory
```

```
Set-Location $module  
git init
```

Then create the root level folders.

PowerShell

```
New-Item -Path 'src' -Type Directory  
New-Item -Path 'Output' -Type Directory  
New-Item -Path 'Tests' -Type Directory  
New-Item -Path $module -Type Directory
```

Binary module setup

This article is focused on the binary module so that's where we'll start. This section pulls examples from the [Creating a cross-platform binary module](#) guide. Review that guide if you need more details or have any issues.

First thing we want to do is check the version of the [dotnet core SDK](#) that we have installed. I'm using 2.1.4, but you should have 2.0.0 or newer before continuing.

PowerShell

```
PS> dotnet --version  
2.1.4
```

I'm working out of the `src` folder for this section.

PowerShell

```
Set-Location 'src'
```

Using the dotnet command, create a new class library.

PowerShell

```
dotnet new classlib --name $module
```

This created the library project in a subfolder but I don't want that extra level of nesting. I'm going to move those files up a level.

PowerShell

```
Move-Item -Path .\$module\* -Destination .\  
Remove-Item $module -Recurse
```

Set the .NET core SDK version for the project. I have the 2.1 SDK so I'm going to specify `2.1.0`. Use `2.0.0` if you're using the 2.0 SDK.

PowerShell

```
dotnet new globaljson --sdk-version 2.1.0
```

Add the **PowerShell Standard Library** [NuGet package](#) to the project. Make sure you use the most recent version available for the level of compatibility that you need. I would default to the latest version but I don't think this module leverages any features newer than PowerShell 3.0.

PowerShell

```
dotnet add package PowerShellStandard.Library --version 7.0.0-preview.1
```

We should have a src folder that looks like this:

PowerShell

```
PS> Get-ChildItem  
Directory: \MyModule\src  

| Mode  | LastWriteTime      | Length | Name            |
|-------|--------------------|--------|-----------------|
| -     | -----              | -----  | -----           |
| d---- | 7/14/2018 9:51 PM  |        | obj             |
| -a--- | 7/14/2018 9:51 PM  | 86     | Class1.cs       |
| -a--- | 7/14/2018 10:03 PM | 259    | MyModule.csproj |
| -a--- | 7/14/2018 10:05 PM | 45     | global.json     |

```

Now we're ready to add our own code to the project.

Building a binary cmdlet

We need to update the `src\Class1.cs` to contain this starter cmdlet:

C#

```
using System;  
using System.Management.Automation;  
  
namespace MyModule
```

```
{
    [Cmdlet( VerbsDiagnostic.Resolve , "MyCmdlet")]
    public class ResolveMyCmdletCommand : PSCmdlet
    {
        [Parameter(Position=0)]
        public Object InputObject { get; set; }

        protected override void EndProcessing()
        {
            this.WriteObject(this.InputObject);
            base.EndProcessing();
        }
    }
}
```

Rename the file to match the class name.

PowerShell

```
Rename-Item .\Class1.cs .\ResolveMyCmdletCommand.cs
```

Then we can build our module.

PowerShell

```
PS> dotnet build

Microsoft (R) Build Engine version 15.5.180.51428 for .NET Core
Copyright (C) Microsoft Corporation. All rights reserved.

Restore completed in 18.19 ms for C:\workspace\MyModule\src\MyModule.csproj.
MyModule -> C:\workspace\MyModule\src\bin\Debug\netstandard2.0\MyModule.dll

Build succeeded.
  0 Warning(s)
  0 Error(s)

Time Elapsed 00:00:02.19
```

We can call `Import-Module` on the new dll to load our new cmdlet.

PowerShell

```
PS> Import-Module .\bin\Debug\netstandard2.0\$module.dll
PS> Get-Command -Module $module

 CommandType Name                Version Source
 ----- ----
 Cmdlet      Resolve-MyCmdlet   1.0.0.0 MyModule
```

If the import fails on your system, try updating .NET to 4.7.1 or newer. The [Creating a cross-platform binary module](#) guide goes into more details on .NET support and compatibility for older versions of .NET.

Module manifest

It's cool that we can import the dll and have a working module. I like to keep going with it and create a module manifest. We need the manifest if we want to publish to the PSGallery later.

From the root of our project, we can run this command to create the module manifest that we need.

```
PowerShell

$manifestSplat = @{
    Path          = ".\${module}\${module}.psd1"
    Author        = 'Kevin Marquette'
    NestedModules = @('bin\MyModule.dll')
    RootModule     = "\${module}.psm1"
    FunctionsToExport = @('Resolve-MyCmdlet')
}
New-ModuleManifest @manifestSplat
```

I'm also going to create an empty root module for future PowerShell functions.

```
PowerShell

Set-Content -Value '' -Path ".\${module}\${module}.psm1"
```

This allows me to mix both normal PowerShell functions and binary cmdlets in the same project.

Building the full module

I compile everything together into an output folder. We need to create a build script to do that. I would normally add this to an `Invoke-Build` script, but we can keep it simple for this example. Add this to a `build.ps1` at the root of the project.

```
PowerShell

$module = 'MyModule'
Push-Location $PSScriptRoot

dotnet build $PSScriptRoot\src -o $PSScriptRoot\output\$module\bin
```

```
Copy-Item "$PSScriptRoot\$module\*" "$PSScriptRoot\output\$module" -Recurse  
-Force  
  
Import-Module "$PSScriptRoot\Output\$module\$module.psd1"  
Invoke-Pester "$PSScriptRoot\Tests"
```

These commands build our DLL and place it into our `output\$module\bin` folder. It then copies the other module files into place.

```
Output  
└── MyModule  
    ├── MyModule.psd1  
    ├── MyModule.psm1  
    └── bin  
        ├── MyModule.deps.json  
        ├── MyModule.dll  
        └── MyModule.pdb
```

At this point, we can import our module with the `psd1` file.

```
PowerShell  
  
Import-Module ".\Output\$module\$module.psd1"
```

From here, we can drop the `.\Output\$module` folder into our `$Env:PSModulePath` directory and it autoloads our command whenever we need it.

Update: dotnet new PSModule

I learned that the `dotnet` tool has a `PSModule` template.

All the steps that I outlined above are still valid, but this template cuts many of them out. It's still a fairly new template that's still getting some polish placed on it. Expect it to keep getting better from here.

This is how you use install and use the `PSModule` template.

```
PowerShell  
  
dotnet new -i Microsoft.PowerShell.Standard.Module.Template  
dotnet new psmodule  
dotnet build  
Import-Module "bin\Debug\netstandard2.0\$module.dll"  
Get-Module $module
```

This minimally-viable template takes care of adding the .NET SDK, PowerShell Standard Library, and creates an example class in the project. You can build it and run it right away.

Important details

Before we end this article, here are a few other details worth mentioning.

Unloading DLLs

Once a binary module is loaded, you can't really unload it. The DLL file is locked until you unload it. This can be annoying when developing because every time you make a change and want to build it, the file is often locked. The only reliable way to resolve this is to close the PowerShell session that loaded the DLL.

VS Code reload window action

I do most of my PowerShell dev work in [VS Code](#). When I'm working on a binary module (or a module with classes), I've gotten into the habit of reloading VS Code every time I build. `Ctrl + Shift + P` pops the command window and `Reload Window` is always at the top of my list.

Nested PowerShell sessions

One other option is to have good Pester test coverage. Then you can adjust the `build.ps1` script to start a new PowerShell session, perform the build, run the tests, and close the session.

Updating installed modules

This locking can be annoying when trying to update your locally installed module. If any session has it loaded, you have to go hunt it down and close it. This is less of an issue when installing from a PSGallery because module versioning places the new one in a different folder.

You can set up a local PSGallery and publish to that as part of your build. Then do your local install from that PSGallery. This sounds like a lot of work, but this can be as simple as starting a docker container. I cover a way to do that in my post on [Using a NuGet server for a PSRepository](#).

Final thoughts

I didn't touch on the C# syntax for creating a cmdlet, but there is plenty of documentation on it in the [Windows PowerShell SDK](#). It's definitely something worth experimenting with as a stepping stone into more serious C#.

Choosing the right PowerShell NuGet package for your .NET project

Article • 11/17/2022

Alongside the `pwsh` executable packages published with each PowerShell release, the PowerShell team also maintains several packages available on [NuGet](#). These packages allow targeting PowerShell as an API platform in .NET.

As a .NET application that provides APIs and expects to load .NET libraries implementing its own (binary modules), it's essential that PowerShell be available in the form of a NuGet package.

Currently there are several NuGet packages that provide some representation of the PowerShell API surface area. Which package to use with a particular project hasn't always been made clear. This article sheds some light on a few common scenarios for PowerShell-targeting .NET projects and how to choose the right NuGet package to target for your PowerShell-oriented .NET project.

Hosting vs referencing

Some .NET projects seek to write code to be loaded into a pre-existing PowerShell runtime (such as `pwsh`, `powershell.exe`, the PowerShell Integrated Console or the ISE), while others want to run PowerShell in their own applications.

- **Referencing** is for when a project, usually a module, is intended to be loaded into PowerShell. It must be compiled against the APIs that PowerShell provides in order to interact with it, but the PowerShell implementation is supplied by the PowerShell process loading it in. For referencing, a project can use [reference assemblies](#) or the actual runtime assemblies as a compilation target, but must ensure that it does not publish any of these with its build.
- **Hosting** is when a project needs its own implementation of PowerShell, usually because it is a standalone application that needs to run PowerShell. In this case, pure reference assemblies cannot be used. Instead, a concrete PowerShell implementation must be depended upon. Because a concrete PowerShell implementation must be used, a specific version of PowerShell must be chosen for hosting; a single host application cannot multi-target PowerShell versions.

Publishing projects that target PowerShell as a reference

ⓘ Note

We use the term **publish** in this article to refer to running `dotnet publish`, which places a .NET library into a directory with all of its dependencies, ready for deployment to a particular runtime.

In order to prevent publishing project dependencies that are just being used as compilation reference targets, it is recommended to set the `PrivateAssets` attribute:

XML

```
<PackageReference Include="PowerShellStandard.Library" Version="5.1.0.0"
  PrivateAssets="all" />
```

If you forget to do this and use a reference assembly as your target, you may see issues related to using the reference assembly's default implementation instead of the actual implementation. This may take the form of a `NullReferenceException`, since reference assemblies often mock the implementation API by simply returning `null`.

Key kinds of PowerShell-targeting .NET projects

While any .NET library or application can embed PowerShell, there are some common scenarios that use PowerShell APIs:

- **Implementing a PowerShell binary module**

PowerShell binary modules are .NET libraries loaded by PowerShell that must implement PowerShell APIs like the `PSCmdlet` or `CmdletProvider` types in order to expose cmdlets or providers respectively. Because they are loaded in, modules seek to compile against references to PowerShell without publishing it in their build. It's also common for modules to want to support multiple PowerShell versions and platforms, ideally with a minimum of overhead of disk space, complexity, or repeated implementation. See [about_Modules](#) for more information about modules.

- **Implementing a PowerShell Host**

A PowerShell Host provides an interaction layer for the PowerShell runtime. It is a specific form of *hosting*, where a `PSHost` is implemented as a new user interface to PowerShell. For example, the PowerShell ConsoleHost provides a terminal user interface for PowerShell executables, while the PowerShell Editor Services Host and the ISE Host both provide an editor-integrated partially graphical user interface

around PowerShell. While it's possible to load a host onto an existing PowerShell process, it's much more common for a host implementation to act as a standalone PowerShell implementation that redistributes the PowerShell engine.

- **Calling into PowerShell from another .NET application**

As with any application, PowerShell can be called as a subprocess to run workloads. However, as a .NET application, it's also possible to invoke PowerShell in-process to get back full .NET objects for use within the calling application. This is a more general form of *hosting*, where the application holds its own PowerShell implementation for internal use. Examples of this might be a service or daemon running PowerShell to manage machine state or a web application that runs PowerShell on request to do something like manage cloud deployments.

- **Unit testing PowerShell modules from .NET**

While modules and other libraries designed to expose functionality to PowerShell should be primarily tested from PowerShell (we recommend [Pester](#)), sometimes it's necessary to unit test APIs written for a PowerShell module from .NET. This situation involves the module code trying to target a number of PowerShell versions, while testing should run it on specific, concrete implementations.

PowerShell NuGet packages at a glance

In this article, we'll cover the following NuGet packages that expose PowerShell APIs:

- [PowerShellStandard.Library](#), a reference assembly that enables building a single assembly that can be loaded by multiple PowerShell runtimes.
- [Microsoft.PowerShell.SDK](#), the way to target and rehost the whole PowerShell SDK
- The [System.Management.Automation](#) package, the core PowerShell runtime and engine implementation, that can be useful in minimal hosted implementations and for version-specific targeting scenarios.
- The [Windows PowerShell reference assemblies](#), the way to target and effectively rehost Windows PowerShell (PowerShell versions 5.1 and below).

 **Note**

The [PowerShell NuGet](#) package is not a .NET library package at all, but instead provides the PowerShell dotnet global tool implementation. This should not be used by any projects, since it only provides an executable.

PowerShellStandard.Library

The PowerShell Standard library is a reference assembly that captures the intersection of the APIs of PowerShell versions 7, 6 and 5.1. This provides a compile-time-checked API surface to compile .NET code against, allowing .NET projects to target PowerShell versions 7, 6 and 5.1 without risking calling an API that won't be there.

PowerShell Standard is intended for writing PowerShell modules, or other code only intended to be run after loading it into a PowerShell process. Because it is a reference assembly, PowerShell Standard contains no implementation itself, so provides no functionality for standalone applications.

Using PowerShell Standard with different .NET runtimes

PowerShell Standard targets the [.NET Standard 2.0](#) target runtime, which is a façade runtime designed to provide a common surface area shared by .NET Framework and .NET Core. This allows targeting a single runtime to produce a single assembly that will work with multiple PowerShell versions, but has the following consequences:

- The PowerShell loading the module or library must be running a minimum of .NET 4.6.1; .NET 4.6 and .NET 4.5.2 do not support .NET Standard. Note that a newer Windows PowerShell version does not mean a newer .NET Framework version; Windows PowerShell 5.1 may run on .NET 4.5.2.
- In order to work with a PowerShell running .NET Framework 4.7.1 or below, the .NET 4.6.1 [NETStandard.Library](#) implementation is required to provide the netstandard.dll and other shim assemblies in older .NET Framework versions.

PowerShell 6+ provides its own shim assemblies for type forwarding from .NET Framework 4.6.1 (and above) to .NET Core. This means that as long as a module uses only APIs that exist in .NET Core, PowerShell 6+ can load and run it when it has been built for .NET Framework 4.6.1 (the `net461` runtime target).

This means that binary modules using PowerShell Standard to target multiple PowerShell versions with a single published DLL have two options:

1. Publishing an assembly built for the `net461` target runtime. This involves:
 - Publishing the project for the `net461` runtime
 - Also compiling against the `netstandard2.0` runtime (without using its build output) to ensure that all APIs used are also present in .NET Core.
2. Publishing an assembly build for the `netstandard2.0` target runtime. This requires:

- Publishing the project for the `netstandard2.0` runtime
- Taking the `net461` dependencies of `NETStandard.Library` and copying them into the project assembly's publish location so that the assembly is type-forwarded correctly in .NET Framework.

To build PowerShell modules or libraries targeting older .NET Framework versions, it may be preferable to target multiple .NET runtimes. This will publish an assembly for each target runtime, and the correct assembly will need to be loaded at module load time (for example with a small `psm1` as the root module).

Testing PowerShell Standard projects in .NET

When it comes to testing your module in .NET test runners like xUnit, remember that compile-time checks can only go so far. You must test your module against the relevant PowerShell platforms.

To test APIs built against PowerShell Standard in .NET, you should add `Microsoft.PowerShell.SDK` as a testing dependency with .NET Core (with the version set to match the desired PowerShell version), and the appropriate Windows PowerShell reference assemblies with .NET Framework.

For more information on PowerShell Standard and using it to write a binary module that works in multiple PowerShell versions, see [this blog post](#). Also see the [PowerShell Standard repository](#) on GitHub.

Microsoft.PowerShell.SDK

`Microsoft.PowerShell.SDK` is a meta-package that pulls together all of the components of the PowerShell SDK into a single NuGet package. A self-contained .NET application can use `Microsoft.PowerShell.SDK` to run arbitrary PowerShell functionality without depending on any external PowerShell installations or libraries.

ⓘ Note

The PowerShell SDK just refers to all the component packages that make up PowerShell, and which can be used for .NET development with PowerShell.

A given `Microsoft.PowerShell.SDK` version contains the concrete implementation of the same version of the PowerShell application; version 7.0 contains the implementation of PowerShell 7.0 and running commands or scripts with it will largely behave like running them in PowerShell 7.0.

Running PowerShell commands from the SDK is mostly, but not totally, the same as running them from `pwsh`. For example, `Start-Job` currently depends on the `pwsh` executable being available, and so will not work with `Microsoft.PowerShell.SDK` by default.

Targeting `Microsoft.PowerShell.SDK` from a .NET application allows you to integrate with all of PowerShell's implementation assemblies, such as `System.Management.Automation`, `Microsoft.PowerShell.Management`, and other module assemblies.

Publishing an application targeting `Microsoft.PowerShell.SDK` will include all these assemblies, and any dependencies PowerShell requires. It will also include other assets that PowerShell required in its build, such as the module manifests for `Microsoft.PowerShell.*` modules and the `ref` directory required by `Add-Type`.

Given the completeness of `Microsoft.PowerShell.SDK`, it's best suited for:

- Implementation of PowerShell hosts.
- xUnit testing of libraries targeting PowerShell reference assemblies.
- Invoking PowerShell in-process from a .NET application.

`Microsoft.PowerShell.SDK` may also be used as a reference target when a .NET project is intended to be used as a module or otherwise loaded by PowerShell, but depends on APIs only present in a particular version of PowerShell. Note that an assembly published against a specific version of `Microsoft.PowerShell.SDK` will only be safe to load and use in that version of PowerShell. To target multiple PowerShell versions with specific APIs, multiple builds are required, each targeting their own version of `Microsoft.PowerShell.SDK`.

Note

The PowerShell SDK is only available for PowerShell versions 6 and up. To provide equivalent functionality with Windows PowerShell, use the Windows PowerShell reference assemblies described below.

System.Management.Automation

The `System.Management.Automation` package is the heart of the PowerShell SDK. It exists on NuGet, primarily, as an asset for `Microsoft.PowerShell.SDK` to pull in. However, it can also be used directly as a package for smaller hosting scenarios and version-targeting modules.

Specifically, the `System.Management.Automation` package may be a preferable provider of PowerShell functionality when:

- You're only looking to use PowerShell language functionality (in the `System.Management.Automation.Language` namespace) like the PowerShell parser, AST, and AST visitor APIs (for example for static analysis of PowerShell).
- You only wish to execute specific commands from the `Microsoft.PowerShell.Core` module and can execute them in a session state created with the `CreateDefault2` factory method.

Additionally, `System.Management.Automation` is a useful reference assembly when:

- You wish to target APIs that are only present within a specific PowerShell version
- You won't be depending on types occurring outside the `System.Management.Automation` assembly (for example, types exported by cmdlets in `Microsoft.PowerShell.*` modules).

Windows PowerShell reference assemblies

For PowerShell versions 5.1 and older (Windows PowerShell), there is no SDK to provide an implementation of PowerShell, since Windows PowerShell's implementation is a part of Windows.

Instead, the Windows PowerShell reference assemblies provide both reference targets and a way to rehost Windows PowerShell, acting the same as the PowerShell SDK does for versions 6 and up.

Rather than being differentiated by version, Windows PowerShell reference assemblies have a different package for each version of Windows PowerShell:

- [PowerShell 5.1 ↗](#)
- [PowerShell 4 ↗](#)
- [PowerShell 3 ↗](#)

Information on how to use the Windows PowerShell reference assemblies can be found in the [Windows PowerShell SDK](#).

Real-world examples using these NuGet packages

Different PowerShell tooling projects target different PowerShell NuGet packages depending on their needs. Listed here are some notable examples.

PSReadLine

[PSReadLine](#), the PowerShell module that provides much of PowerShell's rich console experience, targets PowerShell Standard as a dependency rather than a specific PowerShell version, and targets the `net461` .NET runtime in its [csproj](#).

PowerShell 6+ supplies its own shim assemblies that allow a DLL targeting the `net461` runtime to "just work" when loaded in (by redirecting binding to .NET Framework's `mscorlib.dll` to the relevant .NET Core assembly).

This simplifies PSReadLine's module layout and delivery significantly, since PowerShell Standard ensures the only APIs used will be present in both PowerShell 5.1 and PowerShell 6+, while also allowing the module to ship with only a single assembly.

The .NET 4.6.1 target does mean that Windows PowerShell running on .NET 4.5.2 and .NET 4.6 is not supported though.

PowerShell Editor Services

[PowerShell Editor Services](#) (PSES) is the backend for the [PowerShell extension](#) for [Visual Studio Code](#), and is actually a form of PowerShell module that gets loaded by a PowerShell executable and then takes over that process to rehost PowerShell within itself while also providing Language Service Protocol and Debug Adapter features.

PSES provides concrete implementation targets for `netcoreapp2.1` to target PowerShell 6+ (since PowerShell 7's `netcoreapp3.1` runtime is backwards compatible) and `net461` to target Windows PowerShell 5.1, but contains most of its logic in a second assembly that targets `netstandard2.0` and PowerShell Standard. This allows it to pull in dependencies required for .NET Core and .NET Framework platforms, while still simplifying most of the codebase behind a uniform abstraction.

Because it is built against PowerShell Standard, PSES requires a runtime implementation of PowerShell in order to be tested correctly. To do this, [PSES's xUnit](#) tests pull in `Microsoft.PowerShell.SDK` and `Microsoft.PowerShell.5.ReferenceAssemblies` in order to provide a PowerShell implementation in the test environment.

As with PSReadLine, PSES cannot support .NET 4.6 and below, but it [performs a check](#) at runtime before calling any of the APIs that could cause a crash on the lower .NET Framework runtimes.

PSScriptAnalyzer

[PSScriptAnalyzer](#), the linter for PowerShell, must target syntactic elements only introduced in certain versions of PowerShell. Because recognition of these syntactic elements is accomplished by implementing an [AstVisitor2](#), it's not possible to use `PowerShellStandard` and also implement AST visitor methods for newer PowerShell syntaxes.

Instead, PSScriptAnalyzer [targets each PowerShell version](#) as a build configuration, and produces a separate DLL for each of them. This increases build size and complexity, but allows:

- Version-specific API targeting
- Version-specific functionality to be implemented with essentially no runtime cost
- Total support for Windows PowerShell all the way down to .NET Framework 4.5.2

Summary

In this article, we've listed and discussed the NuGet packages available to target when implementing a .NET project that uses PowerShell, and the reasons you might have for using one over another.

If you've skipped to the summary, some broad recommendations are:

- PowerShell **modules** should compile against PowerShell Standard if they only require APIs common to different PowerShell versions.
- PowerShell **hosts and applications** that need to run PowerShell internally should target the PowerShell SDK for PowerShell 6+ or the relevant Windows PowerShell reference assemblies for Windows PowerShell.
- PowerShell modules that need **version-specific APIs** should target the PowerShell SDK or Windows PowerShell reference assemblies for the required PowerShell versions, using them as reference assemblies (that is, not publishing the PowerShell dependencies).

Resolving PowerShell module assembly dependency conflicts

Article • 09/08/2022

When writing a binary PowerShell module in C#, it's natural to take dependencies on other packages or libraries to provide functionality. Taking dependencies on other libraries is desirable for code reuse. PowerShell always loads assemblies into the same context. This presents issues when a module's dependencies conflict with already-loaded DLLs and may prevent using two otherwise unrelated modules in the same PowerShell session.

If you've had this problem, you've seen an error message like this:

```
C:\Users\Robert Holt\Documents\Dev\sandbox\ModuleConflict
> ipmo .\FunCsv\FunCsv
C:\Users\Robert Holt\Documents\Dev\sandbox\ModuleConflict
> Get-FunCsv -Path .\ex.csv
C:\Users\Robert Holt\Documents\Dev\sandbox\ModuleConflict
> ipmo .\TotallyUnrelatedModule\TotallyUnrelatedModule\
C:\Users\Robert Holt\Documents\Dev\sandbox\ModuleConflict
> Test-UnrelatedThing -path .\ex.csv
Test-UnrelatedThing: Could not load file or assembly 'CsvHelper, Version=15.0.0.0, Culture=neutral, PublicKeyToken=8c4959082be5c823'. Could not find or load a specific file. (0x80131621)
```

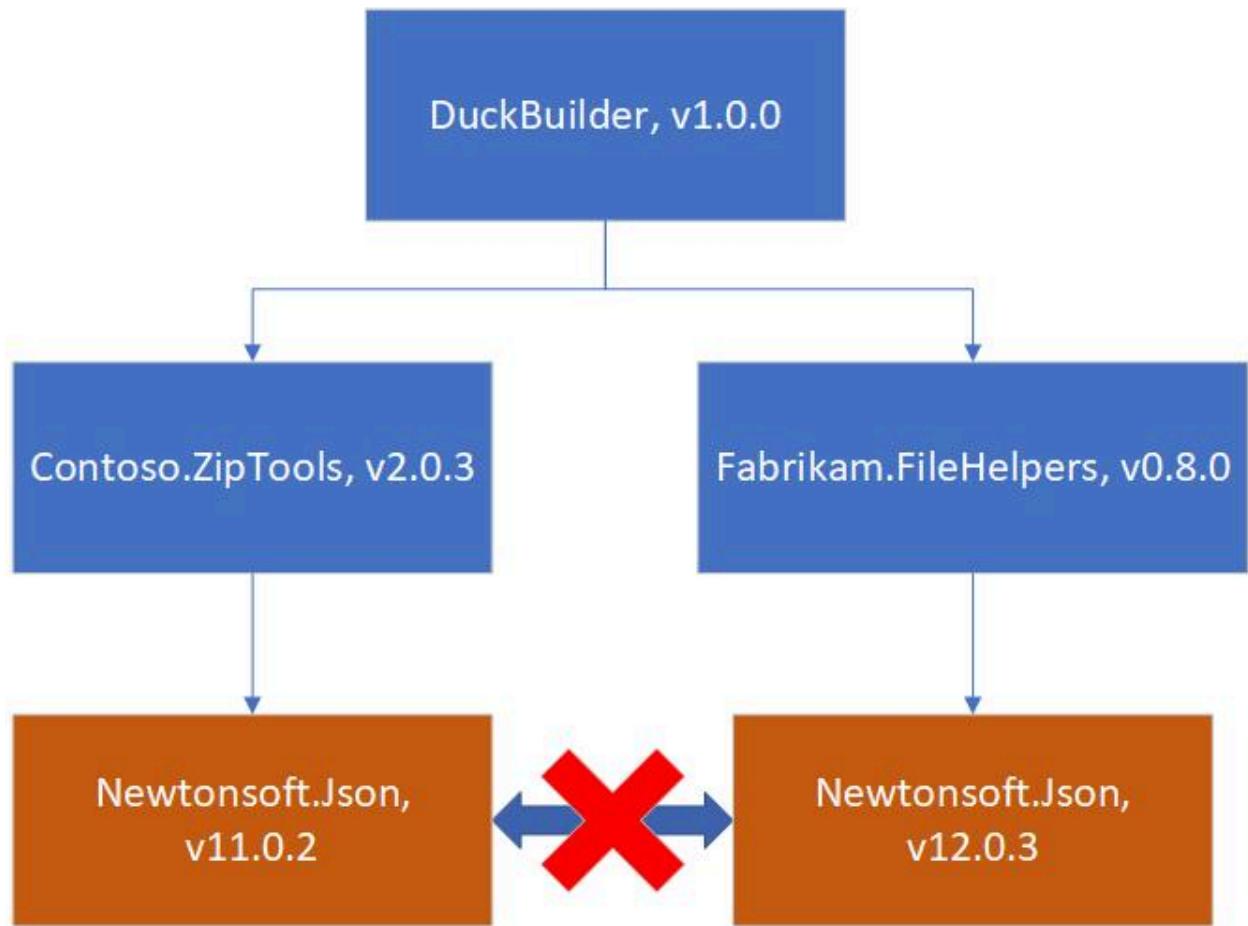

This article looks at some ways dependency conflicts occur in PowerShell and ways to mitigate dependency conflict issues. Even if you're not a module author, there are some tricks in here that might help you with dependency conflicts occurring in modules that you use.

Why do dependency conflicts occur?

In .NET, dependency conflicts occur when two versions of the same assembly are loaded into the same *Assembly Load Context*. This term means slightly different things on different .NET platforms, which is covered [later](#) in this article. This conflict is a common problem that occurs in any software where versioned dependencies are used.

Conflict issues are compounded by the fact that a project almost never deliberately or directly depends on two versions of the same dependency. Instead, the project has two or more dependencies that each require a different version of the same dependency.

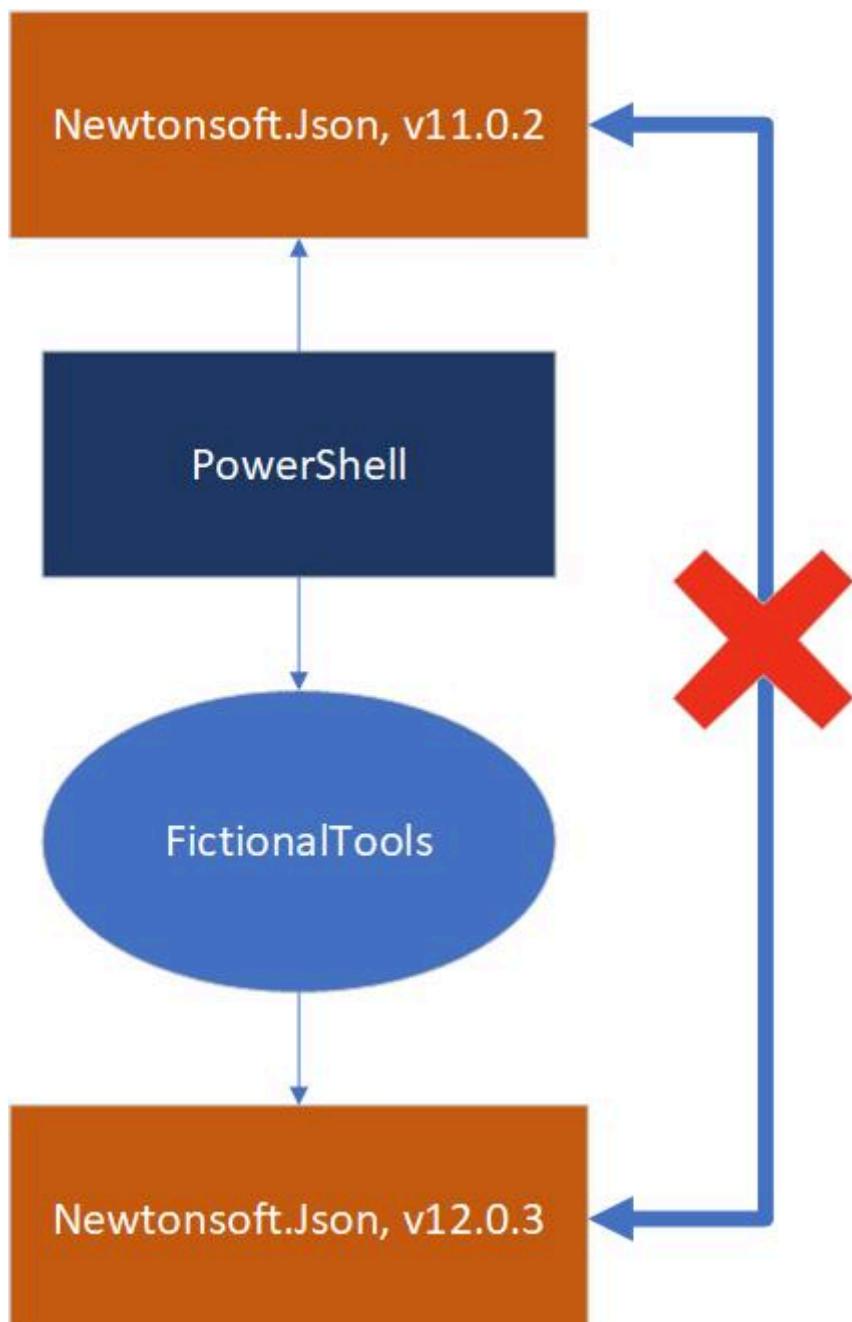

For example, say your .NET application, `DuckBuilder`, brings in two dependencies, to perform parts of its functionality and looks like this:

Because `Contoso.ZipTools` and `Fabrikam.FileHelpers` both depend on different versions of `Newtonsoft.Json`, there may be a dependency conflict depending on how each dependency is loaded.

Conflicting with PowerShell's dependencies

In PowerShell, the dependency conflict issue is magnified because PowerShell's own dependencies are loaded into the same shared context. This means the PowerShell engine and all loaded PowerShell modules must not have conflicting dependencies. A classic example of this is `Newtonsoft.Json`:

In this example, the module `FictionalTools` depends on `Newtonsoft.Json` version `12.0.3`, which is a newer version of `Newtonsoft.Json` than `11.0.2` that ships in the example `PowerShell`.

! Note

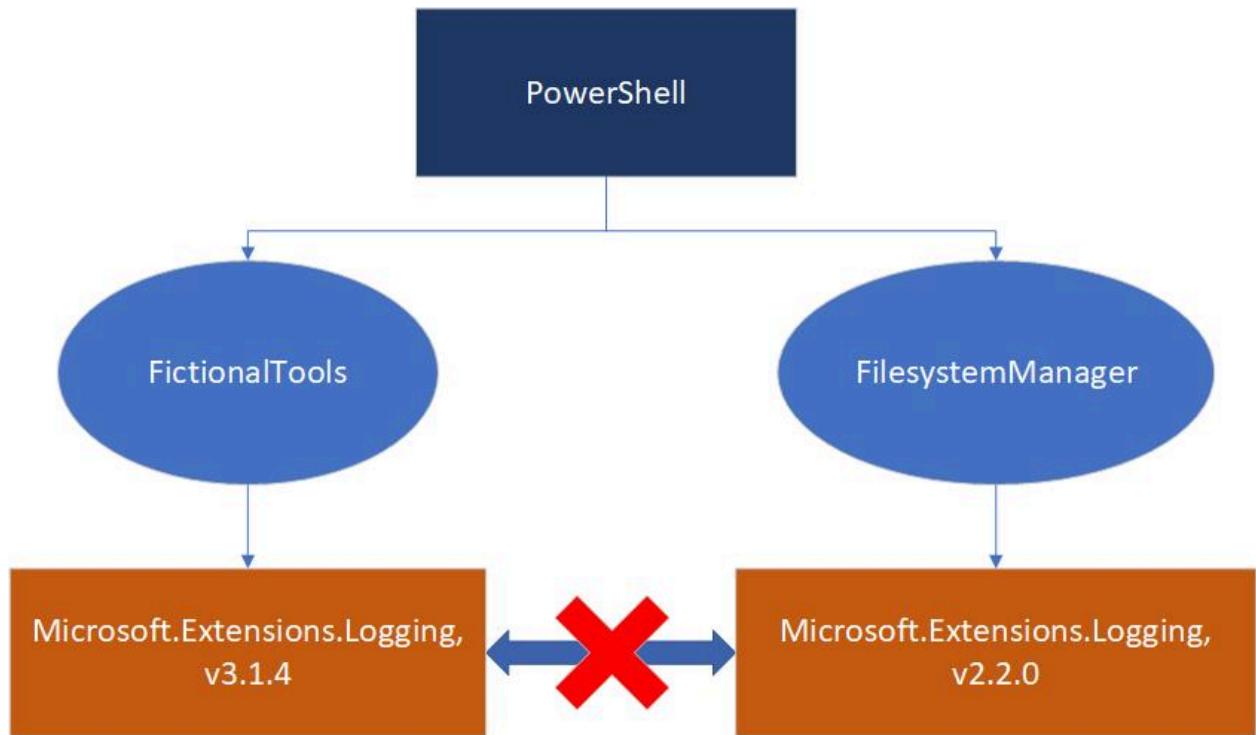

This is an example. PowerShell 7.0 currently ships with `Newtonsoft.Json 12.0.3`. Newer versions of PowerShell have newer versions of `Newtonsoft.Json`.

Because the module depends on a newer version of the assembly, it won't accept the version that PowerShell already has loaded. But because PowerShell has already loaded a version of the assembly, the module can't load its own version using the conventional load mechanism.

Conflicting with another module's dependencies

Another common scenario in PowerShell is that a module is loaded that depends on one version of an assembly, and then another module is loaded later that depends on a different version of that assembly.

This often looks like the following:

In this case, the `FictionalTools` module requires a newer version of `Microsoft.Extensions.Logging` than the `FilesystemManager` module.

Imagine these modules load their dependencies by placing the dependency assemblies in the same directory as the root module assembly. This allows .NET to implicitly load them by name. If we're running PowerShell 7.0 (on top of .NET Core 3.1), we can load and run `FictionalTools`, then load and run `FilesystemManager` without issue. However, in a new session, if we load and run `FilesystemManager`, then load `FictionalTools`, we get a `FileNotFoundException` from the `FictionalTools` command because it requires a newer version of `Microsoft.Extensions.Logging` than the one loaded. `FictionalTools` can't load the version needed because an assembly of the same name has already been loaded.

PowerShell and .NET

PowerShell runs on the .NET platform, which is responsible for resolving and loading assembly dependencies. We must understand how .NET operates here to understand dependency conflicts.

We must also confront the fact that different versions of PowerShell run on different .NET implementations. In general, PowerShell 5.1 and below run on .NET Framework, while PowerShell 6 and above run on .NET Core. These two implementations of .NET load and handle assemblies differently. This means that resolving dependency conflicts can vary depending on the underlying .NET platform.

Assembly Load Contexts

In .NET, an *Assembly Load Context* (ALC) is a runtime namespace into which assemblies are loaded. The assemblies' names must be unique. This concept allows assemblies to be uniquely resolved by name in each ALC.

Assembly reference loading in .NET

The semantics of assembly loading depend on both the .NET implementation (.NET Core vs .NET Framework) and the .NET API used to load a particular assembly. Rather than go into detail here, there are links in the [Further reading](#) section that go into great detail on how .NET assembly loading works in each .NET implementation.

In this article we'll refer to the following mechanisms:

- Implicit assembly loading (effectively `Assembly.Load(AssemblyName)`), when .NET implicitly tries to load an assembly by name from a static assembly reference in .NET code.
- `Assembly.LoadFrom()`, a plugin-oriented loading API that adds handlers to resolve dependencies of the loaded DLL. This method may not resolve dependencies the way we want.
- `Assembly.LoadFile()`, a basic loading API intended to load only the assembly asked for and does not handle any dependencies.

Differences in .NET Framework vs .NET Core

The way these APIs work has changed in subtle ways between .NET Core and .NET Framework, so it's worth reading through the included [links](#). Importantly, Assembly Load Contexts and other assembly resolution mechanisms have changed between .NET Framework and .NET Core.

In particular, .NET Framework has the following features:

- The Global Assembly Cache, for machine-wide assembly resolution
- Application Domains, which work like in-process sandboxes for assembly isolation, but also present a serialization layer to contend with

- A limited assembly load context model that has a fixed set of assembly load contexts, each with their own behavior:
 - The default load context, where assemblies are loaded by default
 - The load-from context, for loading assemblies manually at runtime
 - The reflection-only context, for safely loading assemblies to read their metadata without running them
 - The mysterious void that assemblies loaded with `Assembly.LoadFile(string path)` and `Assembly.Load(byte[] asmBytes)` live in

For more information, see [Best Practices for Assembly Loading](#).

.NET Core (and .NET 5+) has replaced this complexity with a simpler model:

- No Global Assembly Cache. Applications bring all their own dependencies. This removes an external factor for dependency resolution in applications, making dependency resolution more reproducible. PowerShell, as the plugin host, complicates this slightly for modules. Its dependencies in `$PSHOME` are shared with all modules.
- Only one Application Domain, and no ability to create new ones. The Application Domain concept is maintained in .NET to be the global state of the .NET process.
- A new, extensible Assembly Load Context (ALC) model. Assembly resolution can be namespaced by putting it in a new ALC. .NET processes begin with a single default ALC into which all assemblies are loaded (except for those loaded with `Assembly.LoadFile(string)` and `Assembly.Load(byte[])`). But the process can create and define its own custom ALCs with its own loading logic. When an assembly is loaded, the first ALC it's loaded into is responsible for resolving its dependencies. This creates opportunities to implement powerful .NET plugin loading mechanisms.

In both implementations, assemblies are loaded lazily. This means that they're loaded when a method requiring their type is run for the first time.

For example, here are two versions of the same code that load a dependency at different times.

The first always loads its dependency when `Program.GetRange()` is called, because the dependency reference is lexically present within the method:

C#

```
using Dependency.Library;

public static class Program
{
```

```

public static List<int> GetRange(int limit)
{
    var list = new List<int>();
    for (int i = 0; i < limit; i++)
    {
        if (i >= 20)
        {
            // Dependency.Library will be loaded when GetRange is run
            // because the dependency call occurs directly within the
method
            DependencyApi.Use();
        }

        list.Add(i);
    }
    return list;
}

```

The second loads its dependency only if the `limit` parameter is 20 or more, because of the internal indirection through a method:

```

C#

using Dependency.Library;

public static class Program
{
    public static List<int> GetNumbers(int limit)
    {
        var list = new List<int>();
        for (int i = 0; i < limit; i++)
        {
            if (i >= 20)
            {
                // Dependency.Library is only referenced within
                // the UseDependencyApi() method,
                // so will only be loaded when limit >= 20
                UseDependencyApi();
            }

            list.Add(i);
        }
        return list;
    }

    private static void UseDependencyApi()
    {
        // Once UseDependencyApi() is called, Dependency.Library is loaded
        DependencyApi.Use();
    }
}

```

This is a good practice since it minimizes the memory and filesystem I/O and uses the resources more efficiently. The unfortunate side effect of this is that we won't know that the assembly fails to load until we reach the code path that tries to load the assembly.

It can also create a timing condition for assembly load conflicts. If two parts of the same program try to load different versions of the same assembly, the version loaded depends on which code path is run first.

For PowerShell, this means that the following factors can affect an assembly load conflict:

- Which module was loaded first?
- Was the code path that uses the dependency library run?
- Does PowerShell load a conflicting dependency at startup or only under certain code paths?

Quick fixes and their limitations

In some cases, it's possible to make small adjustments to your module and fix things with minimal effort. But these solutions tend to come with caveats. While they may apply to your module, they won't work for every module.

Change your dependency version

The simplest way to avoid dependency conflicts is to agree on a dependency. This may be possible when:

- Your conflict is with a direct dependency of your module and you control the version.
- Your conflict is with an indirect dependency, but you can configure your direct dependencies to use a workable indirect dependency version.
- You know the conflicting version and can rely on it not changing.

The **Newtonsoft.Json** package is a good example of this last scenario. This is a dependency of PowerShell 6 and above, and isn't used in Windows PowerShell. Meaning a simple way to resolve versioning conflicts is to target the lowest version of **Newtonsoft.Json** across the PowerShell versions you wish to target.

For example, PowerShell 6.2.6 and PowerShell 7.0.2 both currently use **Newtonsoft.Json** version 12.0.3. To create a module targeting Windows PowerShell, PowerShell 6, and PowerShell 7, you would target **Newtonsoft.Json 12.0.3** as a dependency and include it

in your built module. When the module is loaded in PowerShell 6 or 7, PowerShell's own **Newtonsoft.Json** assembly is already loaded. Since it's the version required for your module, resolution succeeds. In Windows PowerShell, the assembly isn't already present in PowerShell, so it's loaded from your module folder instead.

Generally, when targeting a concrete PowerShell package, like **Microsoft.PowerShell.Sdk** or **System.Management.Automation**, NuGet should be able to resolve the right dependency versions required. Targeting both Windows PowerShell and PowerShell 6+ becomes more difficult because you must choose between targeting multiple frameworks or **PowerShellStandard.Library**.

Circumstances where pinning to a common dependency version won't work include:

- The conflict is with an indirect dependency, and none of your dependencies can be configured to use a common version.
- The other dependency version is likely to change often, so settling on a common version is only a short-term fix.

Use the dependency out of process

This solution is more for module users than module authors. This is a solution to use when confronted with a module that won't work due to an existing dependency conflict.

Dependency conflicts occur because two versions of the same assembly are loaded into the same .NET process. A simple solution is to load them into different processes, as long as you can still use the functionality from both together.

In PowerShell, there are several ways to achieve this:

- Invoke PowerShell as a subprocess

To run a PowerShell command out of the current process, start a new PowerShell process directly with the command call:

```
PowerShell  
pwsh -c 'Invoke-ConflictingCommand'
```

The main limitation here is that restructuring the result can be trickier or more error prone than other options.

- The PowerShell job system

The PowerShell job system also runs commands out of process, by sending commands to a new PowerShell process and returning the results:

```
PowerShell  
  
$result = Start-Job { Invoke-ConflictingCommand } | Receive-Job -Wait
```

In this case, you just need to be sure that any variables and state are passed in correctly.

The job system can also be slightly cumbersome when running small commands.

- PowerShell remoting

When it's available, PowerShell remoting can be a useful way to run commands out of process. With remoting, you can create a fresh **PSSession** in a new process, call its commands over PowerShell remoting, then use the results locally with the other modules containing the conflicting dependencies.

An example might look like this:

```
PowerShell  
  
# Create a local PowerShell session  
# where the module with conflicting assemblies will be loaded  
$s = New-PSSession  
  
# Import the module with the conflicting dependency via remoting,  
# exposing the commands locally  
Import-Module -PSSession $s -Name ConflictingModule  
  
# Run a command from the module with the conflicting dependencies  
Invoke-ConflictingCommand
```

- Implicit remoting to Windows PowerShell

Another option in PowerShell 7 is to use the `-UseWindowsPowerShell` flag on `Import-Module`. This imports the module through a local remoting session into Windows PowerShell:

```
PowerShell  
  
Import-Module -Name ConflictingModule -UseWindowsPowerShell
```

Be aware that modules may not be compatible with or may work differently with Windows PowerShell.

When out-of-process invocation should not be used

As a module author, out-of-process command invocation is difficult to bake into a module and may have edge cases that cause issues. In particular, remoting and jobs may not be available in all environments where your module needs to work. However, the general principle of moving the implementation out of process and allowing the PowerShell module to be a thinner client, may still be applicable.

As a module user, there are cases where out-of-process invocation won't work:

- When PowerShell remoting is unavailable because you don't have privileges to use it or it is not enabled.
- When a particular .NET type is needed from output as input to a method or another command. Commands running over PowerShell remoting emit serialized objects rather than strongly-typed .NET objects. This means that method calls and strongly typed APIs don't work with the output of commands imported over remoting.

More robust solutions

The previous solutions all had scenarios and modules that don't work. However, they also have the virtue of being relatively simple to implement correctly. The following solutions are more robust, but require more effort to implement correctly and can introduce subtle bugs if not written carefully.

Loading through .NET Core Assembly Load Contexts

[Assembly Load Contexts](#) (ALCs) were introduced in .NET Core 1.0 to specifically address the need to load multiple versions of the same assembly into the same runtime.

Within .NET, they offer the most robust solution to the problem of loading conflicting versions of an assembly. However, custom ALCs are not available in .NET Framework. This means that this solution only works in PowerShell 6 and above.

Currently, the best example of using an ALC for dependency isolation in PowerShell is in PowerShell Editor Services, the language server for the PowerShell extension for Visual Studio Code. An [ALC is used](#) to prevent PowerShell Editor Services' own dependencies from clashing with those in PowerShell modules.

Implementing module dependency isolation with an ALC is conceptually difficult, but we will work through a minimal example. Imagine we have a simple module that is only intended to work in PowerShell 7. The source code is organized as follows:

```
+ AlcModule.psd1
+ src/
  + TestAlcModuleCommand.cs
  + AlcModule.csproj
```

The cmdlet implementation looks like this:

C#

```
using Shared.Dependency;

namespace AlcModule
{
    [Cmdlet(VerbsDiagnostic.Test, "AlcModule")]
    public class TestAlcModuleCommand : Cmdlet
    {
        protected override void EndProcessing()
        {
            // Here's where our dependency gets used
            Dependency.Use();
            // Something trivial to make our cmdlet do *something*
            WriteObject("done!");
        }
    }
}
```

The (heavily simplified) manifest, looks like this:

PowerShell

```
@{
    Author = 'Me'
    ModuleVersion = '0.0.1'
    RootModule = 'AlcModule.dll'
    CmdletsToExport = @('Test-AlcModule')
    PowerShellVersion = '7.0'
}
```

And the `csproj` looks like this:

XML

```
<Project Sdk="Microsoft.NET.Sdk">
  <PropertyGroup>
    <TargetFramework>netcoreapp3.1</TargetFramework>
  </PropertyGroup>
  <ItemGroup>
    <PackageReference Include="Shared.Dependency" Version="1.0.0" />
```

```
<PackageReference Include="Microsoft.PowerShell.Sdk" Version="7.0.1"
PrivateAssets="all" />
</ItemGroup>
</Project>
```

When we build this module, the generated output has the following layout:

```
AlcModule/
+ AlcModule.psd1
+ AlcModule.dll
+ Shared.Dependency.dll
```

In this example, our problem is in the `Shared.Dependency.dll` assembly, which is our imaginary conflicting dependency. This is the dependency that we need to put behind an ALC so that we can use the module-specific version.

We need to re-engineer the module so that:

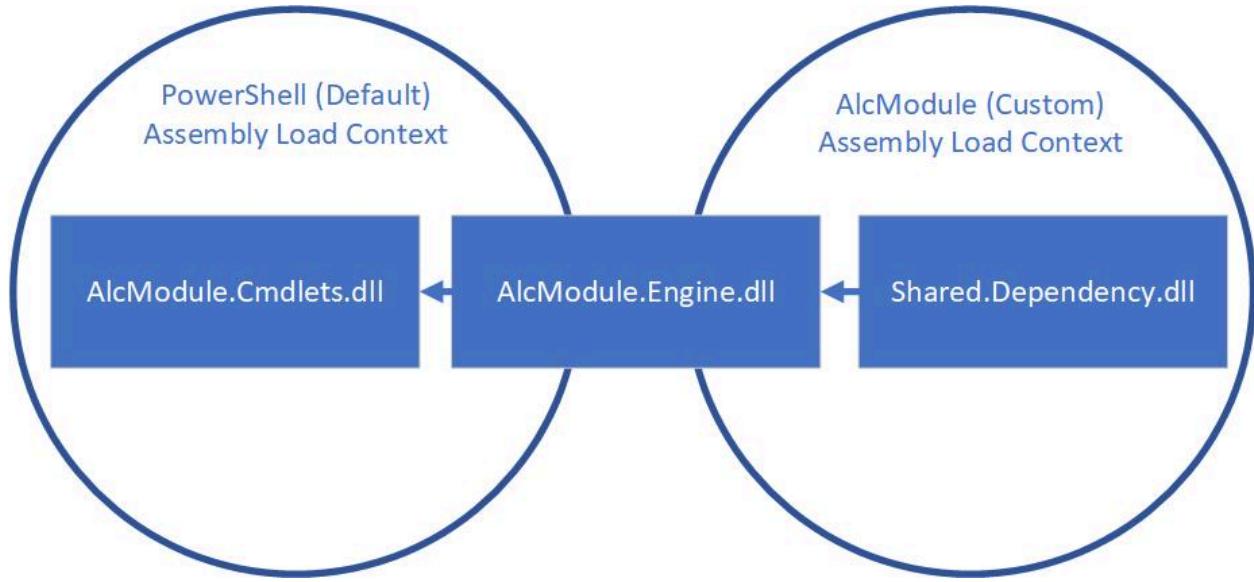

- Module dependencies are only loaded into our custom ALC, and not into PowerShell's ALC, so there can be no conflict. Moreover, as we add more dependencies to our project, we don't want to continuously add more code to keep loading working. Instead, we want reusable, generic dependency resolution logic.
- Loading the module still works as normal in PowerShell. Cmdlets and other types that the PowerShell module system needs are defined within PowerShell's own ALC.

To mediate these two requirements, we must break up our module into two assemblies:

- A cmdlets assembly, `AlcModule.Cmdlets.dll`, that contains definitions of all the types that PowerShell's module system needs to load our module correctly. Namely, any implementations of the `Cmdlet` base class and the class that implements `IModuleAssemblyInitializer`, which sets up the event handler for `AssemblyLoadContext.Default.Resolving` to properly load `AlcModule.Engine.dll` through our custom ALC. Since PowerShell 7 deliberately hides types defined in assemblies loaded in other ALCs, any types that are meant to be publicly exposed to PowerShell must also be defined here. Finally, our custom ALC definition needs to be defined in this assembly. Beyond that, as little code as possible should live in this assembly.
- An engine assembly, `AlcModule.Engine.dll`, that handles the actual implementation of the module. Types from this are available in the PowerShell ALC,

but it's initially loaded through our custom ALC. Its dependencies are only loaded into the custom ALC. Effectively, this becomes a *bridge* between the two ALCs.

Using this bridge concept, our new assembly situation looks like this:

To make sure the default ALC's dependency probing logic doesn't resolve the dependencies to be loaded into the custom ALC, we need to separate these two parts of the module in different directories. The new module layout has the following structure:

```
AlcModule/
  AlcModule.Cmdlets.dll
  AlcModule.psd1
  Dependencies/
    + AlcModule.Engine.dll
    + Shared.Dependency.dll
```

To see how the implementation changes, we'll start with the implementation of `AlcModule.Engine.dll`:

```
C#  
  
using Shared.Dependency;  
  
namespace AlcModule.Engine  
{  
    public class AlcEngine  
    {  
        public static void Use()  
        {  
            Dependency.Use();  
        }  
    }  
}
```

```
    }  
}
```

This is a simple container for the dependency, `Shared.Dependency.dll`, but you should think of it as the .NET API for your functionality that the cmdlets in the other assembly wrap for PowerShell.

The cmdlet in `AlcModule.Cmdlets.dll` looks like this:

```
C#  
  
// Reference our module's Engine implementation here  
using AlcModule.Engine;  
  
namespace AlcModule.Cmdlets  
{  
    [Cmdlet(VerbsDiagnostic.Test, "AlcModule")]  
    public class TestAlcModuleCommand : Cmdlet  
    {  
        protected override void EndProcessing()  
        {  
            AlcEngine.Use();  
            WriteObject("done!");  
        }  
    }  
}
```

At this point, if we were to load `AlcModule` and run `Test-AlcModule`, we get a `FileNotFoundException` when the default ALC tries to load `Alc.Engine.dll` to run `EndProcessing()`. This is good, since it means the default ALC can't find the dependencies we want to hide.

Now we need to add code to `AlcModule.Cmdlets.dll` so that it knows how to resolve `AlcModule.Engine.dll`. First we must define our custom ALC to resolve assemblies from our module's `Dependencies` directory:

```
C#  
  
namespace AlcModule.Cmdlets  
{  
    internal class AlcModuleAssemblyLoadContext : AssemblyLoadContext  
    {  
        private readonly string _dependencyDirPath;  
  
        public AlcModuleAssemblyLoadContext(string dependencyDirPath)  
        {  
            _dependencyDirPath = dependencyDirPath;  
        }  
    }  
}
```

```

protected override Assembly Load(AssemblyName assemblyName)
{
    // We do the simple logic here of looking for an assembly of the
    // given name
    // in the configured dependency directory.
    string assemblyPath = Path.Combine(
        _dependencyDirPath,
        $"{assemblyName.Name}.dll");

    if (File.Exists(assemblyPath))
    {
        // The ALC must use inherited methods to load assemblies.
        // Assembly.Load*() won't work here.
        return LoadFromAssemblyPath(assemblyPath);
    }

    // For other assemblies, return null to allow other resolutions
    // to continue.
    return null;
}
}
}

```

Then we need to hook up our custom ALC to the default ALC's `Resolving` event, which is the ALC version of the `AssemblyResolve` event on Application Domains. This event is fired to find `AlcModule.Engine.dll` when `EndProcessing()` is called.

C#

```

namespace AlcModule.Cmdlets
{
    public class AlcModuleResolveEventHandler : IModuleAssemblyInitializer,
    IModuleAssemblyCleanup
    {
        // Get the path of the dependency directory.
        // In this case we find it relative to the AlcModule.Cmdlets.dll
        location
            private static readonly string s_dependencyDirPath =
        Path.GetFullPath(
            Path.Combine(
                Path.GetDirectoryName(Assembly.GetExecutingAssembly().Location),
                "Dependencies"));

        private static readonly AlcModuleAssemblyLoadContext s_dependencyAlc
        =
            new AlcModuleAssemblyLoadContext(s_dependencyDirPath);

        public void OnImport()
        {
            // Add the Resolving event handler here
        }
    }
}

```

```

        AssemblyLoadContext.Default.Resolving += ResolveAlcEngine;
    }

    public void OnRemove(PSModuleInfo psModuleInfo)
    {
        // Remove the Resolving event handler here
        AssemblyLoadContext.Default.Resolving -= ResolveAlcEngine;
    }

    private static Assembly ResolveAlcEngine(AssemblyLoadContext
defaultAlc, AssemblyName assemblyToResolve)
    {
        // We only want to resolve the Alc.Engine.dll assembly here.
        // Because this will be loaded into the custom ALC,
        // all of *its* dependencies will be resolved
        // by the logic we defined for that ALC's implementation.
        //
        // Note that we are safe in our assumption that the name is
enough
        // to distinguish our assembly here,
        // since it's unique to our module.
        // There should be no other AlcModule.Engine.dll on the system.
        if (!assemblyToResolve.Name.Equals("AlcModule.Engine"))
        {
            return null;
        }

        // Allow our ALC to handle the directory discovery concept
        //
        // This is where Alc.Engine.dll is loaded into our custom ALC
        // and then passed through into PowerShell's ALC,
        // becoming the bridge between both
        return s_dependencyAlc.LoadFromAssemblyName(assemblyToResolve);
    }
}

```

With the new implementation, take a look at the sequence of calls that occurs when the module is loaded and `Test-AlcModule` is run:

Some points of interest are:

- The `IModuleAssemblyInitializer` is run first when the module loads and sets the `Resolving` event.
- We don't load the dependencies until `Test-AlcModule` is run and its `EndProcessing()` method is called.
- When `EndProcessing()` is called, the default ALC fails to find `AlcModule.Engine.dll` and fires the `Resolving` event.
- Our event handler hooks up the custom ALC to the default ALC and loads `AlcModule.Engine.dll` only.
- When `AlcEngine.Use()` is called within `AlcModule.Engine.dll`, the custom ALC again kicks in to resolve `Shared.Dependency.dll`. Specifically, it always loads *our* `Shared.Dependency.dll` since it never conflicts with anything in the default ALC and only looks in our `Dependencies` directory.

Assembling the implementation, our new source code layout looks like this:

```
+ AlcModule.psd1
+ src/
  + AlcModule.Cmdlets/
    | + AlcModule.Cmdlets.csproj
    | + TestAlcModuleCommand.cs
    | + AlcModuleAssemblyLoadContext.cs
    | + AlcModuleInitializer.cs
  |
  + AlcModule.Engine/
```

```
| + AlcModule.Engine.csproj  
| + AlcEngine.cs
```

AlcModule.Cmdlets.csproj looks like:

XML

```
<Project Sdk="Microsoft.NET.Sdk">  
  <PropertyGroup>  
    <TargetFramework>netcoreapp3.1</TargetFramework>  
  </PropertyGroup>  
  <ItemGroup>  
    <ProjectReference Include=".\\AlcModule.Engine\\AlcModule.Engine.csproj" />  
    <PackageReference Include="Microsoft.PowerShell.Sdk" Version="7.0.1" PrivateAssets="all" />  
  </ItemGroup>  
</Project>
```

AlcModule.Engine.csproj looks like this:

XML

```
<Project Sdk="Microsoft.NET.Sdk">  
  <PropertyGroup>  
    <TargetFramework>netcoreapp3.1</TargetFramework>  
  </PropertyGroup>  
  <ItemGroup>  
    <PackageReference Include="Shared.Dependency" Version="1.0.0" />  
  </ItemGroup>  
</Project>
```

So, when we build the module, our strategy is:

- Build `AlcModule.Engine`
- Build `AlcModule.Cmdlets`
- Copy everything from `AlcModule.Engine` into the `Dependencies` directory, and remember what we copied
- Copy everything from `AlcModule.Cmdlets` that wasn't in `AlcModule.Engine` into the base module directory

Since the module layout here is so crucial to dependency separation, here's a build script to use from the source root:

PowerShell

```

param(
    # The .NET build configuration
    [ValidateSet('Debug', 'Release')]
    [string]
    $Configuration = 'Debug'
)

# Convenient reusable constants
$mod = "AlcModule"
$netcore = "netcoreapp3.1"
$copyExtensions = @('.dll', '.pdb')

# Source code locations
$src = "$PSScriptRoot/src"
$engineSrc = "$src/$mod.Engine"
$cmdletsSrc = "$src/$mod.Cmdlets"

# Generated output locations
$outDir = "$PSScriptRoot/out/$mod"
$outDeps = "$outDir/Dependencies"

# Build AlcModule.Engine
Push-Location $engineSrc
dotnet publish -c $Configuration
Pop-Location

# Build AlcModule.Cmdlets
Push-Location $cmdletsSrc
dotnet publish -c $Configuration
Pop-Location

# Ensure out directory exists and is clean
Remove-Item -Path $outDir -Recurse -ErrorAction Ignore
New-Item -Path $outDir -ItemType Directory
New-Item -Path $outDeps -ItemType Directory

# Copy manifest
Copy-Item -Path "$PSScriptRoot/$mod.psd1"

# Copy each Engine asset and remember it
$deps = [System.Collections.Generic.Hashtable[string]]::new()
Get-ChildItem -Path "$engineSrc/bin/$Configuration/$netcore/publish/" |
    Where-Object { $_.Extension -in $copyExtensions } |
        ForEach-Object { [void]$deps.Add($_.Name); Copy-Item -Path $_.FullName -
Destination $outDeps }

# Now copy each Cmdlets asset, not taking any found in Engine
Get-ChildItem -Path "$cmdletsSrc/bin/$Configuration/$netcore/publish/" |
    Where-Object { -not $deps.Contains($_.Name) -and $_.Extension -in
$copyExtensions } |
        ForEach-Object { Copy-Item -Path $_.FullName -Destination $outDir }

```

Finally, we have a general way to isolate our module's dependencies in an Assembly Load Context that remains robust over time as more dependencies are added.

For a more detailed example, go to this [GitHub repository](#). This example demonstrates how to migrate a module to use an ALC, while keeping that module working in .NET Framework. It also shows how to use .NET Standard and PowerShell Standard to simplify the core implementation.

This solution is also used by the [Bicep PowerShell module](#), and the blog post [Resolving PowerShell Module Conflicts](#) is another good read about this solution.

Assembly resolving handler for side-by-side loading

Although being robust, the solution described above requires the module assembly to not directly reference the dependency assemblies, but instead, reference a wrapper assembly that references the dependency assemblies. The wrapper assembly acts like a bridge, forwarding the calls from the module assembly to the dependency assemblies. This makes it usually a non-trivial amount of work to adopt this solution:

- For a new module, this would add additional complexity to the design and implementation
- For an existing module, this would require significant refactoring

There is a simplified solution to achieve side-by-side assembly loading, by hooking up a `Resolving` event with a custom `AssemblyLoadContext` instance. Using this method is easier for the module author but has two limitations. Check out the [PowerShell-ALC-Samples](#) repository for sample code and documentation that describes these limitations and detailed scenarios for this solution.

Important

Do not use `Assembly.LoadFile` for the dependency isolation purpose. Using `Assembly.LoadFile` creates a *Type Identity* issue when another module loads a different version of the same assembly into the default `AssemblyLoadContext`. While this API loads an assembly to a separate `AssemblyLoadContext` instance, the assemblies loaded are discoverable by PowerShell's [type resolution code](#). Therefore, there could be duplicate types with the same fully qualified type name available from two different ALCs.

Custom Application Domains

The final and most extreme option for assembly isolation is to use custom **Application Domains**. **Application Domains** are only available in .NET Framework. They are used to provide in-process isolation between parts of a .NET application. One of the uses is to isolate assembly loads from each other within the same process.

However, **Application Domains** are serialization boundaries. Objects in one application domain can't be referenced and used directly by objects in another application domain. You can work around this by implementing `MarshalByRefObject`. But when you don't control the types, as is often the case with dependencies, it's not possible to force an implementation here. The only solution is to make large architectural changes. The serialization boundary also has serious performance implications.

Because **Application Domains** have this serious limitation, are complicated to implement, and only work in .NET Framework, we won't give an example of how you might use them here. While they're worth mentioning as a possibility, they're not recommended.

If you're interested in trying to use a custom application domain, the following links might help:

- [Conceptual documentation on Application Domains](#)
- [Examples for using Application Domains](#)

Solutions for dependency conflicts that don't work for PowerShell

Finally, we'll address some possibilities that come up when researching .NET dependency conflicts in .NET that can look promising, but generally won't work for PowerShell.

These solutions have the common theme that they are changes to deployment configurations for an environment where you control the application and possibly the entire machine. These solutions are oriented toward scenarios like web servers and other applications deployed to server environments, where the environment is intended to host the application and is free to be configured by the deploying user. They also tend to be very much .NET Framework oriented, meaning they don't work with PowerShell 6 or higher.

If you know that your module is only used in Windows PowerShell 5.1 environments that you have total control over, some of these may be options. In general however, **modules shouldn't modify global machine state like this**. It can break configurations

that cause problems in `powershell.exe`, other modules, or other dependent applications that cause your module to fail in unexpected ways.

Static binding redirect with app.config to force using the same dependency version

.NET Framework applications can take advantage of an `app.config` file to configure some application behaviors declaratively. It's possible to write an `app.config` entry that configures assembly binding to redirect assembly loading to a particular version.

Two issues with this for PowerShell are:

- .NET Core doesn't support `app.config`, so this solution only applies to `powershell.exe`.
- `powershell.exe` is a shared application that lives in the `System32` directory. It's likely that your module won't be able to modify its contents on many systems. Even if it can, modifying the `app.config` could break an existing configuration or affect the loading of other modules.

Setting `codebase` with app.config

For the same reasons, trying to configure the `codebase` setting in `app.config` is not going to work in PowerShell modules.

Installing dependencies to the Global Assembly Cache (GAC)

Another way to resolve dependency version conflicts in .NET Framework is to install dependencies to the GAC, so that different versions can be loaded side-by-side from the GAC.

Again, for PowerShell modules, the chief issues here are:

- The GAC only applies to .NET Framework, so this does not help in PowerShell 6 and above.
- Installing assemblies to the GAC is a modification of global machine state and may cause side-effects in other applications or to other modules. It may also be difficult to do correctly, even when your module has the required access privileges. Getting it wrong could cause serious, machine-wide issues in other .NET applications.

How to create a command-line predictor

Article • 07/10/2023

PSReadLine 2.1.0 introduced the concept of a smart command-line predictor by implementing the Predictive IntelliSense feature. PSReadLine 2.2.2 expanded on that feature by adding a plugin model that allows you create your own command-line predictors.

Predictive IntelliSense enhances tab completion by providing suggestions, on the command line, as you type. The prediction suggestion appears as colored text following your cursor. This enables you to discover, edit, and execute full commands based on matching predictions from your command history or additional domain-specific plugins.

System requirements

To create and use a plugin predictor, you must be using the following versions of software:

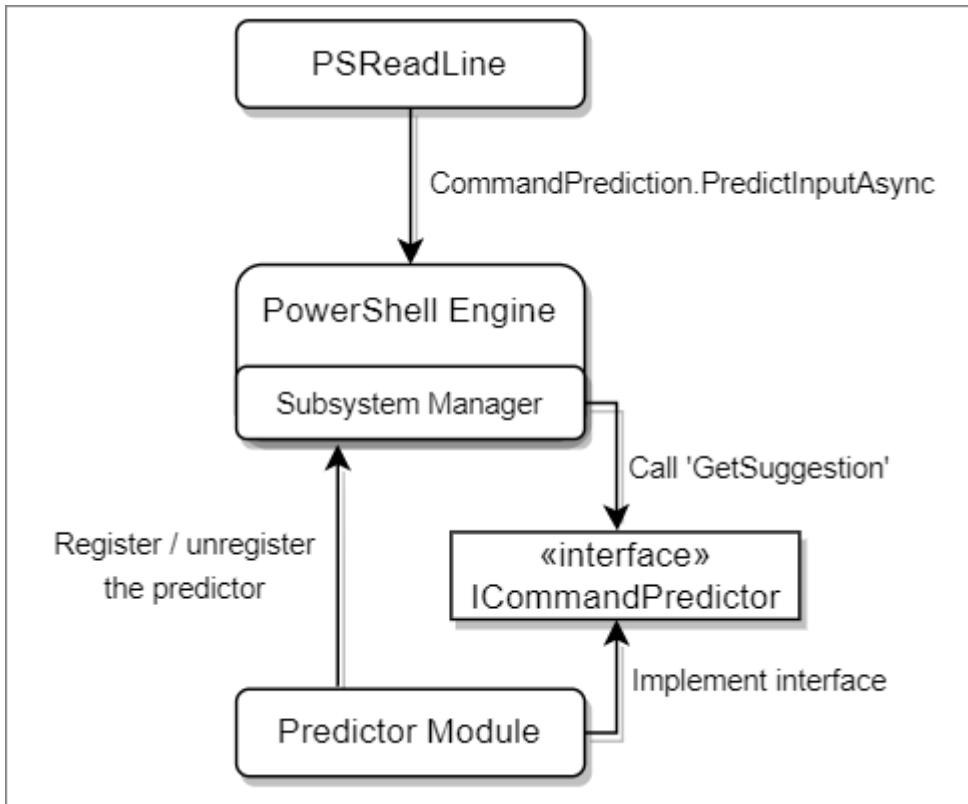

- PowerShell 7.2 (or higher) - provides the APIs necessary for creating a command predictor
- PSReadLine 2.2.2 (or higher) - allows you to configure PSReadLine to use the plugin

Overview of a predictor

A predictor is a PowerShell binary module. The module must implement the `System.Management.Automation.Subsystem.Prediction.ICommandPredictor` interface. This interface declares the methods used to query for prediction results and provide feedback.

A predictor module must register a `CommandPredictor` subsystem with PowerShell's `SubsystemManager` when loaded and unregister itself when unloaded.

The following diagram shows the architecture of a predictor in PowerShell.

Creating the code

To create a predictor, you must have the .NET 6 SDK installed for your platform. For more information on the SDK, see [Download .NET 6.0](#).

Create a new PowerShell module project by following these steps:

1. Use the `dotnet` command-line tool to create a starter classlib project.

```

PowerShell
dotnet new classlib --name SamplePredictor

```

2. Edit the `SamplePredictor.csproj` to contain the following information:

```

XML
<Project Sdk="Microsoft.NET.Sdk">

  <PropertyGroup>
    <TargetFramework>net6.0</TargetFramework>
  </PropertyGroup>

  <ItemGroup>
    <PackageReference Include="Microsoft.PowerShell.SDK"
Version="7.2.0" />
  </ItemGroup>

```

```
</Project>
```

3. Delete the default `Class1.cs` file created by `dotnet` and copy the following code to a `SamplePredictorClass.cs` file in your project folder.

C#

```
using System;
using System.Collections.Generic;
using System.Threading;
using System.Management.Automation;
using System.Management.Automation.Subsystem;
using System.Management.Automation.Subsystem.Prediction;

namespace PowerShell.Sample
{
    public class SamplePredictor : ICommandPredictor
    {
        private readonly Guid _guid;

        internal SamplePredictor(string guid)
        {
            _guid = new Guid(guid);
        }

        /// <summary>
        /// Gets the unique identifier for a subsystem implementation.
        /// </summary>
        public Guid Id => _guid;

        /// <summary>
        /// Gets the name of a subsystem implementation.
        /// </summary>
        public string Name => "SamplePredictor";

        /// <summary>
        /// Gets the description of a subsystem implementation.
        /// </summary>
        public string Description => "A sample predictor";

        /// <summary>
        /// Get the predictive suggestions. It indicates the start of a
        suggestion rendering session.
        /// </summary>
        /// <param name="client">Represents the client that initiates
        the call.</param>
        /// <param name="context">The <see cref="PredictionContext"/>
        object to be used for prediction.</param>
        /// <param name="cancellationToken">The cancellation token to
        cancel the prediction.</param>
        /// <returns>An instance of <see cref="SuggestionPackage"/>.
    </returns>
```

```

        public SuggestionPackage GetSuggestion(PredictionClient client,
PredictionContext context, CancellationToken cancellationToken)
{
    string input = context.InputAst.Extent.Text;
    if (string.IsNullOrWhiteSpace(input))
    {
        return default;
    }

    return new SuggestionPackage(new List<PredictiveSuggestion>
{
    new PredictiveSuggestion(string.Concat(input, " HELLO
WORLD"))
});
}

#region "interface methods for processing feedback"

/// <summary>
/// Gets a value indicating whether the predictor accepts a
specific kind of feedback.
/// </summary>
/// <param name="client">Represents the client that initiates
the call.</param>
/// <param name="feedback">A specific type of feedback.</param>
/// <returns>True or false, to indicate whether the specific
feedback is accepted.</returns>
public bool CanAcceptFeedback(PredictionClient client,
PredictorFeedbackKind feedback) => false;

/// <summary>
/// One or more suggestions provided by the predictor were
displayed to the user.
/// </summary>
/// <param name="client">Represents the client that initiates

/// returned in <paramref name="session"/>, starting from the
index 0. When the value is
/// less than or equal to 0, it means a single suggestion from
the list got displayed, and
/// the index is the absolute value.
/// </param>
public void OnSuggestionDisplayed(PredictionClient client, uint
session, int countOrIndex) { }

/// <summary>
/// The suggestion provided by the predictor was accepted.
/// </summary>
/// <param name="client">Represents the client that initiates
the call.</param>

```

```

        ///<param name="session">Represents the mini-session where the
accepted suggestion came from.</param>
        ///<param name="acceptedSuggestion">The accepted suggestion
text.</param>
        public void OnSuggestionsAccepted(PredictionClient client, uint
session, string acceptedSuggestion) { }

        ///<summary>
        /// A command line was accepted to execute.
        /// The predictor can start processing early as needed with the
latest history.
        ///</summary>
        ///<param name="client">Represents the client that initiates
the call.</param>
        ///<param name="history">History command lines provided as
references for prediction.</param>
        public void OnCommandLineAccepted(PredictionClient client,
IReadOnlyList<string> history) { }

        ///<summary>
        /// A command line was done execution.
        ///</summary>
        ///<param name="client">Represents the client that initiates
the call.</param>
        ///<param name="commandLine">The last accepted command line.
</param>
        ///<param name="success">Shows whether the execution was
successful.</param>
        public void OnCommandLineExecuted(PredictionClient client,
string commandLine, bool success) { }

        #endregion;
    }

    ///<summary>
    /// Register the predictor on module loading and unregister it on
module un-loading.
    ///</summary>
    public class Init : IModuleAssemblyInitializer,
IModuleAssemblyCleanup
{
    private const string Identifier = "843b51d0-55c8-4c1a-8116-
f0728d419306";

    ///<summary>
    /// Gets called when assembly is loaded.
    ///</summary>
    public void OnImport()
    {
        var predictor = new SamplePredictor(Identifier);

SubsystemManager.RegisterSubsystem(SubsystemKind.CommandPredictor,
predictor);
    }
}

```

```
    /// <summary>
    /// Gets called when the binary module is unloaded.
    /// </summary>
    public void OnRemove(PSModuleInfo psModuleInfo)
    {

        SubsystemManager.UnregisterSubsystem(SubsystemKind.CommandPredictor,
        new Guid(Identifier));
    }
}
```

The following example code returns the string "HELLO WORLD" for the prediction result for all user input. Since the sample predictor doesn't process any feedback, the code doesn't implement the feedback methods from the interface. Change the prediction and feedback code to meet the needs of your predictor.

 **Note**

The list view of **PSReadLine** doesn't support multiline suggestions. Each suggestion should be a single line. If your code has a multiline suggestion, you should split the lines into separate suggestions or join the lines with a semicolon (;).

4. Run `dotnet build` to produce the assembly. You can find the compiled assembly in the `bin/Debug/net6.0` location of your project folder.

 **Note**

To ensure a responsive user experience, the **ICommandPredictor** interface has a 20ms time out for responses from the Predictors. Your predictor code must return results in less than 20ms to be displayed.

Using your predictor plugin

To try out your new predictor, open a new PowerShell 7.2 session and run the following commands:

PowerShell

```
Set-PSReadLineOption -PredictionSource HistoryAndPlugin
Import-Module .\bin\Debug\net6.0\SamplePredictor.dll
```

With the assembly is loaded in the session, you see the text "HELLO WORLD" appear as you type in the terminal. You can press **F2** to switch between the **Inline** view and the **List** view.

For more information about PSReadLine options, see [Set-PSReadLineOption](#).

You can get a list of installed predictors, using the following command:

PowerShell

```
Get-PSSubsystem -Kind CommandPredictor
```

Output

Kind	SubsystemType	IsRegistered	Implementations
CommandPredictor	ICommandPredictor	True	{SamplePredictor}

ⓘ Note

`Get-PSSubsystem` is an experimental cmdlet that was introduced in PowerShell 7.1. You must enable the `PSSubsystemPluginModel` experimental feature to use this cmdlet. For more information, see [Using Experimental Features](#).

How to create a feedback provider

Article • 04/11/2024

PowerShell 7.4 introduced the concept of feedback providers. A feedback provider is a PowerShell module that implements the `IFeedbackProvider` interface to provide command suggestions based on user command execution attempts. The provider is triggered when there's a success or failure execution. Feedback providers use information from the success or failure to provide feedback.

Prerequisites

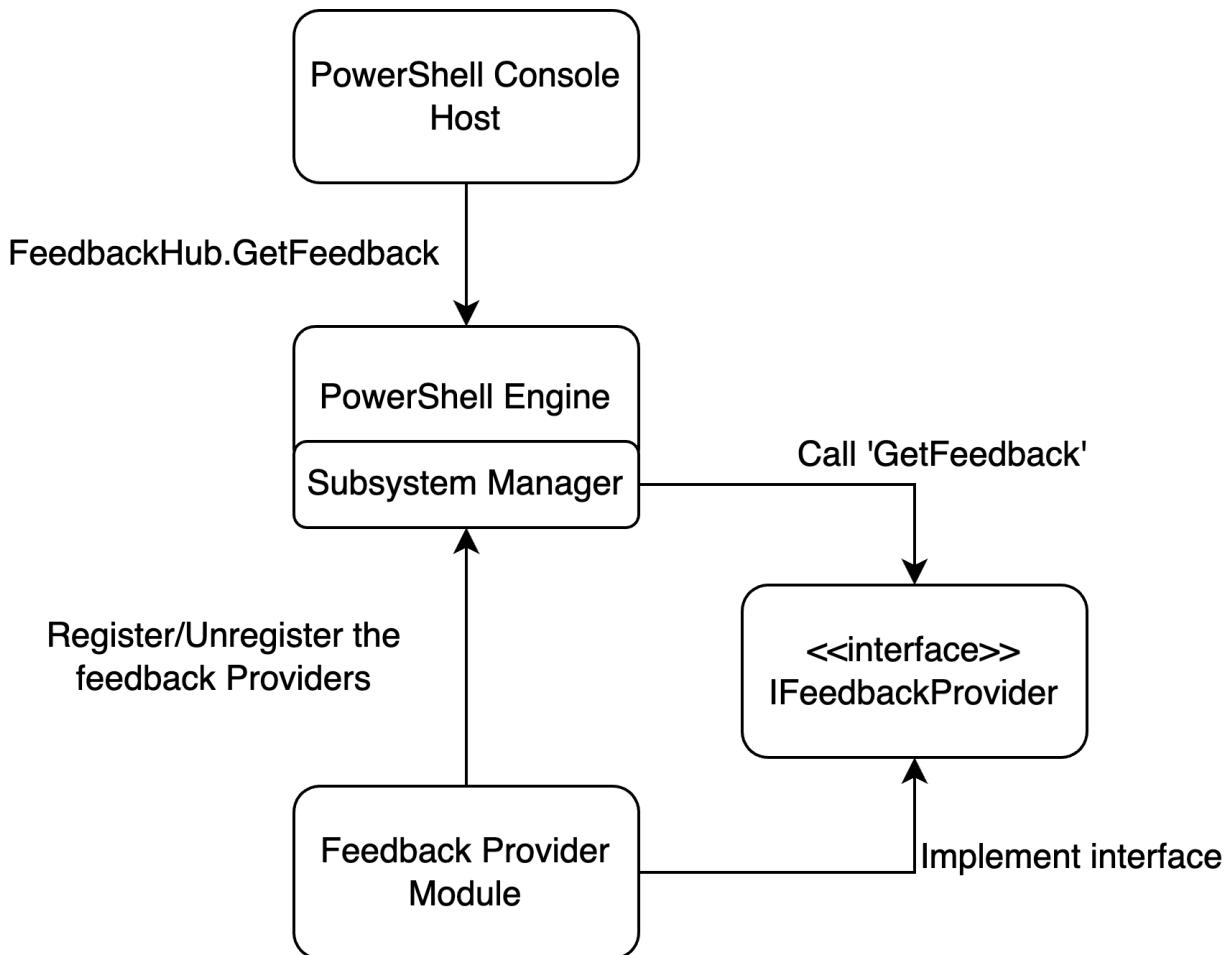

To create a feedback provider, you must satisfy the following prerequisites:

- Install PowerShell 7.4 or higher
 - You must enable the `PSFeedbackProvider` experimental feature to enable support for feedback providers and predictors. For more information, see [Using Experimental Features](#).
- Install .NET 8 SDK - 8.0.0 or higher
 - See the [Download .NET 8.0](#) page to get the latest version of the SDK.

Overview of a feedback provider

A feedback provider is a PowerShell binary module that implements the `System.Management.Automation.Subsystem.Feedback.IFeedbackProvider` interface. This interface declares the methods to get feedback based on the command line input. The feedback interface can provide suggestions based on the success or failure of the command invoked by the user. The suggestions can be anything that you want. For example, you might suggest ways to address an error or better practices, like avoiding the use of aliases. For more information, see the [What are Feedback Providers?](#) blog post.

The following diagram shows the architecture of a feedback provider:

The following examples walk you through the process of creating a simple feedback provider. Also, you can register the provider with the command predictor interface to add feedback suggestions to the command-line predictor experience. For more information about predictors, see [Using predictors in PSReadLine](#) and [How to create a command line predictor](#).

Step 1 - Create a new class library project

Use the following command to create a new project in the project directory:

```

PowerShell
dotnet new classlib --name MyFeedbackProvider
  
```

Add a package reference for the `System.Management.Automation` package to your `.csproj` file. The following example shows the updated `.csproj` file:

```

XML
<Project Sdk="Microsoft.NET.Sdk">
  <PropertyGroup>
    
```

```
<TargetFramework>net8.0</TargetFramework>
<ImplicitUsings>enable</ImplicitUsings>
<Nullable>enable</Nullable>
</PropertyGroup>

<ItemGroup>
    <PackageReference Include="System.Management.Automation" Version="7.4.0-preview.3">
        <ExcludeAssets>contentFiles</ExcludeAssets>
        <PrivateAssets>All</PrivateAssets>
    </PackageReference>
</ItemGroup>
</Project>
```

ⓘ Note

You should change the version of the `System.Management.Automation` assembly to match the version of the PowerShell preview that you are targeting. The minimum version is 7.4.0-preview.3.

Step 2 - Add the class definition for your provider

Change the name of the `Class1.cs` file to match the name of your provider. This example uses `myFeedbackProvider.cs`. This file contains the two main classes that define the feedback provider. The following example shows the basic template for the class definitions.

C#

```
using System.Management.Automation;
using System.Management.Automation.Subsystem;
using System.Management.Automation.Subsystem.Feedback;
using System.Management.Automation.Subsystem.Prediction;
using System.Management.Automation.Language;

namespace myFeedbackProvider;

public sealed class myFeedbackProvider : IFeedbackProvider,
ICommandPredictor
{

}

public class Init : IModuleAssemblyInitializer, IModuleAssemblyCleanup
{
```

```
}
```

Step 3 - Implement the Init class

The `Init` class registers and unregisters the feedback provider with the subsystem manager. The `OnImport()` method runs when the binary module is being loaded. The `OnRemove()` method runs when the binary module is being removed. This example registers both the feedback provider and command predictor subsystem.

C#

```
public class Init : IModuleAssemblyInitializer, IModuleAssemblyCleanup
{
    private const string Id = "<ADD YOUR GUID HERE>";

    public void OnImport()
    {
        var feedback = new myFeedbackProvider(Id);
        SubsystemManager.RegisterSubsystem(SubsystemKind.FeedbackProvider,
feedback);
        SubsystemManager.RegisterSubsystem(SubsystemKind.CommandPredictor,
feedback);
    }

    public void OnRemove(PSModuleInfo psModuleInfo)
    {
        SubsystemManager.UnregisterSubsystem< ICommandPredictor>(new
Guid(Id));
        SubsystemManager.UnregisterSubsystem< IFeedbackProvider>(new
Guid(Id));
    }
}
```

Replace the `<ADD YOUR GUID HERE>` placeholder value with a unique Guid. You can generate a Guid using the `New-Guid` cmdlet.

PowerShell

```
New-Guid
```

The Guid is a unique identifier for your provider. The provider must have a unique Id to be registered with the subsystem.

Step 4 - Add class members and define the constructor

The following code implements the properties defined in the interfaces, adds needed class members, and creates the constructor for the `myFeedbackProvider` class.

C#

```
/// <summary>
/// Gets the global unique identifier for the subsystem implementation.
/// </summary>
private readonly Guid _guid;
public Guid Id => _guid;

/// <summary>
/// Gets the name of a subsystem implementation, this will be the name
displayed when triggered
/// </summary>
public string Name => "myFeedbackProvider";

/// <summary>
/// Gets the description of a subsystem implementation.
/// </summary>
public string Description => "This is very simple feedback provider";

/// <summary>
/// Default implementation. No function is required for a feedback provider.
/// </summary>
Dictionary<string, string>? ISubsystem.FunctionsToDefine => null;

/// <summary>
/// Gets the types of trigger for this feedback provider.
/// </summary>
/// <remarks>
/// The default implementation triggers a feedback provider by <see
/// cref="FeedbackTrigger.CommandNotFound"/> only.
/// </remarks>
public FeedbackTrigger Trigger => FeedbackTrigger.All;

/// <summary>
/// List of candidates from the feedback provider to be passed as predictor
results
/// </summary>
private List<string>? _candidates;

/// <summary>
/// PowerShell session used to run PowerShell commands that help create
suggestions.
/// </summary>
private PowerShell _powershell;

internal myFeedbackProvider(string guid)
```

```
{  
    _guid = new Guid(guid); // Save guid  
    _powershell = PowerShell.Create(); // Create PowerShell instance  
}
```

Step 5 - Create the GetFeedback() method

The `GetFeedback` method takes two parameters, `context` and `token`. The `context` parameter receives the information about the trigger so you can decide how to respond with suggestions. The `token` parameter is used for cancellation. This function returns a `FeedbackItem` containing the suggestion.

C#

```
/// <summary>  
/// Gets feedback based on the given commandline and error record.  
/// </summary>  
/// <param name="context">The context for the feedback call.</param>  
/// <param name="token">The cancellation token to cancel the operation.  
</param>  
/// <returns>The feedback item.</returns>  
public FeedbackItem? GetFeedback(FeedbackContext context, CancellationToken  
token)  
{  
    // Target describes the different kinds of triggers to activate on,  
    var target = context.Trigger;  
    var commandLine = context.CommandLine;  
    var ast = context.CommandLineAst;  
  
    // defining the header and footer variables  
    string header;  
    string footer;  
  
    // List of the actions  
    List<string>? actions = new List<string>();  
  
    // Trigger on success code goes here  
  
    // Trigger on error code goes here  
  
    return null;  
}
```

The following image shows how these fields are used in the suggestions that are displayed to the user.

```
[this is the name of feedback provider]
  this is the header
    > these
    > are
    > actions

  this is the footer
```

Create suggestions for a Success trigger

For a successful invocation, we want to expand any aliases used in the last execution. Using the `CommandLineAst`, we identify any aliased commands and create a suggestion to use the fully qualified command name instead.

C#

```
// Trigger on success
if (target == FeedbackTrigger.Success)
{
    // Getting the commands from the AST and only finding those that are
    Commands
    var astCmds = ast.FindAll((cAst) => cAst is CommandAst, true);

    // Inspect each of the commands
    foreach(var command in astCmds)
    {

        // Get the command name
        var aliasedCmd = ((CommandAst) command).GetCommandName();

        // Check if its an alias or not, if so then add it to the list of
        actions
        if(TryGetAlias(aliasedCmd, out string commandString))
        {
            actions.Add($"{aliasedCmd} --> {commandString}");
        }
    }

    // If no alias was found return null
    if(actions.Count == 0)
    {
        return null;
    }

    // If aliases are found, set the header to a description and return a
    new FeedbackItem.
    header = "You have used an aliased command:";
    // Copy actions to _candidates for the predictor
    _candidates = actions;
```

```
        return new FeedbackItem(header, actions);
    }
```

Implement the TryGetAlias() method

The `TryGetAlias()` method is a private helper function that returns a boolean value to indicate whether the command is an alias. In the class constructor, we created a PowerShell instance that we can use to run PowerShell commands. The `TryGetAlias()` method uses this PowerShell instance to invoke the `GetCommand` method to determine if the command is an alias. The `AliasInfo` object returned by `GetCommand` contains full name of the aliased command.

C#

```
/// <summary>
/// Checks if a command is an alias.
/// </summary>
/// <param name="command">The command to check if alias</param>
/// <param name="targetCommand">The referenced command by the aliased
/// command</param>
/// <returns>True if an alias and false if not</returns>
private bool TryGetAlias(string command, out string targetCommand)
{
    // Create PowerShell runspace as a session state proxy to run GetCommand
    // and check
    // if its an alias
    AliasInfo? pwshAliasInfo =
        _powershell.Runspace.SessionStateProxy.InvokeCommand.GetCommand(command,
        CommandTypes.Alias) as AliasInfo;

    // if its null then it is not an aliased command so just return false
    if(pwshAliasInfo is null)
    {
        targetCommand = String.Empty;
        return false;
    }

    // Set targetCommand to referenced command name
    targetCommand = pwshAliasInfo.ReferencedCommand.Name;
    return true;
}
```

Create suggestions for a Failure trigger

When a command execution fails, we want to suggest that the user `Get-Help` to get more information about how to use the command.

C#

```
// Trigger on error
if (target == FeedbackTrigger.Error)
{
    // Gets the command that caused the error.
    var erroredCommand = context.LastError?.InvocationInfo.MyCommand;
    if (erroredCommand is null)
    {
        return null;
    }

    header = $"You have triggered an error with the command
{erroredCommand}. Try using the following command to get help:";

    actions.Add($"Get-Help {erroredCommand}");
    footer = $"You can also check online documentation at
https://learn.microsoft.com/en-us/powershell/module/?term={erroredCommand}";

    // Copy actions to _candidates for the predictor
    _candidates = actions;
    return new FeedbackItem(header, actions, footer,
FeedbackDisplayLayout.Portrait);
}
```

Step 6 - Send suggestions to the command line predictor

Another way your feedback provider can enhance the user experience is to provide command suggestions to the **ICommandPredictor** interface. For more information about creating a command line predictor, see [How to create a command line predictor](#).

The following code implements the methods necessary from the **ICommandPredictor** interface to add predictor behavior to your feedback provider.

- `CanAcceptFeedback()` - This method returns a Boolean value that indicates whether the predictor accepts a specific type of feedback.
- `GetSuggestion()` - This method returns a `SuggestionPackage` object that contains the suggestions to be displayed by the predictor.
- `OnCommandLineAccepted()` - This method is called when a command line is accepted to execute.

C#

```
/// <summary>
/// Gets a value indicating whether the predictor accepts a specific kind of
/// feedback.
```

```

    ///> </summary>
    ///> <param name="client">Represents the client that initiates the call.</param>
    ///> <param name="feedback">A specific type of feedback.</param>
    ///> <returns>True or false, to indicate whether the specific feedback is accepted.</returns>
    public bool CanAcceptFeedback(PredictionClient client, PredictorFeedbackKind feedback)
    {
        return feedback switch
        {
            PredictorFeedbackKind.CommandLineAccepted => true,
            _ => false,
        };
    }

    ///> <summary>
    ///> Get the predictive suggestions. It indicates the start of a suggestion rendering session.
    ///> </summary>
    ///> <param name="client">Represents the client that initiates the call.</param>
    ///> <param name="context">The <see cref="PredictionContext"/> object to be used for prediction.</param>
    ///> <param name="cancellationToken">The cancellation token to cancel the prediction.</param>
    ///> <returns>An instance of <see cref="SuggestionPackage"/>.</returns>
    public SuggestionPackage GetSuggestion(
        PredictionClient client,
        PredictionContext context,
        CancellationToken cancellationToken)
    {
        if (_candidates is not null)
        {
            string input = context.InputAst.Extent.Text;
            List<PredictiveSuggestion>? result = null;

            foreach (string c in _candidates)
            {
                if (c.StartsWith(input, StringComparison.OrdinalIgnoreCase))
                {
                    result ??= new List<PredictiveSuggestion>(_candidates.Count);
                    result.Add(new PredictiveSuggestion(c));
                }
            }

            if (result is not null)
            {
                return new SuggestionPackage(result);
            }
        }

        return default;
    }
}

```

```

/// <summary>
/// A command line was accepted to execute.
/// The predictor can start processing early as needed with the latest
/// history.
/// </summary>
/// <param name="client">Represents the client that initiates the call.
</param>
/// <param name="history">History command lines provided as references for
/// prediction.</param>
public void OnCommandLineAccepted(PredictionClient client,
IReadOnlyList<string> history)
{
    // Reset the candidate state once the command is accepted.
    _candidates = null;
}

```

Step 7 - Build the feedback provider

Now you are ready to build and begin using your feedback provider! To build the project, run the following command:

PowerShell

```
dotnet build
```

This command create the PowerShell module as a DLL file in the following path of your project folder: `bin/Debug/net8.0/myFeedbackProvider`

You may run into the error `error NU1101: Unable to find package`

`System.Management.Automation`. when building on Windows machines. To fix this add a `nuget.config` file to your project directory and add the following:

YAML

```

<?xml version="1.0" encoding="utf-8"?>
<configuration>
    <packageSources>
        <clear />
        <add key="nuget.org" value="https://api.nuget.org/v3/index.json" />
    </packageSources>
    <disabledPackageSources>
        <clear />
    </disabledPackageSources>
</configuration>

```

Using a feedback provider

To test your new feedback provider, import the compiled module into your PowerShell session. This can be done by importing the folder described after building has succeeded:

```
PowerShell
```

```
Import-Module ./bin/Debug/net8.0/myFeedbackProvider
```

Once you're satisfied with your module, you should create a module manifest, publish it to the PowerShell Gallery, and install it in your `$Env:PSModulePath`. For more information, see [How to create a module manifest](#). You can add the `Import-Module` command to your `$PROFILE` script so the module is available in PowerShell session.

You can get a list of installed feedback providers, using the following command:

```
PowerShell
```

```
Get-PSSubsystem -Kind FeedbackProvider
```

```
Output
```

Kind	SubsystemType	IsRegistered	Implementations
---	-----	-----	-----
FeedbackProvider	IFeedbackProvider	True	{general}

ⓘ Note

`Get-PSSubsystem` is an experimental cmdlet that was introduced in PowerShell 7.1. You must enable the `PSSubsystemPluginModel` experimental feature to use this cmdlet. For more information, see [Using Experimental Features](#).

The following screenshot shows some example suggestions from the new provider.

```
PS C:\Users\stevenbucher.REDMOND> Get-ChildItem -badparameter
Get-ChildItem: A parameter cannot be found that matches parameter name 'badparameter'.

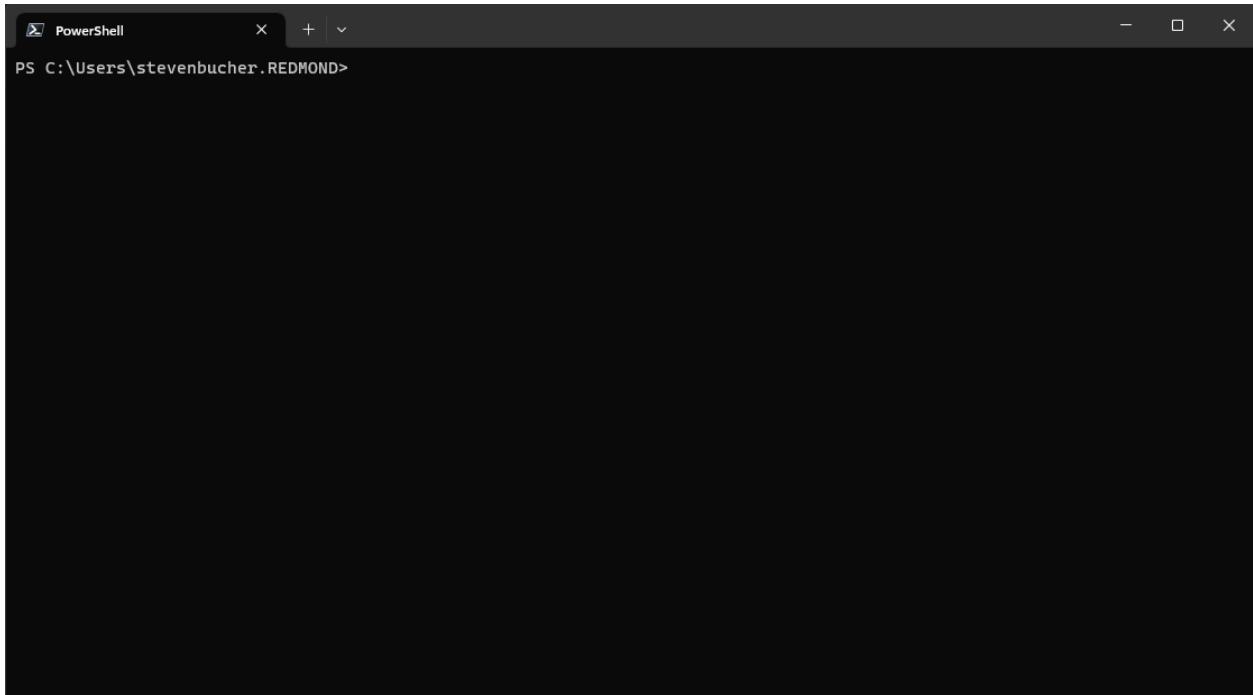

[myFeedbackProvider]
You have triggered an error with the command Get-ChildItem. Try using the following command to get help:
  > Get-Help Get-ChildItem

You can also check online documentation at https://learn.microsoft.com/en-us/powershell/module/?term=Get-ChildItem

PS C:\Users\stevenbucher.REDMOND> oh -In "Hello World"
Hello World

[myFeedbackProvider]
You have used an aliased command:
  > oh --> Out-Host
```

The following is a GIF showing how the predictor integration works from the new provider.

Other feedback providers

We have created other feedback provider that can be used as a good reference for deeper examples.

command-not-found

The `command-not-found` feedback provider utilizes the `command-not-found` utility tool on Linux systems to provide suggestions when native commands are attempted to run but are missing. You can find the code in the [GitHub Repository](#) or can download for yourself on the [PowerShell Gallery](#).

PowerShell Adapter

The `Microsoft.PowerShell.PowerShellAdapter` is a feedback provider that helps you convert text outputs from native commands into PowerShell objects. It detects "adapters" on your system and suggests you to use them when you use the native command. You can learn more about PowerShell Adapters from, [PowerShell Adapter Feedback Provider](#) blog post. You can also find the code in the [GitHub Repository](#) or can download for yourself on the [PowerShell Gallery](#).

Appendix - Full implementation code

The following code combines the previous examples into the full implementation of the provider class.

C#

```
using System.Management.Automation;
using System.Management.Automation.Subsystem;
using System.Management.Automation.Subsystem.Feedback;
using System.Management.Automation.Subsystem.Prediction;
using System.Management.Automation.Language;

namespace myFeedbackProvider;

public sealed class myFeedbackProvider : IFeedbackProvider,
ICommandPredictor
{
    /// <summary>
    /// Gets the global unique identifier for the subsystem implementation.
    /// </summary>
    private readonly Guid _guid;
    public Guid Id => _guid;

    /// <summary>
    /// Gets the name of a subsystem implementation, this will be the name
    displayed when triggered
    /// </summary>
    public string Name => "myFeedbackProvider";

    /// <summary>
    /// Gets the description of a subsystem implementation.
    /// </summary>
    public string Description => "This is very simple feedback provider";

    /// <summary>
    /// Default implementation. No function is required for a feedback
    provider.
    /// </summary>
    Dictionary<string, string>? ISubsystem.FunctionsToDefine => null;

    /// <summary>
    /// Gets the types of trigger for this feedback provider.
    /// </summary>
```

```

    ///</summary>
    ///<remarks>
    /// The default implementation triggers a feedback provider by <see
    cref="FeedbackTrigger.CommandNotFound"/> only.
    ///</remarks>
    public FeedbackTrigger Trigger => FeedbackTrigger.All;

    ///<summary>
    /// List of candidates from the feedback provider to be passed as
    predictor results
    ///</summary>
    private List<string>? _candidates;

    ///<summary>
    /// PowerShell session used to run PowerShell commands that help create
    suggestions.
    ///</summary>
    private PowerShell _powershell;

    // Constructor
    internal myFeedbackProvider(string guid)
    {
        _guid = new Guid(guid); // Save guid
        _powershell = PowerShell.Create(); // Create PowerShell instance
    }

    #region IFeedbackProvider
    ///<summary>
    /// Gets feedback based on the given commandline and error record.
    ///</summary>
    ///<param name="context">The context for the feedback call.</param>

Create XML-based help using PlatyPS

Article • 12/12/2024

When creating a PowerShell module, it's always recommended that you include detailed help for the cmdlets you create. If your cmdlets are implemented in compiled code, you must use the XML-based help. This XML format is known as the Microsoft Assistance Markup Language (MAML).

The legacy PowerShell SDK documentation covers the details of creating help for PowerShell cmdlets packaged into modules. However, PowerShell doesn't provide any tools for creating the XML-based help. The SDK documentation explains the structure of MAML help, but leaves you the task of creating the complex, and deeply nested, MAML content by hand.

This is where the [PlatyPS](#) module can help.

What is PlatyPS?

PlatyPS is an [open-source](#) tool that started as a *hackathon* project to make the creation and maintenance of MAML easier. PlatyPS documents the syntax of parameter sets and the individual parameters for each cmdlet in your module. PlatyPS creates structured [Markdown](#) files that contain the syntax information. It can't create descriptions or provide examples.

PlatyPS creates placeholders for you to fill in descriptions and examples. After adding the required information, PlatyPS compiles the Markdown files into MAML files. PowerShell's help system also allows for plain-text conceptual help files (about topics). PlatyPS has a cmdlet to create a structured Markdown template for a new *about* file, but these `about_*.help.txt` files must be maintained manually.

You can include the MAML and Text help files with your module. You can also use PlatyPS to compile the help files into a CAB package that can be hosted for updateable help.

Get started using PlatyPS

First you must install PlatyPS from the PowerShell Gallery.

```
PowerShell

# Install using PowerShellGet 2.x
Install-Module platyps -Force

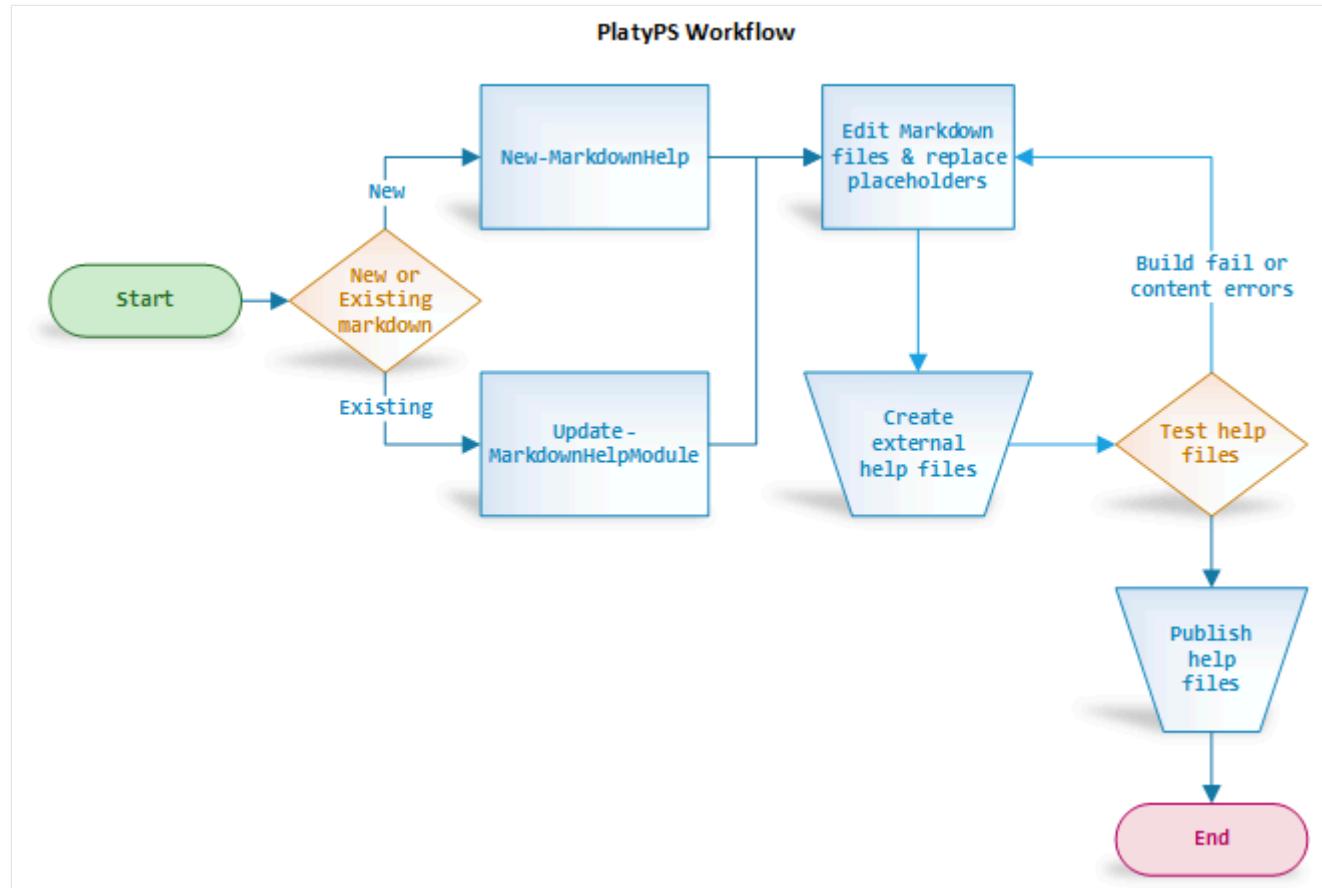

# Install using PSResourceGet 1.x
Install-PSResource platyps -Reinstall
```

After installing PlatyPS, import the module into your session.

PowerShell

```
Import-Module platyp
```

The following flowchart outlines the process for creating or updating PowerShell reference content.

Create Markdown content for a PowerShell module

1. Import your new module into the session. Repeat this step for each module you need to document.

Run the following command to import your modules:

PowerShell

```
Import-Module <your module name>
```

2. Use PlatyPS to generate Markdown files for your module page and all associated cmdlets within the module. Repeat this step for each module you need to document.

PowerShell

```
$OutputFolder = <output path>
$parameters = @{
    Module = <ModuleName>
    OutputFolder = $OutputFolder
    AlphabeticParamsOrder = $true
    WithModulePage = $true
    ExcludeDontShow = $true
    Encoding = [System.Text.Encoding]::UTF8
}
New-MarkdownHelp @parameters

New-MarkdownAboutHelp -OutputFolder $OutputFolder -AboutName "topic_name"
```

If the output folder doesn't exist, `New-MarkdownHelp` creates it. In this example, `New-MarkdownHelp` creates a Markdown file for each cmdlet in the module. It also creates the *module page* in a file named `<ModuleName>.md`. This module page contains a list of the cmdlets contained in the module and placeholders for the *Synopsis* description. The metadata in the module page comes from the module manifest and is used by PlatyPS to create the `HelpInfo` XML file (as explained [below](#)).

`New-MarkdownAboutHelp` creates a new *about* file named `about_topic_name.md`.

For more information, see [New-MarkdownHelp](#) and [New-MarkdownAboutHelp](#).

Update existing Markdown content when the module changes

PlatyPS can also update existing Markdown files for a module. Use this step to update existing modules that have new cmdlets, new parameters, or parameters that have changed.

1. Import your new module into the session. Repeat this step for each module you need to document.

Run the following command to import your modules:

PowerShell

```
Import-Module <your module name>
```

2. Use PlatyPS to update Markdown files for your module landing page and all associated cmdlets within the module. Repeat this step for each module you need to document.

PowerShell

```
$parameters = @{
    Path = <folder with Markdown>
    RefreshModulePage = $true
    AlphabeticParamsOrder = $true
    UpdateInputOutput = $true
    ExcludeDontShow = $true
    LogPath = <path to store log file>
    Encoding = [System.Text.Encoding]::UTF8
}
Update-MarkdownHelpModule @parameters
```

`Update-MarkdownHelpModule` updates the cmdlet and module Markdown files in the specified folder. It doesn't update the `about_*.md` files. The module file (`ModuleName.md`) receives any new **Synopsis** text that has been added to the cmdlet files. Updates to cmdlet files include the following change:

- New parameter sets
- New parameters
- Updated parameter metadata
- Updated input and output type information

For more information, see [Update-MarkdownHelpModule](#).

Edit the new or updated Markdown files

PlatyPS documents the syntax of the parameter sets and the individual parameters. It can't create descriptions or provide examples. The specific areas where content is needed are contained in curly braces. For example: `{{ Fill in the Description }}`

```
File Edit Selection View Go Run Terminal Help New-CMAdministrativeUserPermission.md - ConfigurationManager - Visual Studio Code
New-CMAdministrativeUserPermission.md (deleted) X
New-CMAdministrativeUserPermission.md > # New-CMAdministrativeUserPermission > ## EXAMPLES > ### Example 1
35 [-CollectionName <String[]>] [-Collection <IResultObject[]>] [-DisableWildcardHandling]
36 [-ForceWildcardHandling] [<CommonParameters>]
37
38
39 ## DESCRIPTION
40 {{ Fill in the Description }}
41
42 > [!NOTE]
43 Configuration Manager cmdlets must be run from the Configuration Manager site drive.
44 The examples in this article use the site name **XYZ**. For more information, see the
45 [getting started](/powershell/sccm/overview) documentation.
46
47 ## EXAMPLES
48
49 #### Example 1
50 powershell
51 PS XYZ:\> {{ Add example code here }}
52 ...
53
54 {{ Add example description here }}
55
56 ## PARAMETERS
57
58 #### -Collection
59 {{ Fill Collection Description }}
60
61 ````yaml
62 Type: IResultObject[]
63 Parameter Sets: (All)
64 Aliases: Collections
65
66 Required: False
67 Position: Named
68 Default Value: None
69 Accept Pipeline Input: False
70 Accept Wildcard Characters: False
71 ````
```

You need to add a synopsis, a description of the cmdlet, descriptions for each parameter, and at least one example.

For detailed information about writing PowerShell content, see the following articles:

- [PowerShell style guide](#)
- [Editing reference articles](#)

(!) Note

PlatyPS has a specific schema that's used for cmdlet reference. That schema only allows certain Markdown blocks in specific sections of the document. If you put content in the wrong location, the PlatyPS build step fails. For more information, see the [schema](#) documentation in the PlatyPS repository. For a complete example of well-formed cmdlet reference, see [Get-Item](#).

After providing the required content for each of your cmdlets, you need to make sure that you update the module landing page. Verify your module has the correct [Module Guid](#) and

Download Help Link values in the YAML metadata of the <module-name>.md file. Add any missing metadata.

Also, you may notice that some cmdlets may be missing a **Synopsis** (*short description*). The following command updates the module landing page with your **Synopsis** description text. Open the module landing page to verify the descriptions.

PowerShell

```
Update-MarkdownHelpModule -Path <full path output folder> -RefreshModulePage
```

Now that you have entered all the content, you can create the MAML help files that are displayed by Get-Help in the PowerShell console.

Create the external help files

This step creates the MAML help files that are displayed by Get-Help in the PowerShell console.

To build the MAML files, run the following command:

PowerShell

```
New-ExternalHelp -Path <folder with MDs> -OutputPath <output help folder>
```

New-ExternalHelp converts all cmdlet Markdown files into one (or more) MAML files. About files are converted to plain-text files with the following name format:

about_topic_name.help.txt. The Markdown content must meet the requirement of the PlatyPS schema. New-ExternalHelp exits with errors when the content doesn't follow the schema. You must edit the files to fix the schema violations.

✖ Caution

PlatyPS does a poor job converting the about_*.md files to plain text. You must use very simple Markdown to get acceptable results. You may want to maintain the files in plain-text about_topic_name.help.txt format, rather than allowing PlatyPS to convert them.

Once this step is complete, you will see *-help.xml and about_*.help.txt files in the target output folder.

For more information, see [New-ExternalHelp](#)

Test the compiled help files

You can verify the content with the [Get-HelpPreview](#) cmdlet:

```
PowerShell
```

```
Get-HelpPreview -Path "<ModuleName>-Help.xml"
```

The cmdlet reads the compiled MAML file and outputs the content in the same format you would receive from [Get-Help](#). This allows you to inspect the results to verify that the Markdown files compiled correctly and produce the desired results. If you find an error, re-edit the Markdown files and recompile the MAML.

Now you are ready to publish your help files.

Publishing your help

Now that you have compiled the Markdown files into PowerShell help files, you are ready to make the files available to users. There are two options for providing help in the PowerShell console.

- Package the help files with the module
- Create an updateable help package that users install with the [Update-Help](#) cmdlet

Packaging help with the module

The help files can be packaged with your module. See [Writing Help for Modules](#) for details of the folder structure. You should include the list of Help files in the value of the **FileList** key in the module manifest.

Creating an updateable help package

At a high level, the steps to create updateable help include:

1. Find an internet site to host your help files
2. Add a **HelpInfoURI** key to your module manifest
3. Create a HelpInfo XML file
4. Create CAB files
5. Upload your files

For more information, see [Supporting Updateable Help: Step-by-step](#).

PlatyPS assists you with some of these steps.

The **HelpInfoURI** is a URL that points to location where your help files are hosted on the internet. This value is configured in the module manifest. `Update-Help` reads the module manifest to get this URL and download the updateable help content. This URL should only point to the folder location and not to individual files. `Update-Help` constructs the filenames to download based on other information from the module manifest and the HelpInfo XML file.

Important

The **HelpInfoURI** must end with a forward-slash character (/). Without that character, `Update-Help` can't construct the correct file paths to download the content. Also, most HTTP-based file services are case-sensitive. It's important that the module metadata in the HelpInfo XML file contains the proper letter case.

The `New-ExternalHelp` cmdlet creates the HelpInfo XML file in the output folder. The HelpInfo XML file is built using YAML metadata contained in the module Markdown files (`ModuleName.md`).

The `New-ExternalHelpCab` cmdlet creates ZIP and CAB files containing the MAML and `about_*.help.txt` files you compiled. CAB files are compatible with all versions of PowerShell. PowerShell 6 and higher can use ZIP files.

PowerShell

```
$helpCabParameters = @{
    CabFilesFolder = $MamlOutputFolder
    LandingPagePath = $LandingPage
    OutputFolder = $CabOutputFolder
}
New-ExternalHelpCab @helpCabParameters
```

After creating the ZIP and CAB files, upload the ZIP, CAB, and HelpInfo XML files to your HTTP file server. Put the files in the location indicated by the **HelpInfoURI**.

For more information, see [New-ExternalHelpCab](#).

Other publishing options

Markdown is a versatile format that's easy to transform to other formats for publishing. Using a tool like [Pandoc](#) ↗, you can convert your Markdown help files to many different document formats, including plain text, HTML, PDF, and Office document formats.

Also, the cmdlets [ConvertFrom-Markdown](#) and [Show-Markdown](#) in PowerShell 6 and higher can be used to convert Markdown to HTML or create a colorful display in the PowerShell console.

Known issues

PlatyPS is very sensitive to the [schema](#) for the structure of the Markdown files it creates and compiles. It's very easy write valid Markdown that violates this schema. For more information, see the [PowerShell style guide](#) and [Editing reference articles](#).

Windows PowerShell Language Specification 3.0

Article • 01/08/2025

Editorial note

Important

The *Windows PowerShell Language Specification 3.0* was published in December 2012 and is based on Windows PowerShell 3.0. This specification does not reflect the current state of PowerShell. There is no plan to update this documentation to reflect the current state. This documentation is presented here for historical reference.

The specification document is available as a Microsoft Word document from the Microsoft Download Center at:

<https://www.microsoft.com/download/details.aspx?id=36389> That Word document has been converted for presentation here on Microsoft Learn. During conversion, some editorial changes have been made to accommodate formatting for the Docs platform. Some typos and minor errors have been corrected.

1. Introduction

PowerShell is a command-line *shell* and scripting language, designed especially for system administrators.

Most shells operate by executing a command or utility in a new process, and presenting the results to the user as text. These shells also have commands that are built into the shell and run in the shell process. Because there are few built-in commands, many utilities have been created to supplement them. PowerShell is very different. Instead of processing text, the shell processes objects. PowerShell also includes a large set of built-in commands with each having a consistent interface and these can work with user-written commands.

An *object* is a data entity that has *properties* (i.e., characteristics) and *methods* (i.e., actions that can be performed on the object). All objects of the same type have the same base set of properties and methods, but each *instance* of an object can have different property values.

A major advantage of using objects is that it is much easier to *pipeline* commands; that is, to write the output of one command to another command as input. (In a traditional command-line environment, the text output from one command needs to be manipulated to meet the input format of another.)

PowerShell includes a very rich scripting language that supports constructs for looping, conditions, flow-control, and variable assignment. This language has syntax features and keywords similar to those used in the C# programming language ([§C](#)).

There are four kinds of commands in PowerShell: scripts, functions and methods, cmdlets, and native commands.

- A file of commands is called a *script*. By convention, a script has a filename extension of .ps1. The top-most level of a PowerShell program is a script, which, in turn, can invoke other commands.
- PowerShell supports modular programming via named procedures. A procedure written in PowerShell is called a *function*, while an external procedure made available by the execution environment (and typically written in some other language) is called a *method*.
- A *cmdlet* (pronounced "command-let") is a simple, single-task command-line tool. Although a cmdlet can be used on its own, the full power of cmdlets is realized when they are used in combination to perform complex tasks.
- A *native command* is part of the host environment.

Each time the PowerShell runtime environment begins execution, it begins what is called a *session*. Commands then execute within the context of that session.

This specification defines the PowerShell language, the built-in cmdlets, and the use of objects via the pipeline.

Unlike most shells, which accept and return text, Windows PowerShell is built on top of the .NET Framework common language runtime (CLR) and the .NET Framework, and accepts and returns .NET Framework objects.

2. Lexical Structure

Article • 04/23/2024

Editorial note

Important

The *Windows PowerShell Language Specification 3.0* was published in December 2012 and is based on Windows PowerShell 3.0. This specification does not reflect the current state of PowerShell. There is no plan to update this documentation to reflect the current state. This documentation is presented here for historical reference.

The specification document is available as a Microsoft Word document from the Microsoft Download Center at:

<https://www.microsoft.com/download/details.aspx?id=36389> That Word document has been converted for presentation here on Microsoft Learn. During conversion, some editorial changes have been made to accommodate formatting for the Docs platform. Some typos and minor errors have been corrected.

2.1 Grammars

This specification shows the syntax of the PowerShell language using two grammars. The *lexical grammar* ([§B.1](#)) shows how Unicode characters are combined to form line terminators, comments, white space, and tokens. The *syntactic grammar* ([§B.2](#)) shows how the tokens resulting from the lexical grammar are combined to form PowerShell scripts.

For convenience, fragments of these grammars are replicated in appropriate places throughout this specification.

Any use of the characters 'a' through 'z' in the grammars is case insensitive. This means that letter case in variables, aliases, function names, keywords, statements, and operators is ignored. However, throughout this specification, such names are written in lowercase, except for some automatic and preference variables.

2.2 Lexical analysis

2.2.1 Scripts

Syntax:

Tip

The `~opt~` notation in the syntax definitions indicates that the lexical entity is optional in the syntax.

Syntax

```
input:
    input-elements~opt~    signature-block~opt~

input-elements:
    input-element
    input-elements    input-element

input-element:
    whitespace
    comment
    token

signature-block:
    signature-begin    signature    signature-end

signature-begin:
    new-line-character    # SIG # Begin signature block    new-line-character

signature:
    base64 encoded signature blob in multiple single-line-comments

signature-end:
    new-line-character    # SIG # End signature block    new-line-character
```

Description:

The input source stream to a PowerShell translator is the *input* in a script, which contains a sequence of Unicode characters. The lexical processing of this stream involves the reduction of those characters into a sequence of tokens, which go on to become the input of syntactic analysis.

A script is a group of PowerShell commands stored in a *script-file*. The script itself has no name, per se, and takes its name from its source file. The end of that file indicates the end of the script.

A script may optionally contain a digital signature. A host environment is not required to process any text that follows a signature or anything that looks like a signature. The creation and use of digital signatures are not covered by this specification.

2.2.2 Line terminators

Syntax:

```
Syntax

new-line-character:
    Carriage return character (U+000D)
    Line feed character (U+000A)
    Carriage return character (U+000D) followed by line feed character
(U+000A)

new-lines:
    new-line-character
    new-lines new-line-character
```

Description:

The presence of *new-line-characters* in the input source stream divides it into lines that can be used for such things as error reporting and the detection of the end of a single-line comment.

A line terminator can be treated as white space ([§2.2.4](#)).

2.2.3 Comments

Syntax:

```
Syntax

comment:
    single-line-comment
    requires-comment
    delimited-comment

single-line-comment:
    # input-characters~opt~

input-characters:
    input-character
    input-characters input-character

input-character:
    Any Unicode character except a new-line-character
```

```

requires-comment:
    #Requires whitespace command-arguments

dash:
    - (U+002D)
        EnDash character (U+2013)
        EmDash character (U+2014)
        Horizontal bar character (U+2015)

dashdash:
    dash dash

delimited-comment:
    < # delimited-comment-text~opt~ hashes >

delimited-comment-text:
    delimited-comment-section
    delimited-comment-text delimited-comment-section

delimited-comment-section:
    >
    hashes~opt~ not-greater-than-or-hash

hashes:
    #
    hashes #

not-greater-than-or-hash:
    Any Unicode character except > or #

```

Description:

Source code can be annotated by the use of *comments*.

A *single-line-comment* begins with the character `#` and ends with a *new-line-character*.

A *delimited-comment* begins with the character pair `<#` and ends with the character pair `#>`. It can occur as part of a source line, as a whole source line, or it can span any number of source lines.

A comment is treated as white space.

The productions above imply that

- Comments do not nest.
- The character sequences `<#` and `#>` have no special meaning in a single-line comment.
- The character `#` has no special meaning in a delimited comment.

The lexical grammar implies that comments cannot occur inside tokens.

(See §A for information about creating script files that contain special-valued comments that are used to generate documentation from script files.)

A *requires-comment* specifies the criteria that have to be met for its containing script to be allowed to run. The primary criterion is the version of PowerShell being used to run the script. The minimum version requirement is specified as follows:

```
#Requires -Version N[.n]
```

Where *N* is the (required) major version and *n* is the (optional) minor version.

A *requires-comment* can be present in any script file; however, it cannot be present inside a function or cmdlet. It must be the first item on a source line. A script can contain multiple *requires-comments*.

A character sequence is only recognized as a comment if that sequence begins with # or <#. For example, hello#there is considered a single token whereas hello #there is considered the token hello followed by a single-line comment. As well as following white space, the comment start sequence can also be preceded by any expression-terminating or statement-terminating character (such as), },], ', ", or ;).

A *requires-comment* cannot be present inside a snap-in.

There are four other forms of a *requires-comment*:

Syntax

```
#Requires -Assembly AssemblyId  
#Requires -Module ModuleName  
#Requires -PSSnapin PSSnapin [ -Version *N* [.n] ]  
#Requires -ShellId ShellId
```

2.2.4 White space

Syntax:

Syntax

whitespace:

Any character with Unicode class Zs, Zl, or Zp
Horizontal tab character (U+0009)
Vertical tab character (U+000B)

```
Form feed character (U+000C)
` (The backtick character U+0060) followed by new-line-character
```

Description:

White space consists of any sequence of one or more *whitespace* characters.

Except for the fact that white space may act as a separator for tokens, it is ignored.

Unlike some popular languages, PowerShell does not consider line-terminator characters ([§2.2.2](#)) to be white space. However, a line terminator can be treated as white space by preceding it immediately by a backtick character, ` (U+0060). This is necessary when the contents of a line are complete syntactically, yet the following line contains tokens intended to be associated with the previous line. For example,

PowerShell

```
$number = 10 # assigns 10 to $number; nothing is written to the pipeline
+ 20 # writes 20 to the pipeline
- 50 # writes -50 to the pipeline
$number # writes $number's value, 10, to the pipeline
```

In this example, the backtick indicates the source line is continued. The following expression is equivalent to `$number = 10 + 20 - 50`.

PowerShell

```
$number = 10 `
+ 20 `
- 50
$number # writes $number's value to the pipeline
-20
```

2.3 Tokens

Syntax:

Syntax

```
token:
  keyword
  variable
  command
  command-parameter
  command-argument-token
  integer-literal
```

```
real-literal
string-literal
type-literal
operator-or-punctuator
```

Description:

A *token* is the smallest lexical element within the PowerShell language.

Tokens can be separated by *new-lines*, comments, white space, or any combination thereof.

2.3.1 Keywords

Syntax:

Syntax

```
keyword: one of
begin      break      catch      class
continue   data       define    do
dynamicparam else      elseif    end
exit        filter     finally   for
foreach    from      function  if
in          inlinescript parallel throw
process   return     switch    param
trap       try       until    using
var        while     workflow
```

Description:

A *keyword* is a sequence of characters that has a special meaning when used in a context-dependent place. Most often, this is as the first token in a *statement*; however, there are other locations, as indicated by the grammar. (A token that looks like a keyword, but is not being used in a keyword context, is a *command-name* or a *command-argument*.)

The keywords `class`, `define`, `from`, `using`, and `var` are reserved for future use.

ⓘ Note

Editor's Note: The `class` and `using` keywords were introduced in PowerShell 5.0.

See [about Classes](#) and [about Using](#).

2.3.2 Variables

Syntax:

```
Syntax

variable:
    $$?
    $^
    $  variable-scope~opt~  variable-characters
    @  variable-scope~opt~  variable-characters
    braced-variable

braced-variable:
    ${  variable-scope~opt~  braced-variable-characters  }

variable-scope:
    Global:
    Local:
    Private:
    Script:
    Using:
    Workflow:
    variable-namespace

variable-namespace:
    variable-characters  :

variable-characters:
    variable-character
    variable-characters  variable-character

variable-character:
    A Unicode character of classes Lu, Ll, Lt, Lm, Lo, or Nd
    _  (The underscore character U+005F)
    ?

braced-variable-characters:
    braced-variable-character
    braced-variable-characters  braced-variable-character

braced-variable-character:
    Any Unicode character except
        }  (The closing curly brace character U+007D)
        `  (The backtick character U+0060)
    escaped-character

escaped-character:
    `  (The backtick character U+0060) followed by any Unicode character
```

Description:

Variables are discussed in detail in §5. The variable \$? is discussed in §2.3.2.2. Scopes are discussed in §3.5.

The variables \$\$ and \$^ are reserved for use in an interactive environment, which is outside the scope of this specification.

There are two ways of writing a variable name: A *braced variable name*, which begins with \$, followed by a curly bracket-delimited set of one or more almost-arbitrary characters; and an *ordinary variable name*, which also begins with \$, followed by a set of one or more characters from a more restrictive set than a braced variable name allows. Every ordinary variable name can be expressed using a corresponding braced variable name.

PowerShell

```
$totalCost  
$Maximum_Count_26  
  
$végösszeg # Hungarian  
$и́тог # Russian  
$総計 # Japanese (Kanji)  
  
${Maximum_Count_26}  
${Name with`twhite space and `'{punctuation`'}}  
${E:\\File.txt}
```

There is no limit on the length of a variable name, all characters in a variable name are significant, and letter case is *not* distinct.

There are several different kinds of variables: user-defined (§2.3.2.1), automatic (§2.3.2.2), and preference (§2.3.2.3). They can all coexist in the same scope (§3.5).

Consider the following function definition and calls:

PowerShell

```
function Get-Power ([long]$Base, [int]$Exponent) { ... }  
  
Get-Power 5 3 # $Base is 5, $Exponent is 3  
Get-Power -Exponent 3 -Base 5 # " " "
```

Each argument is passed by position or name, one at a time. However, a set of arguments can be passed as a group with expansion into individual arguments being

handled by the runtime environment. This automatic argument expansion is known as *splatting*. For example,

```
PowerShell

$values = 5,3 # put arguments into an array
Get-Power @values

$hash = @{ Exponent = 3; Base = 5 } # put arguments into a Hashtable
Get-Power @hash

function Get-Power2 { Get-Power @args } # arguments are in an array

Get-Power2 -Exponent 3 -Base 5 # named arguments splatted named in
@args
Get-Power2 5 3 # position arguments splatted positionally in @args
```

This is achieved by using `@` instead of `$` as the first character of the variable being passed. This notation can only be used in an argument to a command.

Names are partitioned into various namespaces each of which is stored on a virtual drive ([§3.1](#)). For example, variables are stored on `Variable:`, environment variables are stored on `Env:`, functions are stored on `Function:`, and aliases are stored on `Alias:`. All of these names can be accessed as variables using the *variable-namespace* production within *variable-scope*. For example,

```
PowerShell

function F { "Hello from F" }
$Function:F # invokes function F

Set-Alias A F
$Alias:A # invokes function F via A

$Count = 10
$Variable:Count # accesses variable Count
$Env:PATH # accesses environment variable PATH
```

Any use of a variable name with an explicit `Variable:` namespace is equivalent to the use of that same variable name without that qualification. For example, `$v` and `$Variable:v` are interchangeable.

As well as being defined in the language, variables can also be defined by the cmdlet `New-Variable`.

2.3.2.1 User-defined variables

Any variable name allowed by the grammar but not used by automatic or preference variables is available for user-defined variables.

User-defined variables are created and managed by user-defined script.

2.3.2.2 Automatic variables

Automatic variables store state information about the PowerShell environment. Their values can be read in user-written script but not written.

ⓘ Note

The table originally found in this document was removed to reduce duplication. For a complete list of automatic variables, see [about Automatic Variables](#).

2.3.2.3 Preference variables

Preference variables store user preferences for the session. They are created and initialized by the PowerShell runtime environment. Their values can be read and written in user-written script.

ⓘ Note

The table originally found in this document was removed to reduce duplication. For a complete list of preference variables, see [about Preference Variables](#).

2.3.3 Commands

Syntax:

Syntax
<pre>generic-token: generic-token-parts generic-token-parts: generic-token-part generic-token-parts generic-token-part generic-token-part: expandable-string-literal verbatim-here-string-literal variable</pre>

```

generic-token-char

generic-token-char:
  Any Unicode character except
    {   }   (   )   ;   ,   |   &   $
    ` (The backtick character U+0060)
  double-quote-character
  single-quote-character
  whitespace
  new-line-character
  escaped-character

generic-token-with-subexpr-start:
  generic-token-parts $(

```

2.3.4 Parameters

Syntax:

```

Syntax

command-parameter:
  dash first-parameter-char parameter-chars colon~opt~

first-parameter-char:
  A Unicode character of classes Lu, Ll, Lt, Lm, or Lo
  _ (The underscore character U+005F)
  ?

parameter-chars:
  parameter-char
  parameter-chars parameter-char

parameter-char:
  Any Unicode character except
    { } ( ) ; , \| & .
    colon
    whitespace
    new-line-character

colon:
  : (The colon character U+003A)

verbatim-command-argument-chars:
  verbatim-command-argument-part
  verbatim-command-argument-chars verbatim-command-argument-part

verbatim-command-argument-part:
  verbatim-command-string
  & non-ampersand-character
  Any Unicode character except
    |

```

```
new-line-character

non-ampersand-character:
    Any Unicode character except &

verbatim-command-string:
    double-quote-character non-double-quote-chars
    double-quote-character

non-double-quote-chars:
    non-double-quote-char
    non-double-quote-chars non-double-quote-char

non-double-quote-char:
    Any Unicode character except
        double-quote-character
```

Description:

When a command is invoked, information may be passed to it via one or more *arguments* whose values are accessed from within the command through a set of corresponding *parameters*. The process of matching parameters to arguments is called *parameter binding*.

There are three kinds of argument:

- Switch parameter ([§8.10.5](#)) -- This has the form *command-parameter* where *first-parameter-char* and *parameter-chars* together make up the switch name, which corresponds to the name of a parameter (without its leading -) in the command being invoked. If the trailing colon is omitted, the presence of this argument indicates that the corresponding parameter be set to `$true`. If the trailing colon is present, the argument immediately following must designate a value of type `bool`, and the corresponding parameter is set to that value. For example, the following invocations are equivalent:

```
PowerShell
```

```
Set-MyProcess -Strict
Set-MyProcess -Strict: $true
```

- Parameter with argument ([§8.10.2](#)) -- This has the form *command-parameter* where *first-parameter-char* and *parameter-chars* together make up the parameter name, which corresponds to the name of a parameter (without its leading -) in the command being invoked. There must be no trailing colon. The argument immediately following designates an associated value. For example, given a

command `Get-Power`, which has parameters `$Base` and `$Exponent`, the following invocations are equivalent:

PowerShell

```
Get-Power -Base 5 -Exponent 3  
Get-Power -Exponent 3 -Base 5
```

- Positional argument ([§8.10.2](#)) - Arguments and their corresponding parameters inside commands have positions with the first having position zero. The argument in position 0 is bound to the parameter in position 0; the argument in position 1 is bound to the parameter in position 1; and so on. For example, given a command `Get-Power`, that has parameters `$Base` and `$Exponent` in positions 0 and 1, respectively, the following invokes that command:

PowerShell

```
Get-Power 5 3
```

See [§8.2](#) for details of the special parameters `--` and `--%`.

When a command is invoked, a parameter name may be abbreviated; any distinct leading part of the full name may be used, provided that is unambiguous with respect to the names of the other parameters accepted by the same command.

For information about parameter binding see [§8.14](#).

2.3.5 Literals

Syntax:

Syntax

```
literal:  
    integer-literal  
    real-literal  
    string-literal
```

2.3.5.1 Numeric literals

There are two kinds of numeric literals: integer ([§2.3.5.1.1](#)) and real ([§2.3.5.1.2](#)). Both can have multiplier suffixes ([§2.3.5.1.3](#)).

2.3.5.1.1 Integer literals

Syntax:

```
Syntax

integer-literal:
    decimal-integer-literal
    hexadecimal-integer-literal

decimal-integer-literal:
    decimal-digits numeric-type-suffix~opt~ numeric-multiplier~opt~

decimal-digits:
    decimal-digit
    decimal-digit decimal-digits

decimal-digit: one of
    0 1 2 3 4 5 6 7 8 9

numeric-type-suffix:
    long-type-suffix
    decimal-type-suffix

hexadecimal-integer-literal:
    0x hexadecimal-digits long-type-suffix~opt~
    numeric-multiplier~opt~

hexadecimal-digits:
    hexadecimal-digit
    hexadecimal-digit decimal-digits

hexadecimal-digit: one of
    0 1 2 3 4 5 6 7 8 9 a b c d e f

long-type-suffix:
    l

numeric-multiplier: one of
    kb mb gb tb pb
```

Description:

The type of an integer literal is determined by its value, the presence or absence of *long-type-suffix*, and the presence of a *numeric-multiplier* ([§2.3.5.1.3](#)).

For an integer literal with no *long-type-suffix*

- If its value can be represented by type int ([§4.2.3](#)), that is its type;
- Otherwise, if its value can be represented by type long ([§4.2.3](#)), that is its type.

- Otherwise, if its value can be represented by type decimal ([§2.3.5.1.2](#)), that is its type.
- Otherwise, it is represented by type double ([§2.3.5.1.2](#)).

For an integer literal with *long-type-suffix*

- If its value can be represented by type long ([§4.2.3](#)), that is its type;
- Otherwise, that literal is ill formed.

In the two's-complement representation of integer values, there is one more negative value than there is positive. For the int type, that extra value is -2147483648. For the long type, that extra value is -9223372036854775808. Even though the token 2147483648 would ordinarily be treated as a literal of type long, if it is preceded immediately by the unary - operator, that operator and literal are treated as a literal of type int having the smallest value. Similarly, even though the token 9223372036854775808 would ordinarily be treated as a real literal of type decimal, if it is immediately preceded by the unary - operator, that operator and literal are treated as a literal of type long having the smallest value.

Some examples of integer literals are 123 (int), 123L (long), and 200000000000 (long).

There is no such thing as an integer literal of type byte.

2.3.5.1.2 Real literals

Syntax:

```

Syntax

real-literal:
    decimal-digits . decimal-digits exponent-part~opt~ decimal-type-
suffix~opt~ numeric-multiplier~opt~
    . decimal-digits exponent-part~opt~ decimal-type-suffix~opt~ numeric-
multiplier~opt~
    decimal-digits exponent-part decimal-type-suffix~opt~ numeric-
multiplier~opt~

exponent-part:
    e sign~opt~ decimal-digits

sign: one of
    +
    dash

decimal-type-suffix:
    d
    l

```

```
numeric-multiplier: one of
  kb mb gb tb pb

dash:
  - (U+002D)
    EnDash character (U+2013)
    EmDash character (U+2014)
    Horizontal bar character (U+2015)
```

Description:

A real literal may contain a *numeric-multiplier* ([§2.3.5.1.3](#)).

There are two kinds of real literal: *double* and *decimal*. These are indicated by the absence or presence, respectively, of *decimal-type-suffix*. (There is no such thing as a *float real literal*.)

A double real literal has type `double` ([§4.2.4.1](#)). A decimal real literal has type `decimal` ([§4.2.4.2](#)). Trailing zeros in the fraction part of a decimal real literal are significant.

If the value of *exponent-part's decimal-digits* in a double real literal is less than the minimum supported, the value of that double real literal is 0. If the value of *exponent-part's decimal-digits* in a decimal real literal is less than the minimum supported, that literal is ill formed. If the value of *exponent-part's decimal-digits* in a double or decimal real literal is greater than the maximum supported, that literal is ill formed.

Some examples of double real literals are `1.`, `1.23`, `.45e35`, `32.e+12`, and `123.456E-231`.

Some examples of decimal real literals are `1d` (which has scale 0), `1.20d` (which has scale 2), `1.23450e1d` (i.e., `12.3450`, which has scale 4), `1.2345e3d` (i.e., `1234.5`, which has scale 1), `1.2345e-1d` (i.e., `0.12345`, which has scale 5), and `1.2345e-3d` (i.e., `0.0012345`, which has scale 7).

ⓘ Note

Because a double real literal need not have a fraction or exponent part, the grouping parentheses in `(123).M` are needed to ensure that the property or method `M` is being selected for the integer object whose value is 123. Without those parentheses, the real literal would be ill-formed.

ⓘ Note

Although PowerShell does not provide literals for infinities and NaNs, double real literal-like equivalents can be obtained from the static read-only properties

`PositiveInfinity`, `NegativeInfinity`, and `NaN` of the types `float` and `double` ([§4.2.4.1](#)).

The grammar permits what starts out as a double real literal to have an `1` or `L` type suffix. Such a token is really an integer literal whose value is represented by type long.

ⓘ Note

This feature has been retained for backwards compatibility with earlier versions of PowerShell. However, programmers are discouraged from using integer literals of this form as they can easily obscure the literal's actual value. For example, `1.2L` has value 1, `1.2345e1L` has value 12, and `1.2345e-5L` has value 0, none of which is immediately obvious.

2.3.5.1.3 Multiplier suffixes

Syntax:

Syntax

```
numeric-multiplier: *one of*
    kb mb gb tb pb
```

Description:

For convenience, integer and real literals can contain a *numeric-multiplier*, which indicates one of a set of commonly used powers of 10. *numeric-multiplier* can be written in any combination of upper- or lowercase letters.

[\[+\] Expand table](#)

Multiplier	Meaning	Example
kb	kilobyte (1024)	<code>1kb</code> \equiv 1024
mb	megabyte (1024 x 1024)	<code>1.30Dmb</code> \equiv 1363148.80
gb	gigabyte (1024 x 1024 x 1024)	<code>0x10Gb</code> \equiv 17179869184
tb	terabyte (1024 x 1024 x 1024 x 1024)	<code>1.4e23tb</code> \equiv 1.5393162788864E+35

    Any Unicode character except* new-line-character  
    new-line-character Any Unicode character except single-quote-character
```

new-line-character single-quote-character Any Unicode character except

@

Description:

There are four kinds of string literals:

- *verbatim-string-literal* (single-line single-quoted), which is a sequence of zero or more characters delimited by a pair of *single-quote-characters*. Examples are " and 'red'.
- *expandable-string-literal* (single-line double-quoted), which is a sequence of zero or more characters delimited by a pair of *double-quote-characters*. Examples are "" and "red".
- *verbatim-here-string-literal* (multi-line single-quoted), which is a sequence of zero or more characters delimited by the character pairs @*single-quote-character* and *single-quote-character*@, respectively, all contained on two or more source lines. Examples are:

PowerShell

```
@'  
'@  
  
@'  
line 1  
'@  
  
@'  
line 1  
line 2  
'@
```

- *expandable-here-string-literal* (multi-line double-quoted), which is a sequence of zero or more characters delimited by the character pairs @*double-quote-character* and *double-quote-character*@, respectively, all contained on two or more source lines. Examples are:

PowerShell

```
@"  
"@  
  
@"  
line 1  
"@"
```

```
@"
line 1
line 2
"@
```

For *verbatim-here-string-literals* and *expandable-here-string-literals*, except for white space (which is ignored) no characters may follow on the same source line as the opening delimiter-character pair, and no characters may precede on the same source line as the closing delimiter character pair.

The *body* of a *verbatim-here-string-literal* or an *expandable-here-string-literal* begins at the start of the first source line following the opening delimiter, and ends at the end of the last source line preceding the closing delimiter. The body may be empty. The line terminator on the last source line preceding the closing delimiter is not part of that literal's body.

A literal of any of these kinds has type string ([§4.3.1](#)).

The character used to delimit a *verbatim-string-literal* or *expandable-string-literal* can be contained in such a string literal by writing that character twice, in succession. For example, `'What''s the time?'` and `"I said, ""Hello""."`. However, a *single-quote-character* has no special meaning inside an *expandable-string-literal*, and a *double-quote-character* has no special meaning inside a *verbatim-string-literal*.

An *expandable-string-literal* and an *expandable-here-string-literal* may contain *escaped-characters* ([§2.3.7](#)). For example, when the following string literal is written to the pipeline, the result is as shown below:

PowerShell

```
"column1`tcolumn2`nsecond line, `"Hello`", ```Q`5`!"
```

Output

```
column1<horizontal-tab>column2<new-line>
second line, "Hello", `Q5!
```

If an *expandable-string-literal* or *expandable-here-string-literal* contains the name of a variable, unless that name is preceded immediately by an escape character, it is replaced by the string representation of that variable's value ([§6.7](#)). This is known as *variable substitution*.

ⓘ Note

If the variable name is part of some larger expression, only the variable name is replaced. For example, if `$a` is an array containing the elements 100 and 200, `">$a.Length<"` results in `>100 200.Length<` while `">$($a.Length)<"` results in `>2<`. See sub-expression expansion below.

For example, the source code

PowerShell

```
$count = 10  
"The value of `$count is $count"
```

results in the *expandable-string-literal*

Output

```
The value of $count is 10.
```

Consider the following:

PowerShell

```
$a = "red", "blue"  
``$a[0] is $a[0], `$a[0] is $($a[0])" # second [0] is taken literally
```

The result is

Output

```
$a[0] is red blue[0], $a[0] is red
```

expandable-string-literals and *expandable-here-string-literals* also support a kind of substitution called *sub-expression expansion*, by treating text of the form `$(...)` as a *sub-expression* ([§7.1.6](#)). Such text is replaced by the string representation of that expression's value ([§6.8](#)). Any white space used to separate tokens within *sub-expression's statement-list* is ignored as far as the result string's construction is concerned.

The examples,

PowerShell

```
$count = 10
"$count + 5 is $($count + 5)"
"$count + 5 is `$(($count + 5))"
"$count + 5 is `$(`$count + 5)"
```

result in the following *expandable-string-literals*:

Output

```
10 + 5 is 15
10 + 5 is $(10 + 5)
10 + 5 is $($count + 5)
```

The following source,

PowerShell

```
$i = 5; $j = 10; $k = 15
``$i, `$j, and `\$k have the values $($i; $j; $k)"
```

results in the following *expandable-string-literal*:

Output

```
$i, $j, and $k have the values 5 10 15
```

These four lines could have been written more succinctly as follows:

PowerShell

```
``$i, `$j, and `\$k have the values $($i = 5); ($j = 10); ($k = 15))"
```

In the following example,

PowerShell

```
"First 10 squares: $($for ($i = 1; $i -le 10; ++$i) { "$i $($i*$i) " })"
```

the resulting *expandable-string-literal* is as follows:

Output

```
First 10 squares: 1 1 2 4 3 9 4 16 5 25 6 36 7 49 8 64 9 81 10 100
```

As shown, a *sub-expression* can contain string literals having both variable substitution and sub-expression expansion. Note also that the inner *expandable-string-literal*'s delimiters need not be escaped; the fact that they are inside a *sub-expression* means they cannot be terminators for the outer *expandable-string-literal*.

An *expandable-string-literal* or *expandable-here-string-literal* containing a variable substitution or sub-expression expansion is evaluated each time that literal is used; for example,

PowerShell

```
$a = 10
\$s1 = "`$a = $($a; ++$a)"
``\$s1 = >$s1<
\$s2 = "`$a = $($a; ++$a)"
``\$s2 = >$s2<
\$s2 = \$s1
``\$s2 = >$s2<"
```

which results in the following *expandable-string-literals*:

Output

```
$s1 = >$a = 10<
$s2 = >$a = 11<
\$s2 = >$a = 10<
```

The contents of a *verbatim-here-string-literal* are taken verbatim, including any leading or trailing white space within the body. As such, embedded *single-quote-characters* need not be doubled-up, and there is no substitution or expansion. For example,

PowerShell

```
$lit = @@
That's it!
2 * 3 = $(2*3)
'@
```

which results in the literal

Output

```
That's it!
2 * 3 = $(2*3)
```

The contents of an *expandable-here-string-literal* are subject to substitution and expansion, but any leading or trailing white space within the body but outside any *sub-expressions* is taken verbatim, and embedded *double-quote-characters* need not be doubled-up. For example,

PowerShell

```
$lit = @@
That's it!
2 * 3 = $(2*3)
"@
```

which results in the following literal when expanded:

PowerShell

```
That's it!
2 * 3 = 6
```

For both *verbatim-here-string-literals* and *expandable-here-string-literals*, each line terminator within the body is represented in the resulting literal in an implementation-defined manner. For example, in

PowerShell

```
$lit = @@
abc
xyz
"@
```

the second line of the body has two leading spaces, and the first and second lines of the body have line terminators; however, the terminator for the second line of the body is *not* part of that body. The resulting literal is equivalent to: "abc<implementation-defined character sequence>xyz".

ⓘ Note

To aid readability of source, long string literals can be broken across multiple source lines without line terminators being inserted. This is done by writing each

part as a separate literal and concatenating the parts with the + operator ([§7.7.2](#)).

This operator allows its operands to designate any of the four kinds of string literal.

ⓘ Note

Although there is no such thing as a character literal per se, the same effect can be achieved by accessing the first character in a 1-character string, as follows:

`[char]"A"` or `"A"[0]`.

For both *verbatim-here-string-literals* and *expandable-here-string-literals*, each line terminator within the body is represented exactly as it was provided.

2.3.5.3 Null literal

See the automatic variable `$null` ([§2.3.2.2](#)).

2.3.5.4 Boolean literals

See the automatic variables `$false` and `$true` ([§2.3.2.2](#)).

2.3.5.5 Array literals

PowerShell allows expressions of array type ([§9](#)) to be written using the unary comma operator ([§7.2.1](#)), *array-expression* ([§7.1.7](#)), the binary comma operator ([§7.3](#)), and the range operator ([§7.4](#)).

2.3.5.6 Hash literals

PowerShell allows expressions of type Hashtable ([§10](#)) to be written using a *hash-literal-expression* ([§7.1.9](#))

2.3.5.7 Type names

Syntax:

Syntax

```
type-name:  
    type-identifier  
    type-name . type-identifier
```

```

type-identifier:
    type-characters

type-characters:
    type-character
    type-characters type-character

type-character:
    A Unicode character of classes Lu, Ll, Lt, Lm, Lo, or Nd
    _ (The underscore character U+005F)

array-type-name:
    type-name [

generic-type-name:
    type-name [

```

2.3.6 Operators and punctuators

Syntax:

```

Syntax

operator-or-punctuator: one of
    { } [ ] ( ) @( @{ $( ;
    && || & | , ++ .. :: .
    ! * / % + - --
    -and -band -bnot -bor
    -bxor -not -or -xor
    assignment-operator
    merging-redirection-operator
    file-redirection-operator
    comparison-operator
    format-operator

assignment-operator: one of
    = -= += *= /= %=

file-redirection-operator: one of
    > >> 2> 2>> 3> 3>> 4> 4>>
    5> 5>> 6> 6>> *> *>> <

merging-redirection-operator: one of
    *>&1 2>&1 3>&1 4>&1 5>&1 6>&1
    *>&2 1>&2 3>&2 4>&2 5>&2 6>&2

comparison-operator: *one of
    -as           -ccontains      -ceq
    -cge          -cgt           -cle
    -clike         -clt           -cmatch
    -cne          -cnotcontains   -cnotlike
    -cnotmatch    -contains       -creplace

```

```
-csplit      -eq          -ge
-gt          -icontains   -ieq
-ige         -igt          -ile
-ilike       -ilt          -imatch
-in          -ine          -inotcontains
-inotlike    -inotmatch  -ireplace
-is          -isnot        -isplit
-join        -le           -like
-lt          -match        -ne
-notcontains -notin        -notlike
-notmatch    -replace     -shl*
-shr         -split
```

format-operator:

```
-f
```

Description:

`&&` and `||` are reserved for future use.

① Note

Editor's Note: The pipeline chain operators `&&` and `||` were introduced in PowerShell 7. See [about Pipeline Chain Operators](#).

The name following *dash* in an operator is reserved for that purpose only in an operator context.

An operator that begins with *dash* must not have any white space between that *dash* and the token that follows it.

2.3.7 Escaped characters

Syntax:

Syntax

```
escaped-character:
` (The backtick character U+0060) followed by any Unicode character
```

Description:

An *escaped character* is a way to assign a special interpretation to a character by giving it a prefix Backtick character (U+0060). The following table shows the meaning of each *escaped-character*:

Escaped Character	Meaning
` a	Alert (U+0007)
` b	Backspace (U+0008)
` f	Form-feed (U+000C)
` n	New-line (U+000A)
` r	Carriage return (U+000D)
` t	Horizontal tab (U+0009)
` v	Vertical tab (U+0009)
` '	Single quote (U+0027)
` "	Double quote (U+0022)
` `	Backtick (U+0060)
` 0	NUL (U+0000)
` x	If x is a character other than those characters shown above, the backtick character is ignored and x is taken literally.

The implication of the final entry in the table above is that spaces that would otherwise separate tokens can be made part of a token instead. For example, a file name containing a space can be written as `Test` Data.txt` (as well as `'Test Data.txt'` or `"Test Data.txt"`).

3. Basic concepts

Article • 09/15/2023

Editorial note

Important

The *Windows PowerShell Language Specification 3.0* was published in December 2012 and is based on Windows PowerShell 3.0. This specification does not reflect the current state of PowerShell. There is no plan to update this documentation to reflect the current state. This documentation is presented here for historical reference.

The specification document is available as a Microsoft Word document from the Microsoft Download Center at: <https://www.microsoft.com/download/details.aspx?id=36389> ↗

That Word document has been converted for presentation here on Microsoft Learn.

During conversion, some editorial changes have been made to accommodate formatting for the Docs platform. Some typos and minor errors have been corrected.

3.1 Providers and drives

A *provider* allows access to data and components that would not otherwise be easily accessible at the command line. The data is presented in a consistent format that resembles a file system drive.

The data that a provider exposes appears on a *drive*, and the data is accessed via a *path* just like with a disk drive. Built-in cmdlets for each provider manage the data on the provider drive.

PowerShell includes the following set of built-in providers to access the different types of data stores:

 Expand table

Provider	Drive Name	Description	Ref.
Alias	Alias:	PowerShell aliases	§3.1.1
Environment	Env:	Environment variables	§3.1.2
FileSystem	A; B; C; ...	Disk drives, directories, and files	§3.1.3
Function	Function:	PowerShell functions	§3.1.4

Provider	Drive Name	Description	Ref.
Variable	Variable:	PowerShell variables	§3.1.5

Windows PowerShell:

 [Expand table](#)

Provider	Drive Name	Description
Certificate	Cert:	x509 certificates for digital signatures
Registry	HKLM: (HKEY_LOCAL_MACHINE), HKCU: (HKEY_CURRENT_USER)	Windows registry
WSMan	WSMan:	WS-Management configuration information

The following cmdlets deal with providers and drives:

- [Get-PSProvider](#): Gets information about one or more providers
- [Get-PSDrive](#): Gets information about one or more drives

The type of an object that represents a provider is described in [§4.5.1](#). The type of an object that represents a drive is described in [§4.5.2](#).

3.1.1 Aliases

An *alias* is an alternate name for a command. A command can have multiple aliases, and the original name and all of its aliases can be used interchangeably. An alias can be reassigned. An alias is an item ([§3.3](#)).

An alias can be assigned to another alias; however, the new alias is not an alias of the original command.

The provider Alias is a flat namespace that contains only objects that represent the aliases. The variables have no child items.

PowerShell comes with a set of built-in aliases.

The following cmdlets deal with aliases:

- [New-Alias](#): Creates an alias
- [Set-Alias](#): Creates or changes one or more aliases
- [Get-Alias](#): Gets information about one or more aliases

- **Export-Alias:** Exports one or more aliases to a file

When an alias is created for a command using `New-Alias`, parameters to that command cannot be included in that alias. However, direct assignment to a variable in the Alias: namespace does permit parameters to be included.

(!) Note

It is a simple matter, however, to create a function that does nothing more than contain the invocation of that command with all desired parameters, and to assign an alias to that function.

The type of an object that represents an alias is described in [§4.5.4](#).

Alias objects are stored on the drive Alias: ([§3.1](#)).

3.1.2 Environment variables

The PowerShell Environment provider allows operating system environment variables to be retrieved, added, changed, cleared, and deleted.

The provider Environment is a flat namespace that contains only objects that represent the environment variables. The variables have no child items.

An environment variable's name cannot include the equal sign (=).

Changes to the environment variables affect the current session only.

An environment variable is an item ([§3.3](#)).

The type of an object that represents an environment variable is described in [§4.5.6](#).

Environment variable objects are stored on the drive Env: ([§3.1](#)).

3.1.3 File system

The PowerShell FileSystem provider allows directories and files to be created, opened, changed, and deleted.

The FileSystem provider is a hierarchical namespace that contains objects that represent the underlying file system.

Files are stored on drives with names like A:, B:, C:, and so on ([§3.1](#)). Directories and files are accessed using path notation ([§3.4](#)).

A directory or file is an item ([§3.3](#)).

3.1.4 Functions

The PowerShell Function provider allows functions ([§8.10](#)) and filters ([§8.10.1](#)) to be retrieved, added, changed, cleared, and deleted.

The provider Function is a flat namespace that contains only the function and filter objects. Neither functions nor filters have child items.

Changes to the functions affect the current session only.

A function is an item ([§3.3](#)).

The type of an object that represents a function is described in [§4.5.10](#). The type of an object that represents a filter is described in [§4.5.11](#).

Function objects are stored on drive Function: ([§3.1](#)).

3.1.5 Variables

Variables can be defined and manipulated directly in the PowerShell language.

The provider Variable is a flat namespace that contains only objects that represent the variables. The variables have no child items.

The following cmdlets also deal with variables:

- [New-Variable](#): Creates a variable
- [Set-Variable](#): Creates or changes the characteristics of one or more variables
- [Get-Variable](#): Gets information about one or more variables
- [Clear-Variable](#): Deletes the value of one or more variables
- [Remove-Variable](#): Deletes one or more variables

As a variable is an item ([§3.3](#)), it can be manipulated by most Item-related cmdlets.

The type of an object that represents a variable is described in [§4.5.3](#).

Variable objects are stored on drive Variable: ([§3.1](#)).

3.2 Working locations

The *current working location* is the default location to which commands point. This is the location used if an explicit path ([§3.4](#)) is not supplied when a command is invoked. This location

includes the *current drive*.

A PowerShell host may have multiple drives, in which case, each drive has its own current location.

When a drive name is specified without a directory, the current location for that drive is implied.

The current working location can be saved on a stack, and then set to a new location. Later, that saved location can be restored from that stack and made the current working location. There are two kinds of location stacks: the *default working location stack*, and zero or more user-defined *named working location stacks*. When a session begins, the default working location stack is also the *current working location stack*. However, any named working location stack can be made the current working location stack.

The following cmdlets deal with locations:

- [Set-Location](#): Establishes the current working location
- [Get-Location](#): Determines the current working location for the specified drive(s), or the working locations for the specified stack(s)
- [Push-Location](#): Saves the current working location on the top of a specified stack of locations
- [Pop-Location](#): Restores the current working location from the top of a specified stack of locations

The object types that represents a working location and a stack of working locations are described in [§4.5.5](#).

3.3 Items

An *item* is an alias ([§3.1.1](#)), a variable ([§3.1.5](#)), a function ([§3.1.4](#)), an environment variable ([§3.1.2](#)), or a file or directory in a file system ([§3.1.3](#)).

The following cmdlets deal with items:

- [New-Item](#): Creates a new item
- [Set-Item](#): Changes the value of one or more items
- [Get-Item](#): Gets the items at the specified location
- [Get-ChildItem](#): Gets the items and child items at the specified location
- [Copy-Item](#): Copies one or more items from one location to another
- [Move-Item](#): Moves one or more items from one location to another
- [Rename-Item](#): Renames an item
- [Invoke-Item](#): Performs the default action on one or more items

- [Clear-Item](#): Deletes the contents of one or more items, but does not delete the items (see [§4.5.17](#))
- [Remove-Item](#): Deletes the specified items

The following cmdlets deal with the content of items:

- [Get-Content](#): Gets the content of the item
- [Add-Content](#): Adds content to the specified items
- [Set-Content](#): Writes or replaces the content in an item
- [Clear-Content](#): Deletes the contents of an item

The type of an object that represents a directory is described in [§4.5.17](#). The type of an object that represents a file is described in [§4.5.18](#).

3.4 Path names

All items in a data store accessible through a PowerShell provider can be identified uniquely by their path names. A *path name* is a combination of the item name, the container and subcontainers in which the item is located, and the PowerShell drive through which the containers are accessed.

Path names are divided into one of two types: fully qualified and relative. A *fully qualified path name* consists of all elements that make up a path. The following syntax shows the elements in a fully qualified path name:

Tip

The `~opt~` notation in the syntax definitions indicates that the lexical entity is optional in the syntax.

Syntax

```
path:  
    provider~opt~  drive~opt~  containers~opt~  item  
  
provider:  
    module~opt~  provider  ::  
  
module:  
    module-name  \  
  
drive:  
    drive-name  :  
  
containers:
```

```
container  \
  containers container  \
```

module-name refers to the parent module.

provider refers to the PowerShell provider through which the data store is accessed.

drive refers to the PowerShell drive that is supported by a particular PowerShell provider.

A *container* can contain other containers, which can contain other containers, and so on, with the final container holding an *item*. Containers must be specified in the hierarchical order in which they exist in the data store.

Here is an example of a path name:

```
E:\Accounting\InvoiceSystem\Production\MasterAccount\MasterFile.dat
```

If the final element in a path contains other elements, it is a *container element*; otherwise, it's a *leaf element*.

In some cases, a fully qualified path name is not needed; a relative path name will suffice. A *relative path name* is based on the current working location. PowerShell allows an item to be identified based on its location relative to the current working location. A relative path name involves the use of some special characters. The following table describes each of these characters and provides examples of relative path names and fully qualified path names. The examples in the table are based on the current working directory being set to C:\Windows:

 Expand table

Symbol	Description	Relative path	Fully qualified path
.	Current working location	.\System	C:\Windows\System
..	Parent of the current working location	..\Program Files	C:\Program Files
\	Drive root of the current working location	\Program Files	C:\Program Files
none	No special characters	System	C:\Windows\System

To use a path name in a command, enter that name as a fully qualified or relative path name.

The following cmdlets deal with paths:

- [Convert-Path](#): Converts a path from a PowerShell path to a PowerShell provider path
- [Join-Path](#): Combines a path and a child path into a single path
- [Resolve-Path](#): Resolves the wildcard characters in a path

- [Split-Path](#): Returns the specified part of a path
- [Test-Path](#): Determines whether the elements of a path exist or if a path is well formed

Some cmdlets (such as [Add-Content](#) and [Copy-Item](#)) use file filters. A *file filter* is a mechanism for specifying the criteria for selecting from a set of paths.

The object type that represents a resolved path is described in [§4.5.5](#). Paths are often manipulated as strings.

3.5 Scopes

3.5.1 Introduction

A name can denote a variable, a function, an alias, an environment variable, or a drive. The same name may denote different items at different places in a script. For each different item that a name denotes, that name is visible only within the region of script text called its *scope*. Different items denoted by the same name either have different scopes, or are in different name spaces.

Scopes may nest, in which case, an outer scope is referred to as a *parent scope*, and any nested scopes are *child scopes* of that parent. The scope of a name is the scope in which it is defined and all child scopes, unless it is made private. Within a child scope, a name defined there hides any items defined with the same name in parent scopes.

Unless dot source notation ([§3.5.5](#)) is used, each of the following creates a new scope:

- A script file
- A script block
- A function or filter

Consider the following example:

```
PowerShell

# Start of script
$x = 2; $y = 3
Get-Power $x $y

# Function defined in script
function Get-Power([int]$x, [int]$y) {
    if ($y -gt 0) {
        return $x * (Get-Power $x (--$y))
    } else {
        return 1
    }
}
```

```
}
```

```
# End of script
```

The scope of the variables `$x` and `$y` created in the script is the body of that script, including the function defined inside it. Function `Get-Power` defines two parameters with those same names. As each function has its own scope, these variables are different from those defined in the parent scope, and they hide those from the parent scope. The function scope is nested inside the script scope.

Note that the function calls itself recursively. Each time it does so, it creates yet another nested scope, each with its own variables `$x` and `$y`.

Here is a more complex example, which also shows nested scopes and reuse of names:

```
PowerShell
```

```
# start of script scope
$x = 2          # top-level script-scope $x created
# $x is 2
F1             # create nested scope with call to function F1
# $x is 2
F3             # create nested scope with call to function F3
# $x is 2

function F1 {      # start of function scope
# $x is 2
    $x = $true     # function-scope $x created
# $x is $true

    & {           # create nested scope with script block
# $x is $true
        $x = 12.345 # scriptblock-scope $x created
# $x is 12.345
    }             # end of scriptblock scope, local $x goes away

# $x is $true
F2             # create nested scope with call to function F2
# $x is $true
}               # end of function scope, local $x goes away

function F2 {      # start of function scope
# $x is $true
    $x = "red"     # function-scope $x created
# $x is "red"
}               # end of function scope, local $x goes away

function F3 {      # start of function scope
# $x is 2
    if ($x -gt 0) {
# $x is 2
        $x = "green"
```

```
        # $x is "green"
    }
    # end of block, but not end of any scope
    # $x is still "green"
}
# end of function scope, local $x goes away
# end of script scope
```

3.5.2 Scope names and numbers

PowerShell supports the following scopes:

- Global: This is the top-most level scope. All automatic and preference variables are defined in this scope. The global scope is the parent scope of all other scopes, and all other scopes are child scopes of the global scope.
- Local: This is the current scope at any execution point within a script, script block, or function. Any scope can be the local scope.
- Script: This scope exists for each script file that is executed. The script scope is the parent scope of all scopes created from within it. A script block does *not* have its own script scope; instead, its script scope is that of its nearest ancestor script file. Although there is no such thing as module scope, script scope provides the equivalent.

Names can be declared private, in which case, they are not visible outside of their parent scope, not even to child scopes. The concept of private is not a separate scope; it's an alias for local scope with the addition of hiding the name if used as a writable location.

Scopes can be referred to by a number, which describes the relative position of one scope to another. Scope 0 denotes the local scope, scope 1 denotes a 1-generation ancestor scope, scope 2 denotes a 2-generation ancestor scope, and so on. (Scope numbers are used by cmdlets that manipulate variables.)

3.5.3 Variable name scope

As shown by the following production, a variable name can be specified with any one of six different scopes:

Syntax

```
variable-scope:
  Global:
  Local:
  Private:
  Script:
  Using:
```

Workflow: variable-namespace

The scope is optional. The following table shows the meaning of each in all possible contexts. It also shows the scope when no scope is specified explicitly:

[Expand table](#)

Scope Modifier	Within a Script File	Within a Script Block	Within a Function
Global	Global scope	Global scope	Global scope
Script	Nearest ancestor script file's scope or Global if there is no nearest ancestor script file	Nearest ancestor script file's scope or Global if there is no nearest ancestor script file	Nearest ancestor script file's scope or Global if there is no nearest ancestor script file
Private	Global/Script/Local scope	Local scope	Local scope
Local	Global/Script/Local scope	Local scope	Local scope
Using	Implementation defined	Implementation defined	Implementation defined
Workflow	Implementation defined	Implementation defined	Implementation defined
None	Global/Script/Local scope	Local scope	Local scope

Variable scope information can also be specified when using the family of cmdlets listed in [\(\\$3.1.5\)](#). In particular, refer to the parameter `Scope`, and the parameters `Option Private` and `Option AllScope` for more information.

The `Using:` scope modifier is used to access variables defined in another scope while running scripts via cmdlets like `Start-Job`, `Invoke-Command`, or within an *inlinescript-statement*. For example:

PowerShell

```
$a = 42
Invoke-Command --ComputerName RemoteServer { $Using:a } # returns 42
workflow foo
{
    $b = "Hello"
    inlinescript { $Using:b }
}
foo # returns "Hello"
```

The scope workflow is used with a *parallel-statement* or *sequence-statement* to access a variable defined in the workflow.

3.5.4 Function name scope

A function name may also have one of the four different scopes, and the visibility of that name is the same as for variables ([§3.5.3](#)).

3.5.5 Dot source notation

When a script file, script block, or function is executed from within another script file, script block, or function, the executed script file creates a new nested scope. For example,

```
PowerShell  
  
Script1.ps1  
& "Script1.ps1"  
& { ... }  
FunctionA
```

However, when *dot source notation* is used, no new scope is created before the command is executed, so additions/changes it would have made to its own local scope are made to the current scope instead. For example,

```
PowerShell  
  
. Script2.ps1  
. "Script2.ps1"  
. { ... }  
. FunctionA
```

3.5.6 Modules

Just like a top-level script file is at the root of a hierarchical nested scope tree, so too is each module ([§3.14](#)). However, by default, only those names exported by a module are available by name from within the importing context. The Global parameter of the cmdlet [Import-Module](#) allows exported names to have increased visibility.

3.6 ReadOnly and Constant Properties

Variables and aliases are described by objects that contain a number of properties. These properties are set and manipulated by two families of cmdlets ([§3.1.5](#), [§3.1.1](#)). One such

property is Options, which can be set to ReadOnly or Constant (using the Option parameter). A variable or alias marked ReadOnly can be removed, and its properties can be changed provided the Force parameter is specified. However, a variable or alias marked Constant cannot be removed nor have its properties changed.

3.7 Method overloads and call resolution

3.7.1 Introduction

As stated in §1, an external procedure made available by the execution environment (and written in some language other than PowerShell) is called a *method*.

The name of a method along with the number and types of its parameters are collectively called that method's *signature*. (Note that the signature does not include the method's return type.) The execution environment may allow a type to have multiple methods with the same name provided each has a different signature. When multiple versions of some method are defined, that method is said to be *overloaded*. For example, the type Math ([§4.3.8](#)) contains a set of methods called `Abs`, which computes the absolute value of a specified number, where the specified number can have one of a number of types. The methods in that set have the following signatures:

```
PowerShell

Abs(decimal)
Abs(float)
Abs(double)
Abs(int)
Abs(long)
Abs(SByte)
Abs(Int16)
```

In this case, all of the methods have the same number of arguments; their signatures differ by argument type only.

Another example involves the type Array ([§4.3.2](#)), which contains a set of methods called Copy that copies a range of elements from one array to another, starting at the beginning of each array (by default) or at some designated element. The methods in that set have the following signatures:

```
PowerShell

Copy(Array, Array, int)
Copy(Array, Array, long)
```

```
Copy(Array, int, Array, int, int)
Copy(Array, long, Array, long, long)
```

In this case, the signatures differ by argument type and, in some cases, by argument number as well.

In most calls to overloaded methods, the number and type of the arguments passed exactly match one of the overloads, and the method selected is obvious. However, if that is not the case, there needs to be a way to resolve which overloaded version to call, if any. For example,

PowerShell

```
[Math]::Abs([byte]10) # no overload takes type byte
[array]::Copy($source, 3, $dest, 5L, 4) # both int and long indexes
```

Other examples include the type **string** (i.e.; `System.String`), which has numerous overloaded methods.

Although PowerShell has rules for resolving method calls that do not match an overloaded signature exactly, PowerShell does not itself provide a way to define overloaded methods.

! Note

Editor's Note: PowerShell 5.0 added the ability to define script-based classes. These classes can contain overloaded methods.

3.7.2 Method overload resolution

Given a method call ([§7.1.3](#)) having a list of argument expressions, and a set of *candidate methods* (i.e., those methods that could be called), the mechanism for selecting the *best method* is called *overload resolution*.

Given the set of applicable candidate methods ([§3.7.3](#)), the best method in that set is selected. If the set contains only one method, then that method is the best method. Otherwise, the best method is the one method that is better than all other methods with respect to the given argument list using the rules shown in [§3.7.4](#). If there is not exactly one method that is better than all other methods, then the method invocation is ambiguous and an error is reported.

The best method must be accessible in the context in which it is called. For example, a PowerShell script cannot call a method that is private or protected.

The best method for a call to a static method must be a static method, and the best method for a call to an instance method must be an instance method.

3.7.3 Applicable method

A method is said to be *applicable* with respect to an argument list A when one of the following is true:

- The number of arguments in A is identical to the number of parameters that the method accepts.
- The method has M required parameters and N optional parameters, and the number of arguments in A is greater than or equal to M, but less than N.
- The method accepts a variable number of arguments and the number of arguments in A is greater than the number of parameters that the method accepts.

In addition to having an appropriate number of arguments, each argument in A must match the parameter-passing mode of the argument, and the argument type must match the parameter type, or there must be a conversion from the argument type to the parameter type.

If the argument type is `ref` ([§4.3.6](#)), the corresponding parameter must also be `ref`, and the argument type for conversion purposes is the type of the property `Value` from the `ref` argument.

If the argument type is `ref`, the corresponding parameter could be `out` instead of `ref`.

If the method accepts a variable number of arguments, the method may be applicable in either *normal form* or *expanded form*. If the number of arguments in A is identical to the number of parameters that the method accepts and the last parameter is an array, then the form depends on the rank of one of two possible conversions:

- The rank of the conversion from the type of the last argument in A to the array type for the last parameter.
- The rank of the conversion from the type of the last argument in A to the element type of the array type for the last parameter.

If the first conversion (to the array type) is better than the second conversion (to the element type of the array), then the method is applicable in normal form, otherwise it is applicable in expanded form.

If there are more arguments than parameters, the method may be applicable in expanded form only. To be applicable in expanded form, the last parameter must have array type. The method is replaced with an equivalent method that has the last parameter replaced with sufficient parameters to account for each unmatched argument in A. Each additional parameter type is the element type of the array type for the last parameter in the original method. The above rules for an applicable method are applied to this new method and argument list A.

3.7.4 Better method

Given an argument list A with a set of argument expressions $\{ E_1, E_2, \dots, E_N \}$ and two application methods $M_{P\sim}$ and $M_{Q\sim}$ with parameter types $\{ P_1, P_2, \dots, P_N \}$ and $\{ Q_1, Q_2, \dots, Q_N \}$, $M_{P\sim}$ is defined to be a better method than $M_{Q\sim}$ if the *cumulative ranking of conversions* for $M_{P\sim}$ is better than that for $M_{Q\sim}$.

The cumulative ranking of conversions is calculated as follows. Each conversion is worth a different value depending on the number of parameters, with the conversion of E_1 worth N, E_2 worth N-1, down to E_N worth 1. If the conversion from $E_{X\sim}$ to $P_{X\sim}$ is better than that from $E_{X\sim}$ to $Q_{X\sim}$, the $M_{P\sim}$ accumulates $N-X+1$; otherwise, $M_{Q\sim}$ accumulates $N-X+1$. If $M_{P\sim}$ and $M_{Q\sim}$ have the same value, then the following tie breaking rules are used, applied in order:

- The cumulative ranking of conversions between parameter types (ignoring argument types) is computed in a manner similar to the previous ranking, so P_1 is compared against Q_1 , P_2 against Q_2 , ..., and P_N against Q_N . The comparison is skipped if the argument was `$null`, or if the parameter types are not numeric types. The comparison is also skipped if the argument conversion $E_{X\sim}$ loses information when converted to $P_{X\sim}$ but does not lose information when converted to $Q_{X\sim}$, or vice versa. If the parameter conversion types are compared, then if the conversion from $P_{X\sim}$ to $Q_{X\sim}$ is better than that from $Q_{X\sim}$ to $P_{X\sim}$, the $M_{P\sim}$ accumulates $N-X+1$; otherwise, $M_{Q\sim}$ accumulates $N-X+1$. This tie breaking rule is intended to prefer the *most specific method* (i.e., the method with parameters having the smallest data types) if no information is lost in conversions, or to prefer the *most general method* (i.e., the method with the parameters with the largest data types) if conversions result in loss of information.
- If both methods use their expanded form, the method with more parameters is the better method.
- If one method uses the expanded form and the other uses normal form, the method using normal form is the better method.

3.7.5 Better conversion

The text below marked like this is specific to Windows PowerShell.

Conversions are ranked in the following manner, from lowest to highest:

- $T_1[]$ to $T_2[]$ where no assignable conversion between T_1 and T_2 exists
- T to string where T is any type
- T_1 to T_2 where T_1 or T_2 define a custom conversion in an implementation-defined manner
- T_1 to T_2 where T_1 implements `IConvertible`

- `T~1~` to `T~2~` where `T~1~` or `T~2~` implements the method `T~2~ op_Implicit(T1)`
- `T~1~` to `T~2~` where `T~1~` or `T~2~` implements the method `T~2~ op_Explicit(T1)`
- `T~1~` to `T~2~` where `T~2~` implements a constructor taking a single argument of type `T~1~`
- Either of the following conversions:
 - string to `T` where `T` implements a static method `T Parse(string)` or `T Parse(string, IFormatProvider)`
 - `T~1~` to `T~2~` where `T~2~` is any enum and `T~1~` is either string or a collection of objects that can be converted to string
- `T` to `PSObject` where `T` is any type
- Any of the following conversions: `Language`
 - `T` to `bool` where `T` is any numeric type
 - string to `T` where `T` is `regex`, `wmisearcher`, `wmi`, `wmiclass`, `adsi`, `adsisearcher`, or `type`
 - `T` to `bool`
 - `T~1~` to `Nullable[T~2~]` where a conversion from `T~1~` to `T~2~` exists
 - `T` to `void`
 - `T~1~[]` to `T~2~[]` where an assignable conversion between `T~1~` and `T~2~` exists
 - `T~1~` to `T~2~[]` where `T~1~` is a collection
 - `IDictionary` to `Hashtable`
 - `T` to `ref`
 - `T` to `xml`
 - `scriptblock` to `delegate`
 - `T~1~` to `T~2~` where `T~1~` is an integer type and `T~2~` is an enum
- `$null` to `T` where `T` is any value type
- `$null` to `T` where `T` is any reference type
- Any of the following conversions:
 - byte to `T` where `T` is `SByte`
 - `UInt16` to `T` where `T` is `SByte`, `byte`, or `Int16`
 - `Int16` to `T` where `T` is `SByte` or `byte`
 - `UInt32` to `T` where `T` is `SByte`, `byte`, `Int16`, `UInt16`, or `int`
 - `int` to `T` where `T` is `SByte`, `byte`, `Int16`, or `UInt16`
 - `UInt64` to `T` where `T` is `SByte`, `byte`, `Int16`, `UInt16`, `int`, `UInt32`, or `long`
 - `long` to `T` where `T` is `SByte`, `byte`, `Int16`, `UInt16`, `int`, or `UInt32`

- `float` to `T` where `T` is any integer type or `decimal`
- `double` to `T` where `T` is any integer type or `decimal`
- `decimal` to `T` where `T` is any integer type
- Any of the following conversions:
 - `SByte` to `T` where `T` is `byte`, `uint6`, `UInt32`, or `UInt64`
 - `Int16` to `T` where `T` is `UInt16`, `UInt32`, or `UInt64`
 - `int` to `T` where `T` is `UInt32` or `UInt64`
 - `long` to `UInt64`
 - `decimal` to `T` where `T` is `float` or `double`
- Any of the following conversions:
 - `T` to `string` where `T` is any numeric type
 - `T` to `char` where `T` is any numeric type
 - `string` to `T` where `T` is any numeric type
- Any of the following conversions, these conversion are considered an assignable conversions:
 - `byte` to `T` where `T` is `Int16`, `UInt16`, `int`, `UInt32`, `long`, `UInt64`, `single`, `double`, or `decimal`
 - `SByte` to `T` where `T` is `Int16`, `UInt16`, `int`, `UInt32`, `long`, `UInt64`, `single`, `double`, or `decimal`
 - `UInt16` to `T` where `T` is `int`, `UInt32`, `long`, or `UInt64`, `single`, `double`, or `decimal`
 - `Int16` to `T` where `T` is `int`, `UInt32`, `long`, or `UInt64`, `single`, `double`, or `decimal`
 - `UInt32` to `T` where `T` is `long`, or `UInt64`, `single`, `double`, or `decimal`
 - `int` to `T` where `T` is `long`, `UInt64`, `single`, `double`, or `decimal`
 - `single` to `double`
- `T~1~` to `T~2~` where `T~2~` is a base class or interface of `T~1~`. This conversion is considered an assignable conversion.
- `string` to `char[]`
- `T` to `T` -- This conversion is considered an assignable conversion.

For each conversion of the form `T~1~` to `T~2~[]` where `T~1~` is not an array and no other conversion applies, if there is a conversion from `T~1~` to `T~2~`, the rank of the conversion is worse than the conversion from `T~1~` to `T~2~`, but better than any conversion ranked less than the conversion from `T~1~` to `T~2~`.

3.8 Name lookup

It is possible to have commands of different kinds all having the same name. The order in which name lookup is performed in such a case is alias, function, cmdlet, and external command.

3.9 Type name lookup

§7.1.10 contains the statement, "A *type-literal* is represented in an implementation by some unspecified *underlying type*. As a result, a type name is a synonym for its underlying type." Example of types are `int`, `double`, `long[]`, and `Hashtable`.

Type names are matched as follows: Compare a given type name with the list of built-in *type accelerators*, such as `int`, `long`, `double`. If a match is found, that is the type. Otherwise, presume the type name is fully qualified and see if such a type exists on the host system. If a match is found, that is the type. Otherwise, add the namespace prefix `System..`. If a match is found, that is the type. Otherwise, the type name is in error. This algorithm is applied for each type argument for generic types. However, there is no need to specify the arity (the number of arguments or operands taken by a function or operator).

3.10 Automatic memory management

Various operators and cmdlets result in the allocation of memory for reference-type objects, such as strings and arrays. The allocation and freeing of this memory is managed by the PowerShell runtime system. That is, PowerShell provides automatic *garbage collection*.

3.11 Execution order

A *side effect* is a change in the state of a command's execution environment. A change to the value of a variable (via the assignment operators or the pre- and post-increment and decrement operators) is a side effect, as is a change to the contents of a file.

Unless specified otherwise, statements are executed in lexical order.

Except as specified for some operators, the order of evaluation of terms in an expression and the order in which side effects take place are both unspecified.

An expression that invokes a command involves the expression that designates the command, and zero or more expressions that designate the arguments whose values are to be passed to that command. The order in which these expressions are evaluated relative to each other is unspecified.

3.12 Error handling

When a command fails, this is considered an *error*, and information about that error is recorded in an *error record*, whose type is unspecified ([§4.5.15](#)); however, this type supports subscripting.

An error falls into one of two categories. Either it terminates the operation (a *terminating error*) or it doesn't (a *non-terminating error*). With a terminating error, the error is recorded and the operation stops. With a non-terminating error, the error is recorded and the operation continues.

Non-terminating errors are written to the error stream. Although that information can be redirected to a file, the error objects are first converted to strings and important information in those objects would not be captured making diagnosis difficult if not impossible. Instead, the error text can be redirected ([§7.12](#)) and the error object saved in a variable, as in `$Error1 = command 2>&1`.

The automatic variable `$Error` contains a collection of error records that represent recent errors, and the most recent error is in `$Error[0]`. This collection is maintained in a buffer such that old records are discarded as new ones are added. The automatic variable `$MaximumErrorCount` controls the number of records that can be stored.

`$Error` contains all of the errors from all commands mixed in together in one collection. To collect the errors from a specific command, use the common parameter `ErrorVariable`, which allows a user-defined variable to be specified to hold the collection.

3.13 Pipelines

A *pipeline* is a series of one or more commands each separated by the pipe operator `|` (U+007C). Each command receives input from its predecessor and writes output to its successor. Unless the output at the end of the pipeline is discarded or redirected to a file, it is sent to the host environment, which may choose to write it to standard output. Commands in a pipeline may also receive input from arguments. For example, consider the following use of commands `Get-ChildItem`, `Sort-Object`, and `Process-File`, which create a list of file names in a given file system directory, sort a set of text records, and perform some processing on a text record, respectively:

PowerShell

```
Get-ChildItem  
Get-ChildItem E:*.txt | Sort-Object -CaseSensitive | Process-File >results.txt
```

In the first case, `Get-ChildItem` creates a collection of names of the files in the current/default directory. That collection is sent to the host environment, which, by default, writes each element's value to standard output.

In the second case, `Get-ChildItem` creates a collection of names of the files in the directory specified, using the argument `E:*.txt`. That collection is written to the command `Sort-Object`, which, by default, sorts them in ascending order, sensitive to case (by virtue of the `CaseSensitive` argument). The resulting collection is then written to command `Process-File`, which performs some (unknown) processing. The output from that command is then redirected to the file `results.txt`.

If a command writes a single object, its successor receives that object and then terminates after writing its own object(s) to its successor. If, however, a command writes multiple objects, they are delivered one at a time to the successor command, which executes once per object. This behavior is called *streaming*. In stream processing, objects are written along the pipeline as soon as they become available, not when the entire collection has been produced.

When processing a collection, a command can be written such that it can do special processing before the initial element and after the final element.

3.14 Modules

A *module* is a self-contained reusable unit that allows PowerShell code to be partitioned, organized, and abstracted. A module can contain commands (such as cmdlets and functions) and items (such as variables and aliases) that can be used as a single unit.

Once a module has been created, it must be *imported* into a session before the commands and items within it can be used. Once imported, commands and items behave as if they were defined locally. A module is imported explicitly with the `Import-Module` command. A module may also be imported automatically as determined in an implementation defined manner.

The type of an object that represents a module is described in §4.5.12.

Modules are discussed in detail in [§11](#).

3.15 Wildcard expressions

A wildcard expression may contain zero or more of the following elements:

Element	Description
Character other than *, ?, or [Matches that one character
*	Matches zero or more characters. To match a * character, use [*].
?	Matches any one character. To match a ? character, use [?].
[set]	<p>Matches any one character from <i>set</i>, which cannot be empty.</p> <p>If <i>set</i> begins with], that right square bracket is considered part of <i>set</i> and the next right square bracket terminates the set; otherwise, the first right square bracket terminates the set.</p> <p>If <i>set</i> begins or ends with -, that hyphen-minus is considered part of <i>set</i>; otherwise, it indicates a range of consecutive Unicode code points with the characters either side of the hyphen-minus being the inclusive range delimiters. For example, A-Z indicates the 26 uppercase English letters, and 0-9 indicates the 10 decimal digits.</p>

ⓘ Note

More information can be found in, [The Open Group Base Specifications: Pattern Matching](#), IEEE Std 1003.1, 2004 Edition. ⓘ . However, in PowerShell, the escape character is backtick, not backslash.

3.16 Regular expressions

A regular expression may contain zero or more of the following elements:

[] [Expand table](#)

Element	Description
Character other than ., [, ^, *, \$, or \	Matches that one character
.	Matches any one character. To match a . character, use \..
[set] [^set]	<p>The [set] form matches any one character from <i>set</i>. The [^set] form matches no characters from <i>set</i>. <i>set</i> cannot be empty.</p> <p>If <i>set</i> begins with] or ^], that right square bracket is considered part of <i>set</i> and the next right square bracket terminates the set; otherwise, the first right square bracket terminates the set.</p>

Element	Description
	If set begins with - or ^-, or ends with -, that hyphen-minus is considered part of <i>set</i> ; otherwise, it indicates a range of consecutive Unicode code points with the characters either side of the hyphen-minus being the inclusive range delimiters. For example, A-Z indicates the 26 uppercase English letters, and 0-9 indicates the 10 decimal digits.
*	Matches zero or more occurrences of the preceding element.
+	Matches one or more occurrences of the preceding element.
?	Matches zero or one occurrences of the preceding element.
^	Matches at the start of the string. To match a ^ character, use \^.
\$	Matches at the end of the string. To match a \$ character, use \\$.
\c	Escapes character <i>c</i> , so it isn't recognized as a regular expression element.

(!) Note

More information can be found in, [The Open Group Base Specifications: Regular Expressions, IEEE Std 1003.1, 2004 Edition](#).

Windows PowerShell: Character classes available in Microsoft .NET Framework regular expressions are supported, as follows:

[Expand table](#)

Element	Description
\p{name}	Matches any character in the named character class specified by <i>name</i> . Supported names are Unicode groups and block ranges such as Ll, Nd, Z, IsGreek, and IsBoxDrawing.
\P{name}	Matches text not included in the groups and block ranges specified in <i>name</i> .
\w	Matches any word character. Equivalent to the Unicode character categories [\p{L1}\p{Lu}\p{Lt}\p{Lo}\p{Nd}\p{Pc}]. If ECMAScript-compliant behavior is specified with the ECMAScript option, \w is equivalent to [a-zA-Z_0-9].
\W	Matches any non-word character. Equivalent to the Unicode categories [\^\p{L1}\p{Lu}\p{Lt}\p{Lo}\p{Nd}\p{Pc}].
\s	Matches any white space character. Equivalent to the Unicode character categories [\f\n\r\t\v\x85\p{Z}].
\S	Matches any non-white-space character. Equivalent to the Unicode character categories [\^\f\n\r\t\v\x85\p{Z}].

Element	Description
\d	Matches any decimal digit. Equivalent to \p{Nd} for Unicode and [0-9] for non-Unicode behavior.
\D	Matches any non-digit. Equivalent to \P{Nd} for Unicode and [\^0-9] for non-Unicode behavior.

Quantifiers available in Microsoft .NET Framework regular expressions are supported, as follows:

[Expand table](#)

Element	Description
*	Specifies zero or more matches; for example, \w* or (abc)*. Equivalent to {0,}.
+	Matches repeating instances of the preceding characters.
?	Specifies zero or one matches; for example, \w? or (abc)? . Equivalent to {0,1}.
{n}	Specifies exactly <i>n</i> matches; for example, (pizza){2}.
{n,}	Specifies at least <i>n</i> matches; for example, (abc){2,}.
{n,m}	Specifies at least <i>n</i> , but no more than <i>m</i> , matches.

4. Types

Article • 09/15/2023

Editorial note

Important

The *Windows PowerShell Language Specification 3.0* was published in December 2012 and is based on Windows PowerShell 3.0. This specification does not reflect the current state of PowerShell. There is no plan to update this documentation to reflect the current state. This documentation is presented here for historical reference.

The specification document is available as a Microsoft Word document from the Microsoft Download Center at:

<https://www.microsoft.com/download/details.aspx?id=36389> That Word document has been converted for presentation here on Microsoft Learn. During conversion, some editorial changes have been made to accommodate formatting for the Docs platform. Some typos and minor errors have been corrected.

In PowerShell, each value has a type, and types fall into one of two main categories: **value types** and **reference types**. Consider the type `int`, which is typical of value types. A value of type `int` is completely self-contained; all the bits needed to represent that value are stored in that value, and every bit pattern in that value represents a valid value for its type. Now, consider the array type `int[]`, which is typical of reference types. A so-called value of an array type can hold either a reference to an object that actually contains the array elements, or the **null reference** whose value is `$null`. The important distinction between the two type categories is best demonstrated by the differences in their semantics during assignment. For example,

PowerShell

```
$i = 100 # $i designates an int value 100
$j = $i # $j designates an int value 100, which is a copy

$a = 10,20,30 # $a designates an object[], Length 3, value 10,20,30
$b = $a # $b designates exactly the same array as does $a, not a copy
$a[1] = 50 # element 1 (which has a value type) is changed from 20 to 50
$b[1] # $b refers to the same array as $a, so $b[1] is 50
```

As we can see, the assignment of a reference type value involves a **shallow copy**; that is, a copy of the reference to the object rather than its actual value. In contrast, a **deep copy** requires making a copy of the object as well.

A **numeric type** is one that allows representation of integer or fractional values, and that supports arithmetic operations on those values. The set of numerical types includes the integer ([§4.2.3](#)) and real number ([§4.2.4](#)) types, but does not include bool ([§4.2.1](#)) or char ([§4.2.2](#)). An implementation may provide other numeric types (such as signed byte, unsigned integer, and integers of other sizes).

A **collection** is a group of one or more related items, which need not have the same type. Examples of collection types are arrays, stacks, queues, lists, and hash tables. A program can *enumerate* (or *iterate*) over the elements in a collection, getting access to each element one at a time. Common ways to do this are with the `foreach` statement ([§8.4.4](#)) and the [ForEach-Object](#) cmdlet. The type of an object that represents an enumerator is described in [§4.5.16](#).

In this chapter, there are tables that list the accessible members for a given type. For methods, the **Type** is written with the following form: *returnType/argumentTypeList*. If the argument type list is too long to fit in that column, it is shown in the **Purpose** column instead.

Other integer types are `SByte`, `Int16`, `UInt16`, `UInt32`, and `UInt64`, all in the namespace **System**.

Many collection classes are defined as part of the **System.Collections** or **System.Collections.Generic** namespaces. Most collection classes implement the interfaces `ICollection`, `IComparer`, `IEnumerable`, `IList`, `IDictionary`, and `IDictionaryEnumerator` and their generic equivalents.

You can also use shorthand names for some types. For more information, see [about_Type_Accelerators](#).

4.1 Special types

4.1.1 The void type

This type cannot be instantiated. It provides a means to discard a value explicitly using the cast operator ([§7.2.9](#)).

4.1.2 The null type

The *null* type has one instance, the automatic variable `$null` ([§2.3.2.2](#)), also known as the null value. This value provides a means for expressing "nothingness" in reference contexts. The characteristics of this type are unspecified.

4.1.3 The object type

Every type in PowerShell except the null type ([§4.1.2](#)) is derived directly or indirectly from the type object, so `object` is the ultimate base type of all non-null types. A variable constrained ([§5.3](#)) to `object` is really not constrained at all, as it can contain a value of any type.

4.2 Value types

4.2.1 Boolean

The Boolean type is `bool`. There are only two values of this type, `False` and `True`, represented by the automatic variables `$false` and `$true`, respectively ([§2.3.2.2](#)).

In PowerShell, `bool` maps to `System.Boolean`.

4.2.2 Character

A character value has type `char`, which is capable of storing any UTF-16-encoded 16-bit Unicode code point.

The type `char` has the following accessible members:

[+] [Expand table](#)

Member	Member Kind	Type	Purpose
MaxValue	Static property (read-only)	char	The largest possible value of type <code>char</code>
MinValue	Static property (read-only)	char	The smallest possible value of type <code>char</code>
IsControl	Static method	bool/char	Tests if the character is a control character
IsDigit	Static method	bool/char	Tests if the character is a decimal digit
IsLetter	Static method	bool/char	Tests if the character is an alphabetic letter

Member	Member Kind	Type	Purpose
IsLetterOrDigit	Static method	bool/char	Tests if the character is a decimal digit or alphabetic letter
IsLower	Static method	bool/char	Tests if the character is a lowercase alphabetic letter
IsPunctuation	Static method	bool/char	Tests if the character is a punctuation mark
IsUpper	Static method	bool/char	Tests if the character is an uppercase alphabetic letter
IsWhiteSpace	Static method	bool/char	Tests if the character is a white space character.
ToLower	Static method	char/string	Converts the character to lowercase
ToUpper	Static method	char/string	Converts the character to uppercase

Windows PowerShell: char maps to System.Char.

4.2.3 Integer

There are two signed integer types, both of which use two's-complement representation for negative values:

- Type `int`, which uses 32 bits giving it a range of -2147483648 to +2147483647, inclusive.
- Type `long`, which uses 64 bits giving it a range of -9223372036854775808 to +9223372036854775807, inclusive.

Type `int` has the following accessible members:

[\[+\] Expand table](#)

Member	Member Kind	Type	Purpose
.MaxValue	Static property (read-only)	int	The largest possible value of type <code>int</code>
..MinValue	Static property (read-only)	int	The smallest possible value of type <code>int</code>

Type `long` has the following accessible members:

[\[+\] Expand table](#)

Member	Member Kind	Type	Purpose
.MaxValue	Static property (read-only)	long	The largest possible value of type long
..MinValue	Static property (read-only)	long	The smallest possible value of type long

There is one unsigned integer type:

- Type `byte`, which uses 8 bits giving it a range of 0 to 255, inclusive.

Type `byte` has the following accessible members:

[\[+\] Expand table](#)

Member	Member Kind	Type	Purpose
..MaxValue	Static property (read-only)	byte	The largest possible value of type byte
..MinValue	Static property (read-only)	byte	The smallest possible value of type byte

In PowerShell, `byte`, `int`, and `long` map to `System.Byte`, `System.Int32`, and `System.Int64`, respectively.

4.2.4 Real number

4.2.4.1 float and double

There are two real (or floating-point) types:

- Type `float` uses the 32-bit IEEE single-precision representation.
- Type `double` uses the 64-bit IEEE double-precision representation.

A third type name, `single`, is a synonym for type `float`; `float` is used throughout this specification.

Although the size and representation of the types `float` and `double` are defined by this specification, an implementation may use extended precision for intermediate results.

Type `float` has the following accessible members:

[\[+\] Expand table](#)

Member	Member Kind	Type	Purpose
..MaxValue	Static property (read-only)	float	The largest possible value of type float

Member	Member Kind	Type	Purpose
MinValue	Static property (read-only)	float	The smallest possible value of type float
NaN	Static property (read-only)	float	The constant value Not-a-Number
NegativeInfinity	Static property (read-only)	float	The constant value negative infinity
PositiveInfinity	Static property (read-only)	float	The constant value positive infinity

Type double has the following accessible members:

[\[+\] Expand table](#)

Member	Member Kind	Type	Purpose
.MaxValue	Static property (read-only)	double	The largest possible value of type double
.MinValue	Static property (read-only)	double	The smallest possible value of type double
.NaN	Static property (read-only)	double	The constant value Not-a-Number
.NegativeInfinity	Static property (read-only)	double	The constant value negative infinity
.PositiveInfinity	Static property (read-only)	double	The constant value positive infinity

In PowerShell, `float` and `double` map to `System.Single` and `System.Double`, respectively.

4.2.4.2 decimal

Type decimal uses a 128-bit representation. At a minimum it must support a scale s such that $0 \leq s \leq$ at least 28, and a value range -79228162514264337593543950335 to 79228162514264337593543950335. The actual representation of decimal is implementation defined.

Type decimal has the following accessible members:

[\[+\] Expand table](#)

Member	Member Kind	Type	Purpose
.MaxValue	Static property (read-only)	decimal	The largest possible value of type decimal
..MinValue	Static property (read-only)	decimal	The smallest possible value of type decimal

ⓘ Note

Decimal real numbers have a characteristic called *scale*, which represents the number of digits to the right of the decimal point. For example, the value 2.340 has a scale of 3 where trailing zeros are significant. When two decimal real numbers are added or subtracted, the scale of the result is the larger of the two scales. For example, $1.0 + 2.000$ is 3.000, while $5.0 - 2.00$ is 3.00. When two decimal real numbers are multiplied, the scale of the result is the sum of the two scales. For example, $1.0 * 2.000$ is 2.0000. When two decimal real numbers are divided, the scale of the result is the scale of the first less the scale of the second. For example, $4.00000/2.000$ is 2.00. However, a scale cannot be less than that needed to preserve the correct result. For example, $3.000/2.000$, $3.00/2.000$, $3.0/2.000$, and $3/2$ are all 1.5.

In PowerShell, `decimal` maps to `System.Decimal`. The representation of decimal is as follows:

- When considered as an array of four `int` values it contains the following elements:
 - Index 0 (bits 0-31) contains the low-order 32 bits of the decimal's coefficient.
 - Index 1 (bits 32-63) contains the middle 32 bits of the decimal's coefficient.
 - Index 2 (bits 64-95) contains the high-order 32 bits of the decimal's coefficient.
 - Index 3 (bits 96-127) contains the sign bit and scale, as follows:
 - bits 0--15 are zero
 - bits 16-23 contains the scale as a value 0--28
 - bits 24-30 are zero
 - bit 31 is the sign (0 for positive, 1 for negative)

4.2.5 The switch type

This type is used to constrain the type of a parameter in a command ([§8.10.5](#)). If an argument having the corresponding parameter name is present the parameter tests `$true`; otherwise, it tests `$false`.

In PowerShell, `switch` maps to `System.Management.Automation.SwitchParameter`.

4.2.6 Enumeration types

An enumeration type is one that defines a set of named constants representing all the possible values that can be assigned to an object of that enumeration type. In some cases, the set of values are such that only one value can be represented at a time. In other cases, the set of values are distinct powers of two, and by using the -bor operator ([§7.8.5](#)), multiple values can be encoded in the same object.

The PowerShell environment provides a number of enumeration types, as described in the following sections.

4.2.6.1 Action-Preference type

This implementation-defined type has the following mutually exclusive-valued accessible members:

[\[+\] Expand table](#)

Member	Member Kind	Purpose
Continue	Enumeration constant	The PowerShell runtime will continue processing and notify the user that an action has occurred.
Inquire	Enumeration constant	The PowerShell runtime will stop processing and ask the user how it should proceed.
SilentlyContinue	Enumeration constant	The PowerShell runtime will continue processing without notifying the user that an action has occurred.
Stop	Enumeration constant	The PowerShell runtime will stop processing when an action occurs.

In PowerShell, this type is `System.Management.Automation.ActionPreference`.

4.2.6.2 Confirm-Impact type

This implementation-defined type has the following mutually exclusive-valued accessible members:

[\[+\] Expand table](#)

Member	Member Kind	Purpose
High	Enumeration constant	The action performed has a high risk of losing data, such as reformatting a hard disk.

Member	Member Kind	Purpose
Low	Enumeration constant	The action performed has a low risk of losing data.
Medium	Enumeration constant	The action performed has a medium risk of losing data.
None	Enumeration constant	Do not confirm any actions (suppress all requests for confirmation).

In PowerShell, this type is `System.Management.Automation.ConfirmImpact`.

4.2.6.3 File-Attributes type

This implementation-defined type has the following accessible members, which can be combined:

[\[+\] Expand table](#)

Member	Member Kind	Purpose
Archive	Enumeration constant	The file's archive status. Applications use this attribute to mark files for backup or removal.
Compressed	Enumeration constant	The file is compressed.
Device		Reserved for future use.
Directory	Enumeration constant	The file is a directory.
Encrypted	Enumeration constant	The file or directory is encrypted. For a file, this means that all data in the file is encrypted. For a directory, this means that encryption is the default for newly created files and directories.
Hidden	Enumeration constant	The file is hidden, and thus is not included in an ordinary directory listing.
Normal	Enumeration constant	The file is normal and has no other attributes set. This attribute is valid only if used alone.
NotContentIndexed	Enumeration constant	The file will not be indexed by the operating system's content indexing service.
Offline	Enumeration constant	The file is offline. The data of the file is not immediately available.

Member	Member Kind	Purpose
ReadOnly	Enumeration constant	The file is read-only.
ReparsePoint	Enumeration constant	The file contains a reparse point, which is a block of user-defined data associated with a file or a directory.
SparseFile	Enumeration constant	The file is a sparse file. Sparse files are typically large files whose data are mostly zeros.
System	Enumeration constant	The file is a system file. The file is part of the operating system or is used exclusively by the operating system.
Temporary	Enumeration constant	The file is temporary. File systems attempt to keep all of the data in memory for quicker access rather than flushing the data back to mass storage. A temporary file should be deleted by the application as soon as it is no longer needed.

In PowerShell, this type is `System.IO.FileAttributes` with attribute `FlagsAttribute`.

4.2.6.4 Regular-Expression-Option type

This implementation-defined type has the following accessible members, which can be combined:

[\[+\] Expand table](#)

Member	Member Kind	Purpose
IgnoreCase	Enumeration constant	Specifies that the matching is case-insensitive.
None	Enumeration constant	Specifies that no options are set.

An implementation may provide other values.

In PowerShell, this type is `System.Text.RegularExpressions.RegexOptions` with attribute `FlagsAttribute`. The following extra values are defined: `Compiled`, `CultureInvariant`, `ECMAScript`, `ExplicitCapture`, `IgnorePatternWhitespace`, `Multiline`, `RightToLeft`, `Singleline`.

4.3 Reference types

4.3.1 Strings

A string value has type `string` and is an immutable sequence of zero or more characters of type `char` each containing a UTF-16-encoded 16-bit Unicode code point.

Type `string` has the following accessible members:

[\[+\] Expand table](#)

Member	Member Kind	Type	Purpose
Length	Instance Property	int (read-only)	Gets the number of characters in the string
ToLower	Instance Method	string	Creates a new string that contains the lowercase equivalent
ToUpper	Instance Method	string	Creates a new string that contains the uppercase equivalent

In PowerShell, `string` maps to `System.String`.

4.3.2 Arrays

All array types are derived from the type `array`. This type has the following accessible members:

[\[+\] Expand table](#)

Member	Member Kind	Type	Purpose
Length	Instance Property (read-only)	int	Number of elements in the array
Rank	Instance Property (read-only)	int	Number of dimensions in the array
Copy	Static Method	void/see Purpose column	Copies a range of elements from one array to another. There are four versions, where <code>source</code> is the source array, <code>destination</code> is the destination array, <code>count</code> is the number of elements to copy, and <code>sourceIndex</code> and <code>destinationIndex</code> are the starting locations in their respective arrays: <code>Copy(source, destination, int count)</code> <code>Copy(source, destination, long count)</code> <code>Copy(source, sourceIndex, destination, destinationIndex,</code>

Member	Member Kind	Type	Purpose
		int <i>count</i>) Copy(<i>source</i> , <i>sourceIndex</i> , <i>destination</i> , <i>destinationIndex</i> , long <i>count</i>)	
GetLength	Instance Method (read-only)	int/none	Number of elements in a given dimension GetLength(int <i>dimension</i>)

For more details on arrays, see [§9](#).

In PowerShell, `array` maps to `System.Array`.

4.3.3 Hashtables

Type `Hashtable` has the following accessible members:

[\[+\] Expand table](#)

Member	Member Kind	Type	Purpose
Count	Instance Property	int	Gets the number of key/value pairs in the Hashtable
Keys	Instance Property	Implementation-defined	Gets a collection of all the keys
Values	Instance Property	Implementation-defined	Gets a collection of all the values
Remove	Instance Method	void/none	Removes the designated key/value

For more details on Hashtables, see [§10](#).

In PowerShell, `Hashtable` maps to `System.Collections.Hashtable`. `Hashtable` elements are stored in an object of type `DictionaryEntry`, and the collections returned by `Keys` and `Values` have type `ICollection`.

4.3.4 The `xml` type

Type `xml` implements the W3C Document Object Model (DOM) Level 1 Core and the Core DOM Level 2. The DOM is an in-memory (cache) tree representation of an XML

document and enables the navigation and editing of this document. This type supports the subscript operator [] ([§7.1.4.4](#)).

In PowerShell, `xml` maps to `System.Xml.XmlDocument`.

4.3.5 The regex type

Type `regex` provides machinery for supporting regular expression processing. It is used to constrain the type of a parameter ([§5.3](#)) whose corresponding argument might contain a regular expression.

In PowerShell, `regex` maps to `System.Text.RegularExpressions.Regex`.

4.3.6 The ref type

Ordinarily, arguments are passed to commands by value. In the case of an argument having some value type a copy of the value is passed. In the case of an argument having some reference type a copy of the reference is passed.

Type `ref` provides machinery to allow arguments to be passed to commands by reference, so the commands can modify the argument's value. Type `ref` has the following accessible members:

[+] [Expand table](#)

Member	Member Kind	Type	Purpose
Value	Instance property (read-write)	The type of the value being referenced.	Gets/sets the value being referenced.

Consider the following function definition and call:

```
PowerShell

function Doubler {
    param ([ref]$x) # parameter received by reference
    $x.Value *= 2.0 # note that 2.0 has type double
}

$number = 8 # designates a value of type int, value 8
Doubler([ref]$number) # argument received by reference
$number # designates a value of type double, value 8.0
```

Consider the case in which `$number` is type-constrained:

PowerShell

```
[int]$number = 8 # designates a value of type int, value 8
Doubler([ref]$number) # argument received by reference
$number # designates a value of type int, value 8
```

As shown, both the argument and its corresponding parameter must be declared `ref`.

In PowerShell, `ref` maps to `System.Management.Automation.PSReference`.

4.3.7 The scriptblock type

Type `scriptblock` represents a precompiled block of script text ([§7.1.8](#)) that can be used as a single unit. It has the following accessible members:

[] [Expand table](#)

Member	Member Kind	Type	Purpose
Attributes	Instance property (read-only)	Collection of attributes	Gets the attributes of the script block.
File	Instance property (read-only)	string	Gets the name of the file in which the script block is defined.
Module	Instance property (read-only)	implementation defined ([§4.5.12] [§4.5.12])	Gets information about the module in which the script block is defined.
GetNewClosure	Instance method	scriptblock /none	Retrieves a script block that is bound to a module. Any local variables that are in the context of the caller will be copied into the module.
Invoke	Instance method	Collection of object/object[]	Invokes the script block with the specified arguments and returns the results.
InvokeReturnAsIs	Instance method	object/object[]	Invokes the script block with the specified arguments and returns any objects generated.
Create	Static method	scriptblock /string	Creates a new scriptblock object that contains the specified script.

In PowerShell, `scriptblock` maps to `System.Management.Automation.ScriptBlock`. `Invoke` returns a collection of `PSObject`.

4.3.8 The math type

Type `math` provides access to some constants and methods useful in mathematical computations. It has the following accessible members:

[+] Expand table

Member	Member Kind	Type	Purpose
E	Static property (read-only)	double	Natural logarithmic base
PI	Static property (read-only)	double	Ratio of the circumference of a circle to its diameter
Abs	Static method	numeric/numeric	Absolute value (the return type is the same as the type of the argument passed in)
Acos	Static method	double / double	Angle whose cosine is the specified number
Asin	Static method	double / double	Angle whose sine is the specified number
Atan	Static method	double / double	Angle whose tangent is the specified number
Atan2	Static method	double / double <i>y</i> , double <i>x</i>	Angle whose tangent is the quotient of two specified numbers <i>x</i> and <i>y</i>
Ceiling	Static method	decimal / decimal double / double	smallest integer greater than or equal to the specified number
Cos	Static method	double / double	Cosine of the specified angle
Cosh	Static method	double / double	Hyperbolic cosine of the specified angle
Exp	Static method	double / double	e raised to the specified power
Floor	Static method	decimal / decimal double / double	Largest integer less than or equal to the specified number
Log	Static method	double / double <i>number</i>	Logarithm of number using base e or base <i>base</i>

Member	Member Kind	Type	Purpose
		double / double <i>number</i> , double <i>base</i>	
Log10	Static method	double / double	Base-10 logarithm of a specified number
Max	Static method	numeric/numeric	Larger of two specified numbers (the return type is the same as the type of the arguments passed in)
Min	Static method	numeric/numeric, numeric	Smaller of two specified numbers (the return type is the same as the type of the arguments passed in)
Pow	Static method	double / double <i>x</i> , double <i>y</i>	A specified number <i>x</i> raised to the specified power <i>y</i>
Sin	Static method	double / double	Sine of the specified angle
Sinh	Static method	double / double	Hyperbolic sine of the specified angle
Sqrt	Static method	double / double	Square root of a specified number
Tan	Static method	double / double	Tangent of the specified angle
Tanh	Static method	double / double	Hyperbolic tangent of the specified angle

In PowerShell, `Math` maps to `System.Math`.

4.3.9 The ordered type

Type `ordered` is a pseudo type used only for conversions.

4.3.10 The pscustomobject type

Type `pscustomobject` is a pseudo type used only for conversions.

4.4 Generic types

A number of programming languages and environments provide types that can be *specialized*. Many of these types are referred to as *container types*, as instances of them are able to contain objects of some other type. Consider a type called Stack that can represent a stack of values, which can be pushed on and popped off. Typically, the user of a stack wants to store only one kind of object on that stack. However, if the language or environment does not support type specialization, multiple distinct variants of the

type Stack must be implemented even though they all perform the same task, just with different type elements.

Type specialization allows a *generic type* to be implemented such that it can be constrained to handling some subset of types when it is used. For example,

- A generic stack type that is specialized to hold strings might be written as `Stack[string]`.
- A generic dictionary type that is specialized to hold int keys with associated string values might be written as `Dictionary[int,string]`.
- A stack of stack of strings might be written as `Stack[Stack[string]]`.

Although PowerShell does not define any built-in generic types, it can use such types if they are provided by the host environment. See the syntax in [§7.1.10](#).

The complete name for the type `Stack[string]` suggested above is

`System.Collections.Generic.Stack[string]`. The complete name for the type

`Dictionary[int,string]` suggested above is

`System.Collections.Generic.Dictionary[int,string]`.

4.5 Anonymous types

In some circumstances, an implementation of PowerShell creates objects of some type, and those objects have members accessible to script. However, the actual name of those types need not be specified, so long as the accessible members are specified sufficiently for them to be used. That is, scripts can save objects of those types and access their members without actually knowing those types' names. The following subsections specify these types.

4.5.1 Provider description type

This type encapsulates the state of a provider. It has the following accessible members:

[+] Expand table

Member	Member Kind	Type	Purpose
Drives	Instance property (read-only)	Implementation defined (§4.5.2)	A collection of drive description objects
Name	Instance property (read-only)	string	The name of the provider

In PowerShell, this type is `System.Management.Automation.ProviderInfo`.

4.5.2 Drive description type

This type encapsulates the state of a drive. It has the following accessible members:

[+] Expand table

Member	Member Kind	Type	Purpose
CurrentLocation	Instance property (read-write)	string	The current working location (§3.1.4) of the drive
Description	Instance property (read-write)	string	The description of the drive
Name	Instance property (read-only)	string	The name of the drive
Root	Instance property (read-only)	string	The name of the drive

In PowerShell, this type is `System.Management.Automation.PSDriveInfo`.

4.5.3 Variable description type

This type encapsulates the state of a variable. It has the following accessible members:

[+] Expand table

Member	Member Kind	Type	Purpose
Attributes	Instance property (read-only)	Implementation defined	A collection of attributes
Description	Instance property (read-write)	string	The description assigned to the variable via the New-Variable or Set-Variable cmdlets.
Module	Instance property (read-only)	Implementation defined (§4.5.12)	The module from which this variable was exported
ModuleName	Instance property (read-only)	string	The module in which this variable was defined

Member	Member Kind	Type	Purpose
Name	Instance property (read-only)	string	The name assigned to the variable when it was created in the PowerShell language or via the <code>New-Variable</code> and <code>Set-Variable</code> cmdlets.
Options	Instance property (read-write)	string	The options assigned to the variable via the <code>New-Variable</code> and <code>Set-Variable</code> cmdlets.
Value	Instance property (read-write)	object	The value assigned to the variable when it was assigned in the PowerShell language or via the <code>New-Variable</code> and <code>Set-Variable</code> cmdlets.

In PowerShell, this type is `System.Management.Automation.PSVariable`.

Windows PowerShell: The type of the attribute collection is `System.Management.Automation.PSVariableAttributeCollection`.

4.5.4 Alias description type

This type encapsulates the state of an alias. It has the following accessible members:

[Expand table](#)

Member	Member Kind	Type	Purpose
CommandType	Instance property (read-only)	Implementation defined	Should compare equal with "Alias".
Definition	Instance property (read-only)	string	The command or alias to which the alias was assigned via the <code>New-Alias</code> or <code>Set-Alias</code> cmdlets.
Description	Instance property (read-write)	string	The description assigned to the alias via the <code>New-Alias</code> or <code>Set-Alias</code> cmdlets.
Module	Instance property (read-only)	Implementation defined (§4.5.12)	The module from which this alias was exported
ModuleName	Instance property (read-only)	string	The module in which this alias was defined

Member	Member Kind	Type	Purpose
Name	Instance property (read-only)	string	The name assigned to the alias when it was created via the <code>New-Alias</code> or <code>Set-Alias</code> cmdlets.
Options	Instance property (read-write)	string	The options assigned to the alias via the New-Alias <code>New-Alias</code> or <code>Set-Alias</code> cmdlets.
OutputType	Instance property (read-only)	Implementation defined collection	Specifies the types of the values output by the command to which the alias refers.
Parameters	Instance property (read-only)	Implementation defined collection	The parameters of the command.
ParameterSets	Instance property (read-only)	Implementation defined collection	Information about the parameter sets associated with the command.
ReferencedCommand	Instance property (read-only)	Implementation defined	Information about the command that is immediately referenced by this alias.
ResolvedCommand	Instance property (read-only)	Implementation defined	Information about the command to which the alias eventually resolves.

In PowerShell, this type is `System.Management.Automation.AliasInfo`.

4.5.5 Working location description type

This type encapsulates the state of a working location. It has the following accessible members:

[+] Expand table

Member	Member Kind	Type	Purpose
Drive	Instance property (read-only)	Implementation defined (§4.5.2)	A drive description object
Path	Instance property (read-only)	string	The working location
Provider	Instance property	Implementation defined	The provider

Member	Member Kind	Type	Purpose
	(read-only)	(§4.5.1)	
ProviderPath	Instance property (read-only)	string	The current path of the provider

A stack of working locations is a collection of working location objects, as described above.

In PowerShell, a current working location is represented by an object of type `System.Management.Automation.PathInfo`. A stack of working locations is represented by an object of type `System.Management.Automation.PathInfoStack`, which is a collection of `PathInfo` objects.

4.5.6 Environment variable description type

This type encapsulates the state of an environment variable. It has the following accessible members:

[+] Expand table

Member	Member Kind	Type	Purpose
Name	Instance property (read-write)	string	The name of the environment variable
Value	Instance property (read-write)	string	The value of the environment variable

In PowerShell, this type is `System.Collections.DictionaryEntry`. The name of the variable is the dictionary key. The value of the environment variable is the dictionary value. `Name` is an `AliasProperty` that equates to `Key`.

4.5.7 Application description type

This type encapsulates the state of an application. It has the following accessible members:

[+] Expand table

Member	Member Kind	Type	Purpose
CommandType	Instance property (read-only)	Implementation defined	Should compare equal with "Application".

Member	Member Kind	Type	Purpose
Definition	Instance property (read-only)	string	A description of the application.
Extension	Instance property (read-write)	string	The extension of the application file.
Module	Instance property (read-only)	Implementation defined (§4.5.12)	The module that defines this command.
ModuleName	Instance property (read-only)	string	The name of the module that defines the command.
Name	Instance property (read-only)	string	The name of the command.
OutputType	Instance property (read-only)	Implementation defined collection	Specifies the types of the values output by the command.
Parameters	Instance property (read-only)	Implementation defined collection	The parameters of the command.
ParameterSets	Instance property (read-only)	Implementation defined collection	Information about the parameter sets associated with the command.
Path	Instance property (read-only)	string	Gets the path of the application file.

In PowerShell, this type is `System.Management.Automation.ApplicationInfo`.

4.5.8 Cmdlet description type

This type encapsulates the state of a cmdlet. It has the following accessible members:

[\[+\] Expand table](#)

Member	Member Kind	Type	Purpose
CommandType	Instance property (read-only)	Implementation defined	Should compare equal with "Cmdlet".
DefaultParameterSet	Instance property (read-only)	Implementation defined	The default parameter set that is used if PowerShell cannot determine which parameter set to use based on the supplied arguments.
Definition	Instance property (read-only)	string	A description of the cmdlet.
HelpFile	Instance property (read-write)	string	The path to the Help file for the cmdlet.
ImplementingType	Instance property (read-write)	Implementation defined	The type that implements the cmdlet.
Module	Instance property (read-only)	Implementation defined (§4.5.12)	The module that defines this cmdlet.
ModuleName	Instance property (read-only)	string	The name of the module that defines the cmdlet.
Name	Instance property (read-only)	string	The name of the cmdlet.
Noun	Instance property (read-only)	string	The noun name of the cmdlet.
OutputType	Instance property (read-only)	Implementation defined collection	Specifies the types of the values output by the cmdlet.
Parameters	Instance property (read-only)	Implementation defined collection	The parameters of the cmdlet.
ParameterSets	Instance property (read-only)	Implementation defined collection	Information about the parameter sets associated with the cmdlet.

Member	Member Kind	Type	Purpose
Verb	Instance property (read-only)	string	The verb name of the cmdlet.
PSSnapIn	Instance property (read-only)	Implementation defined	Windows PowerShell: Information about the Windows PowerShell snap-in that is used to register the cmdlet.

In PowerShell, this type is `System.Management.Automation.CmdletInfo`.

4.5.9 External script description type

This type encapsulates the state of an external script (one that is directly executable by PowerShell, but is not built-in). It has the following accessible members:

[+] Expand table

Member	Member Kind	Type	Purpose
CommandType	Instance property (read-only)	Implementation defined	Should compare equal with "ExternalScript".
Definition	Instance property (read-only)	string	A definition of the script.
Module	Instance property (read-only)	Implementation defined (§4.5.12)	The module that defines this script.
ModuleName	Instance property (read-only)	string	The name of the module that defines the script.
Name	Instance property (read-only)	string	The name of the script.
OriginalEncoding	Instance property (read-only)	Implementation defined	The original encoding used to convert the characters of the script to bytes.

Member	Member Kind	Type	Purpose
OutputType	Instance property (read-only)	Implementation defined collection	Specifies the types of the values output by the script.
Parameters	Instance property (read-only)	Implementation defined collection	The parameters of the script.
ParameterSets	Instance property (read-only)	Implementation defined collection	Information about the parameter sets associated with the script.
Path	Instance property (read-only)	string	The path to the script file.
ScriptBlock	Instance property (read-only)	scriptblock	The external script.
ScriptContents	Instance property (read-only)	string	The original contents of the script.

In PowerShell, this type is `System.Management.Automation.ExternalScriptInfo`.

4.5.10 Function description type

This type encapsulates the state of a function. It has the following accessible members:

[+] Expand table

Member	Member Kind	Type	Purpose
CmdletBinding	Instance property (read-only)	bool	Indicates whether the function uses the same parameter binding that compiled cmdlets use (see §12.3.5).
CommandType	Instance property (read-only)	Implementation defined	Can be compared for equality with "Function" or "Filter" to see which of those this object represents.
DefaultParameterSet	Instance property	string	Specifies the parameter set to use if that cannot be determined from the

Member	Member Kind	Type	Purpose
	(read-only)		arguments (see §12.3.5).
Definition	Instance property (read-only)	string	A string version of ScriptBlock
Description	Instance property (read-write)	string	The description of the function.
Module	Instance property (read-only)	Implementation defined (§4.5.12)	The module from which this function was exported
ModuleName	Instance property (read-only)	string	The module in which this function was defined
Name	Instance property (read-only)	string	The name of the function
Options	Instance property (read-write)	Implementation defined	The scope options for the function (§3.5.4).
OutputType	Instance property (read-only)	Implementation defined collection	Specifies the types of the values output, in order (see §12.3.6).
Parameters	Instance property (read-only)	Implementation defined collection	Specifies the parameter names, in order. If the function acts like a cmdlet (see CmdletBinding above) the common parameters are included at the end of the collection.
ParameterSets	Instance property (read-only)	Implementation defined collection	Information about the parameter sets associated with the command. For each parameter, the result shows the parameter name and type, and indicates

Member	Member Kind	Type	Purpose
			if the parameter is mandatory, by position or a switch parameter. If the function acts like a cmdlet (see CmdletBinding above) the common parameters are included at the end of the collection.
ScriptBlock	Instance property (read-only)	scriptblock (§4.3.6)	The body of the function

In PowerShell, this type is `System.Management.Automation.FunctionInfo`.

- `CommandType` has type `System.Management.Automation.CommandTypes`.
- `Options` has type `System.Management.Automation.ScopedItemOptions`.
- `OutputType` has type
`System.Collections.ObjectModel.ReadOnlyCollection`1[[System.Management.Automation.PSTypeName, System.Management.Automation]]`.
- `Parameters` has type
`System.Collections.Generic.Dictionary`2[[System.String, mscorelib], [System.Management.Automation.ParameterMetadata, System.Management.Automation]]`
- `System.Collections.ObjectModel.ReadOnlyCollection`1[[System.Management.Automation.CommandParameterSetInfo, System.Management.Automation]]`.
- `Visibility` has type `System.Management.Automation.SessionStateEntryVisibility`.
- PowerShell also has a property called `Visibility`.

4.5.11 Filter description type

This type encapsulates the state of a filter. It has the same set of accessible members as the function description type ([§4.5.10](#)).

In PowerShell, this type is `System.Management.Automation.FilterInfo`. It has the same set of properties as `System.Management.Automation.FunctionInfo` ([§4.5.11](#)).

4.5.12 Module description type

This type encapsulates the state of a module. It has the following accessible members:

[\[\] Expand table](#)

Member	Member Kind	Type	Purpose
Description	Instance property (read-write)	string	The description of the module (set by the manifest)
ModuleType	Instance property (read-only)	Implementation defined	The type of the module (Manifest, Script, or Binary)
Name	Instance property (read-only)	string	The name of the module
Path	Instance property (read-only)	string	The module's path

In PowerShell, this type is `System.Management.Automation.PSModuleInfo`. The type of `ModuleType` is `System.Management.Automation.ModuleType`.

4.5.13 Custom object description type

This type encapsulates the state of a custom object. It has no accessible members.

In PowerShell, this type is `System.Management.Automation.PSCustomObject`. The cmdlets `Import-Module` and `New-Object` can generate an object of this type.

4.5.14 Command description type

The automatic variable `$PSCmdlet` is an object that represents the cmdlet or function being executed. The type of this object is implementation defined; it has the following accessible members:

[\[\] Expand table](#)

Member	Member Kind	Type	Purpose
ParameterSetName	Instance property (read-only)	string	Name of the current parameter set (see <code>ParameterSetName</code>)
ShouldContinue	Instance method	Overloaded /bool	Requests confirmation of an operation from the user.
ShouldProcess	Instance method	Overloaded	Requests confirmation from the user before an operation is performed.

Member	Member Kind	Type	Purpose
		/bool	

In PowerShell, this type is `System.Management.Automation.PSScriptCmdlet`.

4.5.15 Error record description type

The automatic variable `$Error` contains a collection of error records that represent recent errors ([§3.12](#)). Although the type of this collection is unspecified, it does support subscripting to get access to individual error records.

In PowerShell, the collection type is `System.Collections.ArrayList`. The type of an individual error record in the collection is `System.Management.Automation.ErrorRecord`. This type has the following public properties:

- `CategoryInfo` - Gets information about the category of the error.
- `ErrorDetails` - Gets and sets more detailed error information, such as a replacement error message.
- `Exception` - Gets the exception that is associated with this error record.
- `FullyQualifiedErrorId` - Gets the fully qualified error identifier for this error record.
- `InvocationInfo` - Gets information about the command that was invoked when the error occurred.
- `PipelineIterationInfo` - Gets the status of the pipeline when this error record was created
- `TargetObject` - Gets the object that was being processed when the error occurred.

4.5.16 Enumerator description type

A number of variables are enumerators for collections ([§4](#)). The automatic variable `$foreach` is the enumerator created for any `foreach` statement. The automatic variable `$input` is the enumerator for a collection delivered to a function from the pipeline. The automatic variable `$switch` is the enumerator created for any `switch` statement.

The type of an enumerator is implementation defined; it has the following accessible members:

[] [Expand table](#)

Member	Member Kind	Type	Purpose
Current	Instance property (read-only)	object	Gets the current element in the collection. If the enumerator is not currently positioned at an element of the collection, the behavior is implementation defined.
MoveNext	Instance method	None/bool	Advances the enumerator to the next element of the collection. Returns \$true if the enumerator was successfully advanced to the next element; \$false if the enumerator has passed the end of the collection.

In PowerShell, these members are defined in the interface `System.IEnumerator`, which is implemented by the types identified below. If the enumerator is not currently positioned at an element of the collection, an exception of type `InvalidOperationException` is raised. For `$foreach`, this type is `System.Array+SZArrayEnumerator`. For `$input`, this type is `System.Collections.ArrayList+ArrayListEnumeratorSimple`. For `$switch`, this type is `System.Array+SZArrayEnumerator`.

4.5.17 Directory description type

The cmdlet [New-Item](#) can create items of various kinds including FileSystem directories. The type of a directory description object is implementation defined; it has the following accessible members:

[+] [Expand table](#)

Member	Member Kind	Type	Purpose
Attributes	Instance property (read-write)	Implementation defined (§4.2.6.3)	Gets or sets one or more of the attributes of the directory object.
CreationTime	Instance property (read-write)	Implementation defined (§4.5.19)	Gets and sets the creation time of the directory object.
Extension	Instance property (read- only)	string	Gets the extension part of the directory name.
FullName	Instance property (read-only)	string	Gets the full path of the directory.
LastWriteTime	Instance property (read-write)	Implementation defined (§4.5.19)	Gets and sets the time when the directory was last written to.
Name	Instance property (read- only)	string	Gets the name of the directory.

In PowerShell, this type is `System.IO.DirectoryInfo`. The type of the **Attributes** property is `System.IO.FileAttributes`.

4.5.18 File description type

The cmdlet `New-Item` can create items of various kinds including FileSystem files. The type of a file description object is implementation defined; it has the following accessible members:

[+] Expand table

Member	Member Kind	Type	Purpose
Attributes	Instance property (read-write)	Implementation defined (§4.2.6.3)	Gets or sets one or more of the attributes of the file object.
BaseName	Instance property (read-only)	string	Gets the name of the file excluding the extension.
CreationTime	Instance property (read-write)	Implementation defined (§4.5.19)	Gets and sets the creation time of the file object.
Extension	Instance property (read-only)	string	Gets the extension part of the file name.
FullName	Instance property (read-only)	string	Gets the full path of the file.
LastWriteTime	Instance property (read-write)	Implementation defined (§4.5.19)	Gets and sets the time when the file was last written to.
Length	Instance property (read-only)	long	Gets the size of the file, in bytes.
Name	Instance property (read-only)	string	Gets the name of the file.
VersionInfo	Instance property	Implementation defined	Windows PowerShell: This ScriptProperty returns a <code>System.DiagnosticsFileVersionInfo</code>

Member	Member Kind	Type	Purpose
	(read-only)		for the file.

In PowerShell, this type is `System.IO.FileInfo`.

4.5.19 Date-Time description type

The type of a date-time description object is implementation defined; it has the following accessible members:

[\[+\] Expand table](#)

Member	Member Kind	Type	Purpose
Day	Instance property (read-only)	int	Gets the day component of the month represented by this instance.
Hour	Instance property (read-only)	int	Gets the hour component of the date represented by this instance.
Minute	Instance property (read-only)	int	Gets the minute component of the date represented by this instance.
Month	Instance property (read-only)	int	Gets the month component of the date represented by this instance.
Second	Instance property (read-only)	int	Gets the seconds component of the date represented by this instance.
Year	Instance property (read-only)	int	Gets the year component of the date represented by this instance.

An object of this type can be created by cmdlet [Get-Date](#).

In PowerShell, this type is `System.DateTime`.

4.5.20 Group-Info description type

The type of a **group-info** description object is implementation defined; it has the following accessible members:

[\[+\] Expand table](#)

Member	Member Kind	Type	Purpose
Count	Instance property (read-only)	int	Gets the number of elements in the group.
Group	Instance property (read-only)	Implementation-defined collection	Gets the elements of the group.
Name	Instance property (read-only)	string	Gets the name of the group.
Values	Instance property (read-only)	Implementation-defined collection	Gets the values of the elements of the group.

An object of this type can be created by cmdlet [Group-Object](#).

In PowerShell, this type is `Microsoft.PowerShell.Commands.GroupInfo`.

4.5.21 Generic-Measure-Info description type

The type of a **generic-measure-info** description object is implementation defined; it has the following accessible members:

[\[+\] Expand table](#)

Member	Member Kind	Type	Purpose
Average	Instance property (read-only)	double	Gets the average of the values of the properties that are measured.
Count	Instance property (read-only)	int	Gets the number of objects with the specified properties.
Maximum	Instance property (read-only)	double	Gets the maximum value of the specified properties.
Minimum	Instance property (read-only)	double	Gets the minimum value of the specified properties.
Property	Instance property (read-only)	string	Gets the property to be measured.
Sum	Instance property (read-only)	double	Gets the sum of the values of the specified properties.

An object of this type can be created by cmdlet [Measure-Object](#).

In PowerShell, this type is `Microsoft.PowerShell.Commands.GenericMeasureInfo`.

4.5.22 Text-Measure-Info description type

The type of a **text-info** description object is implementation defined; it has the following accessible members:

[+] Expand table

Member	Member Kind	Type	Purpose
Characters	Instance property (read-only)	int	Gets the number of characters in the target object.
Lines	Instance property (read-only)	int	Gets the number of lines in the target object.
Property	Instance property (read-only)	string	Gets the property to be measured.
Words	Instance property (read-only)	int	Gets the number of words in the target object.

An object of this type can be created by cmdlet `Measure-Object`.

In PowerShell, this type is `Microsoft.PowerShell.Commands.TextMeasureInfo`.

4.5.23 Credential type

A credential object can then be used in various security operations. The type of a credential object is implementation defined; it has the following accessible members:

[+] Expand table

Member	Member Kind	Type	Purpose
Password	Instance property (read-only)	Implementation defined	Gets the password.
UserName	Instance property (read-only)	string	Gets the username.

An object of this type can be created by cmdlet `Get-Credential`.

In PowerShell, this type is `System.Management.Automation.PSCredential`.

4.5.24 Method designator type

The type of a method designator is implementation defined; it has the following accessible members:

[\[\] Expand table](#)

Member	Member Kind	Type	Purpose
Invoke	Instance method	object/variable number and type	Takes a variable number of arguments, and indirectly calls the method referred to by the parent method designator, passing in the arguments.

An object of this type can be created by an *invocation-expression* ([§7.1.3](#)).

In PowerShell, this type is `System.Management.Automation.PSMethod`.

4.5.25 Member definition type

This type encapsulates the definition of a member. It has the following accessible members:

[\[\] Expand table](#)

Member	Member Kind	Type	Purpose
Definition	Instance property (read-only)	string	Gets the definition of the member.
MemberType	Instance property (read-only)	Implementation defined	Gets the PowerShell type of the member.
Name	Instance property (read-only)	string	Gets the name of the member.
TypeName	Instance property (read-only)	string	Gets the type name of the member.

In PowerShell, this type is `Microsoft.PowerShell.Commands.MemberDefinition`.

4.6 Type extension and adaptation

A PowerShell implementation includes a family of core types (which are documented in this chapter) that each contain their own set of *base members*. Those members can be methods or properties, and they can be instance or static members. For example, the base members of the type `string` ([§4.3.1](#)) are the instance property `Length` and the instance methods `ToLower` and `ToUpper`.

When an object is created, it contains all the instance properties of that object's type, and the instance methods of that type can be called on that object. An object may be customized via the addition of instance members at runtime. The result is called a *custom object*. Any members added to an instance exist only for the life of that instance; other instances of the same core type are unaffected.

The base member set of a type can be augmented by the addition of the following kinds of members:

- *adapted members*, via the *Extended Type System* (ETS), most details of which are unspecified.
- *extended members*, via the cmdlet [Add-Member](#).

In PowerShell, extended members can also be added via `types.ps1xml` files. Adapted and extended members are collectively called **synthetic members**.

The ETS adds the following members to all PowerShell objects: **psbase**, **psadapted**, **psextended**, and **pstypenames**. See the **Force** and **View** parameters in the cmdlet [Get-Member](#) for more information on these members.

An instance member may hide an extended and/or adapted member of the same name, and an extended member may hide an adapted member. In such cases, the member sets **psadapted** and **psextended** can be used to access those hidden members.

If a `types.ps1xml` specifies a member called **Supports**, `obj.psextended` provides access to just that member and not to a member added via [Add-Member](#).

There are three ways create a custom object having a new member M:

1. This approach can be used to add one or more NoteProperty members.

```
PowerShell  
  
$x = New-Object PSObject -Property @{M = 123}
```

2. This approach can be used to add NoteProperty or ScriptMethod members.

```
PowerShell  
  
$x = New-Module -AsCustomObject {$M = 123 ; Export-ModuleMember --Variable M}
```

3. This approach can be used to add any kind of member.

```
PowerShell
```

```
$x = New-Object PSObject  
Add-Member -InputObject $x -Name M -MemberType NoteProperty -Value 123
```

`PSObject` is the base type of all PowerShell types.

5. Variables

Article • 01/08/2025

Editorial note

Important

The *Windows PowerShell Language Specification 3.0* was published in December 2012 and is based on Windows PowerShell 3.0. This specification does not reflect the current state of PowerShell. There is no plan to update this documentation to reflect the current state. This documentation is presented here for historical reference.

The specification document is available as a Microsoft Word document from the Microsoft Download Center at:

<https://www.microsoft.com/download/details.aspx?id=36389> That Word document has been converted for presentation here on Microsoft Learn. During conversion, some editorial changes have been made to accommodate formatting for the Docs platform. Some typos and minor errors have been corrected.

A variable represents a storage location for a value, and that value has a type. Traditional procedural programming languages are statically typed; that is, the runtime type of a variable is that with which it was declared at compile time. Object-oriented languages add the idea of inheritance, which allows the runtime type of a variable to be that with which it was declared at compile time or some type derived from that type. Being a dynamically typed language, PowerShell's variables do not have types, per se. In fact, variables are not defined; they simply come into being when they are first assigned a value. And while a variable may be constrained ([§5.3](#)) to holding a value of a given type, type information in an assignment cannot always be verified statically.

At different times, a variable may be associated with values of different types either through assignment ([§7.11](#)) or the use of the `++` and `--` operators ([§7.1.5](#), [§7.2.6](#)). When the value associated with a variable is changed, that value's type may change. For example,

PowerShell

```
$i = "abc"      # $i holds a value of type string
$i = 2147483647 # $i holds a value of type int
```

```
++$i          # $i now holds a value of type double because  
# 2147483648 is too big to fit in type int
```

Any use of a variable that has not been created results in the value \$null. To see if a variable has been defined, use the [Test-Path](#) cmdlet.

5.1 Writable location

A *writable location* is an expression that designates a resource to which a command has both read and write access. A writable location may be a variable ([§5](#)), an array element ([§9](#)), an associated value in a Hashtable accessed via a subscript ([§10](#)), a property ([§7.1.2](#)), or storage managed by a provider ([§3.1](#)).

5.2 Variable categories

PowerShell defines the following categories of variables: static variables, instance variables, array elements, Hashtable key/value pairs, parameters, ordinary variables, and variables on provider drives. The subsections that follow describe each of these categories.

In the following example

```
PowerShell

function F ($p1, $p2) {
    $radius = 2.45
    $circumference = 2 * ([Math]::PI) * $radius

    $date = Get-Date -Date "2010-2-1 10:12:14 pm"
    $month = $date.Month

    $values = 10, 55, 93, 102
    $value = $values[2]

    $h1 = @{ FirstName = "James"; LastName = "Anderson" }
    $h1.FirstName = "Smith"

    $Alias:A = "Help"
    $Env:MyPath = "E:\Temp"
    ${E:output.txt} = 123
    $Function:F = { "Hello there" }
    $Variable:v = 10
}
```

- `[Math::PI]` is a static variable

- `$date.Month` is an instance variable
- `$values[2]` is an array element
- `$h1.FirstName` is a `Hashtable` key whose corresponding value is `$h1['FirstName']`
- `$p1` and `$p2` are parameters
- `$radius`, `$circumference`, `$date`, `$month`, `$values`, `$value`, and `$h1` are ordinary variables
- `$Alias:A`, `$Env:MyPath`, `${E:output.txt}`, and `$Function:F` are variables on the corresponding provider drives.
- `$Variable:v` is actually an ordinary variable written with its fully qualified provider drive.

5.2.1 Static variables

A data member of an object that belongs to the object's type rather than to that particular instance of the type is called a *static variable*. See [§4.2.3](#), [§4.2.4.1](#), and [§4.3.8](#) for some examples.

PowerShell provides no way to create new types that contain static variables; however, objects of such types may be provided by the host environment.

Memory for creating and deleting objects containing static variables is managed by the host environment and the garbage collection system.

See [§7.1.2](#) for information about accessing a static variable.

A static data member can be a field or a property.

5.2.2 Instance variables

A data member of an object that belongs to a particular instance of the object's type rather than to the type itself is called an *instance variable*. See [§4.3.1](#), [§4.3.2](#), and [§4.3.3](#) for some examples.

A PowerShell host environment might provide a way to create new types that contain instance variables or to add new instance variables to existing types.

Memory for creating and deleting objects containing static variables is managed by the host environment and the garbage collection system.

See [§7.1.2](#) for information about accessing an instance variable.

An instance data member can be a field or a property.

5.2.3 Array elements

An array can be created via a unary comma operator ([§7.2.1](#)), *sub-expression* ([§7.1.6](#)), *array-expression* ([§7.1.7](#)), binary comma operator ([§7.3](#)), range operator ([§7.4](#)), or [New-Object](#) cmdlet.

Memory for creating and deleting arrays is managed by the host environment and the garbage collection system.

Arrays and array elements are discussed in [§9](#).

5.2.4 Hashtable key/value pairs

A Hashtable is created via a hash literal ([§2.3.5.6](#)) or the [New-Object](#) cmdlet. A new key/value pair can be added via the `[]` operator ([§7.1.4.3](#)).

Memory for creating and deleting Hashtables is managed by the host environment and the garbage collection system.

Hashtables are discussed in [§10](#).

5.2.5 Parameters

A parameter is created when its parent command is invoked, and it is initialized with the value of the argument provided in the invocation or by the host environment. A parameter ceases to exist when its parent command terminates.

Parameters are discussed in [§8.10](#).

5.2.6 Ordinary variables

An *ordinary variable* is defined by an *assignment-expression* ([§7.11](#)) or a *foreach-statement* ([§8.4.4](#)). Some ordinary variables are predefined by the host environment while others are transient, coming and going as needed at runtime.

The lifetime of an ordinary variable is that part of program execution during which storage is guaranteed to be reserved for it. This lifetime begins at entry into the scope with which it is associated, and ends no sooner than the end of the execution of that scope. If the parent scope is entered recursively or iteratively, a new instance of the local variable is created each time.

The storage referred to by an ordinary variable is reclaimed independently of the lifetime of that variable.

An ordinary variable can be named explicitly with a **Variable**: namespace prefix ([§5.2.7](#)).

5.2.7 Variables on provider drives

The concept of providers and drives is introduced in [§3.1](#), with each provider being able to provide its own namespace drive(s). This allows resources on those drives to be accessed as though they were ordinary variables ([§5.2.6](#)). In fact, an ordinary variable is stored on the file system provider drive **Variable**: ([§3.1.5](#)) and can be accessed by its ordinary name or its fully qualified namespace name.

Some namespace variable types are constrained implicitly ([§5.3](#)).

5.3 Constrained variables

By default, a variable may designate a value of any type. However, a variable may be *constrained* to designating values of a given type by specifying that type as a type literal before its name in an assignment or a parameter. For example,

PowerShell

```
[int]$i = 10    # constrains $i to designating ints only
$i = "Hello"  # error, no conversion to int
$i = "0x10"   # ok, conversion to int
$i = $true     # ok, conversion to int

function F ([int]$p1, [switch]$p2, [regex]$p3) { ... }
```

Any variable belonging to the namespace **Env**: **Alias**: or to the file system namespace ([§2.3.2](#), [§3.1](#)) is constrained implicitly to the type `string`. Any variable belonging to the namespace **Function**: ([§2.3.2](#), [§3.1](#)) is constrained implicitly to the type `scriptblock`.

6. Conversions

Article • 03/24/2025

Editorial note

Important

The *Windows PowerShell Language Specification 3.0* was published in December 2012 and is based on Windows PowerShell 3.0. This specification does not reflect the current state of PowerShell. There is no plan to update this documentation to reflect the current state. This documentation is presented here for historical reference.

The specification document is available as a Microsoft Word document from the Microsoft Download Center at:

<https://www.microsoft.com/download/details.aspx?id=36389> That Word document has been converted for presentation here on Microsoft Learn. During conversion, some editorial changes have been made to accommodate formatting for the Docs platform. Some typos and minor errors have been corrected.

A *type conversion* is performed when a value of one type is used in a context that requires a different type. If such a conversion happens automatically it is known as *implicit conversion*. (A common example of this is with some operators that need to convert one or more of the values designated by their operands.) Implicit conversion is permitted provided the sense of the source value is preserved, such as no loss of precision of a number when it is converted.

The cast operator ([§7.2.9](#)) allows for *explicit conversion*.

Conversions are discussed below, with supplementary information being provided as necessary in the description of each operator in [§6.19](#).

Explicit conversion of a value to the type it already has causes no change to that value or its representation.

The rules for handing conversion when the value of an expression is being bound to a parameter are covered in [§6.17](#).

6.1 Conversion to void

A value of any type can be discarded explicitly by casting it to type void. There is no result.

6.2 Conversion to bool

The rules for converting any value to type bool are as follows:

- A numeric or char value of zero is converted to False; a numeric or char value of non-zero is converted to True.
- A value of null type is converted to False.
- A string of length 0 is converted to False; a string of length > 0 is converted to True.
- A switch parameter with value `$true` is converted to True, and one with value `$false` is converted to False.
- All other non-null reference type values are converted to True.

If the type implements IList:

- If the object's Length > 2, the value is converted to True.
- If the object's Length is 1 and that first element is not itself an IList, then if that element's value is true, the value is converted to True.
- Otherwise, if the first element's Count ≥ 1 , the value is converted to True.
- Otherwise, the value is converted to False.

6.3 Conversion to char

The rules for converting any value to type char are as follows:

- The conversion of a value of type bool, decimal, float, or double is in error.
- A value of null type is converted to the null (U+0000) character.
- An integer type value whose value can be represented in type char has that value; otherwise, the conversion is in error.
- The conversion of a string value having a length other than 1 is in error.
- A string value having a length 1 is converted to a char having that one character's value.
- A numeric type value whose value after rounding of any fractional part can be represented in the destination type has that rounded value; otherwise, the conversion is in error.
- For other reference type values, if the reference type supports such a conversion, that conversion is used; otherwise, the conversion is in error.

6.4 Conversion to integer

The rules for converting any value to type byte, int, or long are as follows:

- The bool value False is converted to zero; the bool value True is converted to 1.
- A char type value whose value can be represented in the destination type has that value; otherwise, the conversion is in error.
- A numeric type value whose value after rounding of any fractional part can be represented in the destination type has that rounded value; otherwise, the conversion is in error.
- A value of null type is converted to zero.
- A string that represents a number is converted as described in [§6.16](#). If after truncation of the fractional part the result can be represented in the destination type the string is well formed and it has the destination type; otherwise, the conversion is in error. If the string does not represent a number, the conversion is in error.
- For other reference type values, if the reference type supports such a conversion, that conversion is used; otherwise, the conversion is in error.

6.5 Conversion to float and double

The rules for converting any value to type float or double are as follows:

- The bool value False is converted to zero; the bool value True is converted to 1.
- A char value is represented exactly.
- A numeric type value is represented exactly, if possible; however, for int, long, and decimal conversions to float, and for long and decimal conversions to double, some of the least significant bits of the integer value may be lost.
- A value of null type is converted to zero.
- A string that represents a number is converted as described in [§6.16](#); otherwise, the conversion is in error.
- For other reference type values, if the reference type supports such a conversion, that conversion is used; otherwise, the conversion is in error.

6.6 Conversion to decimal

The rules for converting any value to type decimal are as follows:

- The bool value False is converted to zero; the bool value True is converted to 1.
- A char type value is represented exactly.

- A numeric type value is represented exactly; however, if that value is too large or too small to fit in the destination type, the conversion is in error.
- A value of null type is converted to zero.
- A string that represents a number is converted as described in §6.16; otherwise, the conversion is in error.
- For other reference type values, if the reference type supports such a conversion, that conversion is used; otherwise, the conversion is in error.
- The scale of the result of a successful conversion is such that the fractional part has no trailing zeros.

6.7 Conversion to object

The value of any type except the null type (4.1.2) can be converted to type object. The value retains its type and representation.

6.8 Conversion to string

The rules for converting any value to type string are as follows:

- The bool value `$false` is converted to "False"; the bool value `$true` is converted to "True".
- A char type value is converted to a 1-character string containing that char.
- A numeric type value is converted to a string having the form of a corresponding numeric literal. However, the result has no leading or trailing spaces, no leading plus sign, integers have base 10, and there is no type suffix. For a decimal conversion, the scale is preserved. For values of $-\infty$, $+\infty$, and NaN, the resulting strings are "-Infinity", "Infinity", and "NaN", respectively.
- A value of null type is converted to the empty string.
- For a 1-dimensional array, the result is a string containing the value of each element in that array, from start to end, converted to string, with elements being separated by the current Output Field Separator (§2.3.2.2). For an array having elements that are themselves arrays, only the top-level elements are converted. The string used to represent the value of an element that is an array, is implementation defined. For a multi-dimensional array, it is flattened (§9.12) and then treated as a 1-dimensional array.
- A value of null type is converted to the empty string.
- A scriptblock type value is converted to a string containing the text of that block without the delimiting { and } characters.
- For an enumeration type value, the result is a string containing the name of each enumeration constant encoded in that value, separated by commas.

- For other reference type values, if the reference type supports such a conversion, that conversion is used; otherwise, the conversion is in error.

The string used to represent the value of an element that is an array has the form `System.Type[]`, `System.Type[,]`, and so on. For other reference types, the method `ToString` is called. For other enumerable types, the source value is treated like a 1-dimensional array.

6.9 Conversion to array

The rules for converting any value to an array type are as follows:

- The target type may not be a multidimensional array.
- A value of null type is retained as is.
- For a scalar value other than `$null` or a value of type hashtable, a new 1-element array is created whose value is the scalar after conversion to the target element type.
- For a 1-dimensional array value, a new array of the target type is created, and each element is copied with conversion from the source array to the corresponding element in the target array.
- For a multi-dimensional array value, that array is first flattened ([§9.12](#)), and then treated as a 1-dimensional array value.
- A string value is converted to an array of char having the same length with successive characters from the string occupying corresponding positions in the array.

For other enumerable types, a new 1-element array is created whose value is the corresponding element after conversion to the target element type, if such a conversion exists. Otherwise, the conversion is in error.

6.10 Conversion to xml

The object is converted to type string and then into an XML Document object of type `xml`.

6.11 Conversion to regex

An expression that designates a value of type string may be converted to type `regex`.

6.12 Conversion to scriptblock

The rules for converting any value to type `scriptblock` are as follows:

- A string value is treated as the name of a command optionally following by arguments to a call to that command.

6.13 Conversion to enumeration types

The rules for converting any value to an enumeration type are as follows:

- A value of type string that contains one of the named values (with regard for case) for an enumeration type is converted to that named value.
- A value of type string that contains a comma-separated list of named values (with regard for case) for an enumeration type is converted to the bitwise-OR of all those named values.

6.14 Conversion to other reference types

The rules for converting any value to a reference type other than an array type or string are as follows:

- A value of null type is retained as is.
- Otherwise, the behavior is implementation defined.

A number of pieces of machinery come in to play here; these include the possible use of single argument constructors or default constructors if the value is a hashtable, implicit and explicit conversion operators, and Parse methods for the target type; the use of Convert.ConvertTo; and the ETS conversion mechanism.

6.15 Usual arithmetic conversions

If neither operand designates a value having numeric type, then

- If the left operand designates a value of type bool, the conversion is in error.
- Otherwise, all operands designating the value `$null` are converted to zero of type int and the process continues with the numeric conversions listed below.
- Otherwise, if the left operand designates a value of type char and the right operand designates a value of type bool, the conversion is in error.
- Otherwise, if the left operand designates a value of type string but does not represent a number ([§6.16](#)), the conversion is in error.
- Otherwise, if the right operand designates a value of type string but does not represent a number ([§6.16](#)), the conversion is in error.

- Otherwise, all operands designating values of type string are converted to numbers ([§6.16](#)), and the process continues with the numeric conversions listed below.
- Otherwise, the conversion is in error.

Numeric conversions:

- If one operand designates a value of type decimal, the value designated by the other operand is converted to that type, if necessary. The result has type decimal.
- Otherwise, if one operand designates a value of type double, the value designated by the other operand is converted to that type, if necessary. The result has type double.
- Otherwise, if one operand designates a value of type float, the values designated by both operands are converted to type double, if necessary. The result has type double.
- Otherwise, if one operand designates a value of type long, the value designated by the other operand value is converted to that type, if necessary. The result has the type first in the sequence long and double that can represent its value.
- Otherwise, the values designated by both operands are converted to type int, if necessary. The result has the first in the sequence int, long, double that can represent its value without truncation.

6.16 Conversion from string to numeric type

Depending on its contents, a string can be converted explicitly or implicitly to a numeric value. Specifically,

- An empty string is converted to the value zero.
- Leading and trailing spaces are ignored; however, a string may not consist of spaces only.
- A string containing only white space and/or line terminators is converted to the value zero.
- One leading + or - sign is permitted.
- An integer number may have a hexadecimal prefix (0x or 0X).
- An optionally signed exponent is permitted.
- Type suffixes and multipliers are not permitted.
- The case-distinct strings "-Infinity", "Infinity", and "NaN" are recognized as the values $-\infty$, $+\infty$, and NaN, respectively.

6.17 Conversion during parameter binding

For information about parameter binding see [§8.14](#).

When the value of an expression is being bound to a parameter, there are extra conversion considerations, as described below:

- If the parameter type is switch ([§4.2.5](#), [§8.10.5](#)) and the parameter has no argument, the value of the parameter in the called command is set to `$true`. If the parameter type is other than switch, a parameter having no argument is in error.
- If the parameter type is switch and the argument value is `$null`, the parameter value is set to `$false`.
- If the parameter type is object or is the same as the type of the argument, the argument's value is passed without conversion.
- If the parameter type is not object or scriptblock, an argument having type scriptblock is evaluated and its result is passed as the argument's value. (This is known as *delayed script block binding*.) If the parameter type is object or scriptblock, an argument having type scriptblock is passed as is.
- If the parameter type is a collection of type T2, and the argument is a scalar of type T1, that scalar is converted to a collection of type T2 containing one element. If necessary, the scalar value is converted to type T2 using the conversion rules of this section.
- If the parameter type is a scalar type other than object and the argument is a collection, the argument is in error.
- If the expected parameter type is a collection of type T2, and the argument is a collection of type T1, the argument is converted to a collection of type T2 having the same length as the argument collection. If necessary, the argument collection element values are converted to type T2 using the conversion rules of this section.
- If the steps above and the conversions specified earlier in this chapter do not suffice, the rules in [§6.18](#) are applied. If those fail, the parameter binding fails.

6.18 .NET Conversion

For an implicit conversion, PowerShell's built-in conversions are tried first. If they cannot resolve the conversion, the .NET custom converters below are tried, in order, from top to bottom. If a conversion is found, but it throws an exception, the conversion has failed.

- **PSTypeConverter**: There are two ways of associating the implementation of the **PSTypeConverter** class with its target class: through the type configuration file (`types.ps1xml`) or by applying the `System.ComponentModel.TypeConverterAttribute` attribute to the target class. Refer to the PowerShell SDK documentation for more information.

- **TypeConverter**: This CLR type provides a unified way of converting types of values to other types, as well as for accessing standard values and sub-properties. The most common type of converter is one that converts to and from a text representation. The type converter for a class is bound to the class with a `System.ComponentModel.TypeConverterAttribute`. Unless this attribute is overridden, all classes that inherit from this class use the same type converter as the base class. Refer to the PowerShell SDK and the Microsoft .NET framework documentation for more information.
- **Parse Method**: If the source type is string and the destination type has a method called `Parse`, that method is called to perform the conversion.
- **Constructors**: If the destination type has a constructor taking a single argument whose type is that of the source type, that constructor is called to perform the conversion.
- **Implicit Cast Operator**: If the source type has an implicit cast operator that converts to the destination type, that operator is called to perform the conversion.
- **Explicit Cast Operator**: If the source type has an explicit cast operator that converts to the destination type, that operator is called to perform the conversion. If the destination type has an explicit cast operator that converts from the source type, that operator is called to perform the conversion.
- **IConvertible**: `System.Convert.ChangeType` is called to perform the conversion.

6.19 Conversion to ordered

The rules for converting any value to the pseudo-type ordered are as follows:

- If the value is a hash literal ([§2.3.5.6](#)), the result is an object with an implementation defined type that behaves like a hashtable and the order of the keys matches the order specified in the hash literal.
- Otherwise, the behavior is implementation defined.

Only hash literals ([§2.3.5.6](#)) can be converted to ordered. The result is an instance of `System.Collections.Specialized.OrderedDictionary`.

6.20 Conversion to pscustomobject

The rules for converting any value to the pseudo-type pscustomobject are as follows:

- A value of type hashtable is converted to a PowerShell object. Each key in the hashtable becomes a NoteProperty with the corresponding value.
- Otherwise, the behavior is implementation defined.

The conversion is always allowed but does not change the type of the value.

7. Expressions

Article • 04/25/2024

Editorial note

Important

The *Windows PowerShell Language Specification 3.0* was published in December 2012 and is based on Windows PowerShell 3.0. This specification does not reflect the current state of PowerShell. There is no plan to update this documentation to reflect the current state. This documentation is presented here for historical reference.

The specification document is available as a Microsoft Word document from the Microsoft Download Center at:

<https://www.microsoft.com/download/details.aspx?id=36389> That Word document has been converted for presentation here on Microsoft Learn. During conversion, some editorial changes have been made to accommodate formatting for the Docs platform. Some typos and minor errors have been corrected.

Syntax:

```
Syntax

expression:
    primary-expression
    bitwise-expression
    logical-expression
    comparison-expression
    additive-expression
    multiplicative-expression

dash: one of
    - (U+002D)
    EnDash character (U+2013)
    EmDash character (U+2014)
    Horizontal bar character (U+2015)

dashdash:
    dash dash
```

Description:

An *expression* is a sequence of operators and operands that designates a method, a function, a writable location, or a value; specifies the computation of a value; produces one or more side effects; or performs some combination thereof. For example,

- The literal 123 is an expression that designates the int value 123.
- The expression `1,2,3,4` designates the 4-element array object having the values shown.
- The expression `10.4 * $a` specifies a computation.
- The expression `$a++` produces a side effect.
- The expression `$a[$i--] = $b[++$j]` performs a combination of these things.

Except as specified for some operators, the order of evaluation of terms in an expression and the order in which side effects take place are both unspecified. Examples of unspecified behavior include the following: `$i++ + $i`, `$i + --$i`, and `$w[$j++] = $v[$j]`.

An implementation of PowerShell may provide support for user-defined types, and those types may have operations defined on them. All details of such types and operations are implementation defined.

A *top-level expression* is one that is not part of some larger expression. If a top-level expression contains a side-effect operator the value of that expression is not written to the pipeline; otherwise, it is. See [§7.1.1](#) for a detailed discussion of this.

Ordinarily, an expression that designates a collection ([§4§4]) is enumerated into its constituent elements when the value of that expression is used. However, this is not the case when the expression is a cmdlet invocation. For example,

```
PowerShell

$x = 10,20,30
$a = $($x; 99)          # $a.Length is 4

$x = New-Object 'int[]' 3
$a = $($x; 99)          # equivalent, $a.Length is 4

$a = $(New-Object 'int[]' 3; 99)  # $a.Length is 2
```

In the first two uses of the `$(...)` operator, the expression designating the collection is the variable `$x`, which is enumerated resulting in three `int` values, plus the `int` 99. However, in the third case, the expression is a direct call to a cmdlet, so the result is not enumerated, and `$a` is an array of two elements, `int[3]` and `int`.

If an operation is not defined by PowerShell, the type of the value designated by the left operand is inspected to see if it has a corresponding `op_<operation>` method.

7.1 Primary expressions

Syntax:

```
Syntax

primary-expression:
    value
    member-access
    element-access
    invocation-expression
    post-increment-expression
    post-decrement-expression

value:
    parenthesized-expression
    sub-expression
    array-expression
    script-block-expression
    hash-literal-expression
    literal
    type-literal
    variable
```

7.1.1 Grouping parentheses

Syntax:

Tip

The `~opt~` notation in the syntax definitions indicates that the lexical entity is optional in the syntax.

```
Syntax
```

```
parenthesized-expression:
    ( new-lines~opt~ pipeline new-lines~opt~ )
```

Description:

A parenthesized expression is a *primary-expression* whose type and value are the same as those of the expression without the parentheses. If the expression designates a

variable then the parenthesized expression designates that same variable. For example, `$x.m` and `(x).m` are equivalent.

Grouping parentheses may be used in an expression to document the default precedence and associativity within that expression. They can also be used to override that default precedence and associativity. For example,

PowerShell

```
4 + 6 * 2    # 16
4 + (6 * 2)  # 16 document default precedence
(4 + 6) * 2  # 20 override default precedence
```

Ordinarily, grouping parentheses at the top-most level are redundant. However, that is not always the case. Consider the following example:

PowerShell

```
2,4,6      # Length 3; values 2,4,6
(2,4),6    # Length 2; values [Object[],int]
```

In the second case, the parentheses change the semantics, resulting in an array whose two elements are an array of 2 ints and the scalar int 6.

Here's another exception:

PowerShell

```
23.5/2.4      # pipeline gets 9.79166666666667
$a = 1234 * 3.5 # value not written to pipeline
$a            # pipeline gets 4319
```

In the first and third cases, the value of the result is written to the pipeline. However, although the expression in the second case is evaluated, the result is not written to the pipeline due to the presence of the side-effect operator `=` at the top level. (Removal of the `$a =` part allows the value to be written, as `*` is not a side-effect operator.)

To stop a value of any expression not containing top-level side effects from being written to the pipeline, discard it explicitly, as follows:

PowerShell

```
# None of these value are written to pipeline
[void](23.5/2.4)
[void]$a
```

```
$null = $a  
$a > $null
```

To write to the pipeline the value of any expression containing top-level side effects, enclose that expression in parentheses, as follows:

PowerShell

```
($a = 1234 * 3.5) # pipeline gets 4319
```

As such, the grouping parentheses in this case are not redundant.

In the following example, we have variable substitution ([§2.3.5.2](#)) taking place in a string literal:

PowerShell

```
">$($a = -23)<" # value not written to pipeline, get >  
">$(($a = -23))<" # pipeline gets >-23<
```

In the first case, the parentheses represent a *sub-expression's* delimiters *not* grouping parentheses, and as the top-level expression contains a side-effect operator, the expression's value is not written to the pipeline. Of course, the `>` and `<` characters are still written.) If grouping parenthesis are added -- as shown in the second case -- writing is enabled.

The following examples each contain top-level side-effect operators:

PowerShell

```
$a = $b = 0      # value not written to pipeline  
$a = ($b = 0)    # value not written to pipeline  
($a = ($b = 0)) # pipeline gets 0  
  
++$a            # value not written to pipeline  
(++$b)          # pipeline gets 1  
  
$a--            # value not written to pipeline  
($b--)          # pipeline gets 1
```

The use of grouping parentheses around an expression containing no top-level side effects makes those parentheses redundant. For example;

PowerShell

```
$a      # pipeline gets 0  
($a)    # no side effect, so () redundant
```

Consider the following example that has two side effects, neither of which is at the top level:

PowerShell

```
12.6 + ($a = 10 - ++$b) # pipeline gets 21.6.
```

The result is written to the pipeline, as the top-level expression has no side effects.

7.1.2 Member access

Syntax:

Syntax

```
member-access:  
    primary-expression . new-line-opt~ member-name  
    primary-expression :: new-line-opt~ member-name
```

Note that no whitespace is allowed after *primary-expression*.

Description:

The operator `.` is used to select an instance member from an object, or a key from a `Hashtable`. The left operand must designate an object, and the right operand must designate an accessible instance member.

Either the right operand designates an accessible instance member within the type of the object designated by the left operand or, if the left operand designates an array, the right operand designates accessible instance members within each element of the array.

Whitespace is not permitted before the `.` operator.

This operator is left associative.

The operator `::` is used to select a static member from a given type. The left operand must designate a type, and the right-hand operand must designate an accessible static member within that type.

Whitespace is not permitted before the `::` operator.

This operator is left associative.

If the right-hand operand designates a writable location within the type of the object designated by the left operand, then the whole expression designates a writable location.

Examples:

PowerShell

```
$a = 10, 20, 30
$a.Length                                # get instance property

(10, 20, 30).Length

$property = "Length"
$a.$property                               # property name is a variable

$h1 = @{ FirstName = "James"; LastName = "Anderson"; IDNum = 123
}
$h1.FirstName                            # designates the key FirstName
$h1.Keys                                  # gets the collection of keys

[int]::MinValue                         # get static property
[double]::PositiveInfinity             # get static property
$property = "MinValue"
[long]::$property                       # property name is a variable

foreach ($t in [byte], [int], [long]) {
    $t::.MaxValue                        # get static property
}

$a = @{ID = 1 }, @{ID = 2 }, @{ID = 3 }
$a.ID                                    # get ID from each element in the array
```

7.1.3 Invocation expressions

Syntax:

Syntax

```
invocation-expression:
    primary-expression . new-line~opt~ member-name argument-list
    primary-expression :: new-line~opt~ member-name argument-list

argument-list:
    ( argument-expression-list~opt~ new-lines~opt~ )
```

Note that no whitespace is allowed after *primary-expression*.

Description:

An *invocation-expression* calls the method designated by `primary-expression.member-name` or `primary-expression::member-name`. The parentheses in *argument-list* contain a possibly empty, comma-separated list of expressions that designate the *arguments* whose values are passed to the method. Before the method is called, the arguments are evaluated and converted according to the rules of §6, if necessary, to match the types expected by the method. The order of evaluation of `primary-expression.member-name`, `primary-expression::member-name`, and the arguments is unspecified.

This operator is left associative.

The type of the result of an *invocation-expression* is a *method-designator* (§4.5.24).

Examples:

PowerShell

```
[Math]::Sqrt(2.0)          # call method with argument 2.0
[char]::IsUpper("a")       # call method
$b = "abc#$%XYZabc"
$b.ToUpper()               # call instance method

[Math]::Sqrt(2)            # convert 2 to 2.0 and call method
[Math]::Sqrt(2D)           # convert 2D to 2.0 and call method
[Math]::Sqrt($true)         # convert $true to 1.0 and call method
[Math]::Sqrt("20")          # convert "20" to 20 and call method

$a = [Math]::Sqrt           # get method descriptor for Sqrt
$a.Invoke(2.0)              # call Sqrt via the descriptor
$a = [Math]::("Sq"+"rt")    # get method descriptor for Sqrt
$a.Invoke(2.0)              # call Sqrt via the descriptor
$a = [char]::ToLower        # get method descriptor for ToLower
$a.Invoke("X")               # call ToLower via the descriptor
```

7.1.4 Element access

Syntax:

Syntax

```
element-access:
    primary-expression [ new-lines~opt~ expression new-lines~opt~ ]
```

Description:

There must not be any whitespace between *primary-expression* and the left square bracket ([).

7.1.4.1 Subscripting an array

Description:

Arrays are discussed in detail in §9. If *expression* is a 1-dimensional array, see §7.1.4.5.

When *primary-expression* designates a 1-dimensional array *A*, the operator [] returns the element located at *A[0 + expression]* after the value of *expression* has been converted to *int*. The result has the element type of the array being subscripted. If *expression* is negative, *A[expression]* designates the element located at *A[A.Length + expression]*.

When *primary-expression* designates a 2-dimensional array *B*, the operator [] returns the element located at *B[0 + row, 0 + column]* after the value of the *row* and *column* components of *expression* (which are specified as a comma-separated list) have been converted to *int*. The result has the element type of the array being subscripted. Unlike for a 1-dimensional array, negative positions have no special meaning.

When *primary-expression* designates an array of three or more dimensions, the rules for 2-dimensional arrays apply and the dimension positions are specified as a comma-separated list of values.

If a read access on a non-existing element is attempted, the result is \$null. It is an error to write to a non-existing element.

For a multidimensional-array subscript expression, the order of evaluation of the dimension position expressions is unspecified. For example, given a 3-dimensional array \$a, the behavior of \$a[\$i++, \$i, ++\$i] is unspecified.

If *expression* is an array, see §7.1.4.5.

This operator is left associative.

Examples:

PowerShell

```
$a = [int[]](10,20,30) # [int[]], Length 3
$a[1] # returns int 20
$a[20] # no such position, returns $null
$a[-1] # returns int 30, i.e., $a[$a.Length-1]
$a[2] = 5 # changes int 30 to int 5
```

```

$a[20] = 5 # implementation-defined behavior

$a = New-Object 'double[,]' 3,2
$a[0,0] = 10.5 # changes 0.0 to 10.5
$a[0,0]++ # changes 10.5 to 10.6

$list = ("red",$true,10),20,(1.2, "yes")
$list[2][1] # returns string "yes"

$a = @{ A = 10 },@{ B = $true },@{ C = 123.45 }
$a[1]["B"] # $a[1] is a Hashtable, where B is a key

$a = "red","green"
$a[1][4] # returns string "n" from string in $a[1]

```

If a write access to a non-existing element is attempted, an `IndexOutOfRangeException` exception is raised.

7.1.4.2 Subscripting a string

Description:

When *primary-expression* designates a string *S*, the operator `[]` returns the character located in the zero-based position indicated by *expression*, as a `char`. If *expression* is greater than or equal to that string's length, the result is `$null`. If *expression* is negative, `S[expression]` designates the element located at `S[S.Length + expression]`.

Examples:

PowerShell

```

$s = "Hello"    # string, Length 5, positions 0-4
$c = $s[1]      # returns "e" as a string
$c = $s[20]     # no such position, returns $null
$c = $s[-1]     # returns "o", i.e., $s[$s.Length-1]

```

7.1.4.3 Subscripting a Hashtable

Description:

When *primary-expression* designates a Hashtable, the operator `[]` returns the value(s) associated with the key(s) designated by *expression*. The type of *expression* is not restricted.

When *expression* is a single key name, the result is the associated value and has that type, unless no such key exists, in which case, the result is `$null`. If `$null` is used as the

key the behavior is implementation defined. If *expression* is an array of key names, see §7.1.4.5.

If *expression* is an array, see §7.1.4.5.

Examples:

PowerShell

```
$h1 = @{ FirstName = "James"; LastName = "Anderson"; IDNum = 123 }
$h1['FirstName']      # the value associated with key FirstName
$h1['BirthDate']      # no such key, returns $null

$h1 = @{ 10 = "James"; 20.5 = "Anderson"; $true = 123 }
$h1[10]                # returns value "James" using key 10
$h1[20.5]              # returns value "Anderson" using key 20.5
$h1[$true]              # returns value 123 using key $true
```

When *expression* is a single key name, if `$null` is used as the only value to subscript a Hashtable, a `NullArrayIndex` exception is raised.

7.1.4.4 Subscripting an XML document

Description:

When *primary-expression* designates an object of type `xml`, *expression* is converted to string, if necessary, and the operator `[]` returns the first child element having the name specified by *expression*. The type of *expression* must be string. The type of the result is implementation defined. The result can be subscripted to return its first child element. If no child element exists with the name specified by *expression*, the result is `$null`. The result does not designate a writable location.

Examples:

PowerShell

```
$x = [xml]@"
<Name>
<FirstName>Mary</FirstName>
<LastName>King</LastName>
</Name>
"@

$x['Name']           # refers to the element Name
$x['Name']['FirstName'] # refers to the element FirstName within Name
$x['FirstName']       # No such child element at the top level, result
is $null
```

The type of the result is `System.Xml.XmlElement` or `System.String`.

7.1.4.5 Generating array slices

When *primary-expression* designates an object of a type that is enumerable (§4) or a `Hashtable`, and *expression* is a 1-dimensional array, the result is an array slice (§9.9) containing the elements of *primary-expression* designated by the elements of *expression*.

In the case of a `Hashtable`, the array slice contains the associated values to the keys provided, unless no such key exists, in which case, the corresponding element is `$null`.

If `$null` is used as any key name the behavior is implementation defined.

Examples:

PowerShell

```
$a = [int[]](30,40,50,60,70,80,90)
$a[1,3,5]                      # slice has Length 3, value 40,60,80
$a[,5]                          # slice with Length 1
$a[@()]                         # slice with Length 0
$a[-1..-3]                      # slice with Length 3, value 90,80,70
$a = New-Object 'int[,]' 3,2
$a[0,0] = 10; $a[0,1] = 20; $a[1,0] = 30
$a[1,1] = 40; $a[2,0] = 50; $a[2,1] = 60
$a[(0,1),(1,0)]                # slice with Length 2, value 20,30, parens needed
$h1 = @{ FirstName = "James"; LastName = "Anderson"; IDNum = 123 }
$h1['FirstName']                # the value associated with key FirstName
$h1['BirthDate']                # no such key, returns $null
$h1['FirstName','IDNum']        # returns [Object[]], Length 2 (James/123)
$h1['FirstName','xxx']          # returns [Object[]], Length 2 (James/$null)
$h1[$null,'IDNum']              # returns [Object[]], Length 2 ($null/123)
```

Windows PowerShell: When *expression* is a collection of two or more key names, if `$null` is used as any key name that key is ignored and has no corresponding element in the resulting array.

7.1.5 Postfix increment and decrement operators

Syntax:

Syntax

```
post-increment-expression:
    primary-expression ++
```

```
post-decrement-expression:  
    primary-expression dashdash
```

Description:

The *primary-expression* must designate a writable location having a value of numeric type (§4) or the value `$null`. If the value designated by the operand is `$null`, that value is converted to type int and value zero before the operator is evaluated. The type of the value designated by *primary-expression* may change when the result is stored. See §7.11 for a discussion of type change via assignment.

The result produced by the postfix `++` operator is the value designated by the operand. After that result is obtained, the value designated by the operand is incremented by 1 of the appropriate type. The type of the result of expression `E++` is the same as for the result of the expression `E + 1` (§7.7).

The result produced by the postfix `--` operator is the value designated by the operand. After that result is obtained, the value designated by the operand is decremented by 1 of the appropriate type. The type of the result of expression `E--` is the same as for the result of the expression `E - 1` (§7.7).

These operators are left associative.

Examples:

```
PowerShell  
  
$i = 0          # $i = 0  
$i++           # $i is incremented by 1  
$j = $i--       # $j takes on the value of $i before the decrement  
  
$a = 1,2,3  
$b = 9,8,7  
$i = 0  
$j = 1  
$b[$j--] = $a[$i++] # $b[1] takes on the value of $a[0], then $j is  
# decremented, $i incremented  
  
$i = 2147483647 # $i holds a value of type int  
$i++           # $i now holds a value of type double because  
# 2147483648 is too big to fit in type int  
  
[int]$k = 0      # $k is constrained to int  
$k = [int]::MaxValue # $k is set to 2147483647  
$k++           # 2147483648 is too big to fit, imp-def behavior
```

```
$x = $null          # target is unconstrained, $null goes to [int]0
$x++                # value treated as int, 0->1
```

7.1.6 \$(...) operator

Syntax:

Syntax

sub-expression:

```
$( new-lines~opt~ statement-list~opt~ new-lines~opt~ )
```

Description:

If *statement-list* is omitted, the result is `$null`. Otherwise, *statement-list* is evaluated. Any objects written to the pipeline as part of the evaluation are collected in an unconstrained 1-dimensional array, in order. If the array of collected objects is empty, the result is `$null`. If the array of collected objects contains a single element, the result is that element; otherwise, the result is the unconstrained 1-dimensional array of collected results.

Examples:

PowerShell

```
$j = 20
 $($i = 10) # pipeline gets nothing
 $($i = 10) # pipeline gets int 10
 $($i = 10; $j) # pipeline gets int 20
 $($i = 10; $j) # pipeline gets [Object[]](10,20)
 $($i = 10; ++$j) # pipeline gets int 10
 $($i = 10; (++$j)) # pipeline gets [Object[]](10,22)
 $($i = 10; ++$j) # pipeline gets nothing
 $(2,4,6) # pipeline gets [Object[]](2,4,6)
```

7.1.7 @(...) operator

Syntax:

Syntax

array-expression:

```
@( new-lines~opt~ statement-list~opt~ new-lines~opt~ )
```

Description:

If *statement-list* is omitted, the result is an unconstrained 1-dimensional array of length zero. Otherwise, *statement-list* is evaluated, and any objects written to the pipeline as part of the evaluation are collected in an unconstrained 1-dimensional array, in order. The result is the (possibly empty) unconstrained 1-dimensional array.

Examples:

PowerShell

```
$j = 20
@($i = 10)           # 10 not written to pipeline, result is array of 0
@(($i = 10))         # pipeline gets 10, result is array of 1
@($i = 10; $j)        # 10 not written to pipeline, result is array of 1
@(($i = 10); $j)      # pipeline gets 10, result is array of 2
@(($i = 10); ++$j)    # pipeline gets 10, result is array of 1
@(($i = 10); (++$j))  # pipeline gets both values, result is array of 2
@($i = 10; ++$j)       # pipeline gets nothing, result is array of 0

$a = @(2,4,6)          # result is array of 3
@($a)                  # result is the same array of 3
(@(@($a)))             # result is the same array of 3
```

7.1.8 Script block expression

Syntax:

Syntax

```
script-block-expression:
{ new-lines~opt~ script-block new-lines~opt~ }

script-block:
param-block~opt~ statement-terminators~opt~ script-block-body~opt~

script-block-body:
named-block-list
statement-list
```

Description:

param-block is described in §8.10.9. *named-block-list* is described in §8.10.7.

A script block is an unnamed block of statements that can be used as a single unit. Script blocks can be used to invoke a block of code as if it was a single command, or they can be assigned to variables that can be executed.

The *named-block-list* or *statement-list* is executed and the type and value(s) of the result are the type and value(s) of the results of those statement sets.

A *script-block-expression* has type `scriptblock` ([§4.3.7](#)).

If *param-block* is omitted, any arguments passed to the script block are available via `$args` ([§8.10.1](#)).

During parameter binding, a script block can be passed either as a script block object or as the result after the script block has been evaluated. See [§6.17](#) for further information.

7.1.9 Hash literal expression

Syntax:

```
Syntax

hash-literal-expression:
    @{ new-lines~opt~ hash-literal-body~opt~ new-lines~opt~ }

hash-literal-body:
    hash-entry
    hash-literal-body statement-terminators hash-entry

hash-entry:
    key-expression = new-lines~opt~ statement

key-expression:
    simple-name
    unary-expression

statement-terminators:
    statement-terminator
    statement-terminators statement-terminator

statement-terminator:
    ;
    new-line-character
```

Description:

A *hash-literal-expression* is used to create a Hashtable ([§10](#)) of zero or more elements each of which is a key/value pair.

The key may have any type except the null type. The associated values may have any type, including the null type, and each of those values may be any expression that designates the desired value, including `$null`.

The ordering of the key/value pairs is not significant.

Examples:

PowerShell

```
$h1 = @{ FirstName = "James"; LastName = "Anderson"; IDNum = 123 }
$last = "Anderson"; $IDNum = 120
$h2 = @{ FirstName = "James"; LastName = $last; IDNum = $IDNum + 3 }
$h3 = @{
$h4 = @{ 10 = "James"; 20.5 = "Anderson"; $true = 123 }
```

which creates two Hashtables, `$h1` and `$h2`, each containing three key/value pairs, and a third, `$h3`, that is empty. Hashtable `$h4` has keys of various types.

7.1.10 Type literal expression

Syntax:

Syntax

```
type-literal:
    [ type-spec ]

type-spec:
    array-type-name new-lines~opt~ dimension~opt~ ]
    generic-type-name new-lines~opt~ generic-type-arguments ]
    type-name

dimension:
    ,
    dimension ,

generic-type-arguments:
    type-spec new-lines~opt~
    generic-type-arguments , new-lines~opt~ type-spec

array-type-name:
    type-name []

generic-type-name:
    type-name []
```

Description:

A *type-literal* is represented in an implementation by some unspecified *underlying type*. As a result, a type name is a synonym for its underlying type.

Type literals are used in a number of contexts:

- Specifying an explicit conversion (§6, [§7.2.9](#))
- Creating a type-constrained array ([§9.4](#))
- Accessing the static members of an object ([§7.1.2](#))
- Specifying a type constraint on a variable ([§5.3](#)) or a function parameter ([§8.10.2](#))

Examples:

PowerShell

```
[int].IsPrimitive      # $true
[Object[]].FullName    # "System.Object[]"
[int[,]].GetArrayRank() # 3
```

A generic stack type ([§4.4](#)) that is specialized to hold strings might be written as `[Stack[string]]`, and a generic dictionary type that is specialized to hold `int` keys with associated string values might be written as `[Dictionary[int,string]]`.

The type of a *type-literal* is `System.Type`. The complete name for the type `Stack[string]` suggested above is `System.Collections.Generic.Stack[int]`. The complete name for the type `Dictionary[int,string]` suggested above is `System.Collections.Generic.Dictionary[int,string]`.

7.2 Unary operators

Syntax:

Syntax

```
unary-expression:
    primary-expression
    expression-with-unary-operator

expression-with-unary-operator:
    , new-lines~opt~ unary-expression
    -not new-lines~opt~ unary-expression
    ! new-lines~opt~ unary-expression
    -bnot new-lines~opt~ unary-expression
    + new-lines~opt~ unary-expression
    dash new-lines~opt~ unary-expression
    pre-increment-expression
    pre-decrement-expression
    cast-expression
    -split new-lines~opt~ unary-expression
    -join new-lines~opt~ unary-expression
```

```

pre-increment-expression:
++ new-lines~opt~ unary-expression

pre-decrement-expression:
dashdash new-lines~opt~ unary-expression

dash: one of
- (U+002D)
EnDash character (U+2013)
EmDash character (U+2014)
Horizontal bar character (U+2015)

cast-expression:
type-literal unary-expression

dashdash:
dash dash

```

7.2.1 Unary comma operator

Description:

The comma operator (,) creates an unconstrained 1-dimensional array having one element, whose type and value are that of *unary-expression*.

This operator is right associative.

Examples:

PowerShell

```

$a = ,10          # create an unconstrained array of 1 element, $a[0],
# which has type int

$a = ,(10,"red") # create an unconstrained array of 1 element,
$a[0],           # which is an unconstrained array of 2 elements,
# $a[0][0] an int, and $a[0][1] a string

$a = ,,10         # create an unconstrained array of 1 element, which is
# an unconstrained array of 1 element, which is an int
# $a[0][0] is the int. Contrast this with @(@(10))

```

7.2.2 Logical NOT

Syntax:

Syntax

```
logical-not-operator:  
    dash not  
  
dash: one of  
    - (U+002D)  
        EnDash character (U+2013)  
        EmDash character (U+2014)  
        Horizontal bar character (U+2015)
```

Description:

The operator `-not` converts the value designated by *unary-expression* to type `bool` ([§6.2](#)), if necessary, and produces a result of that type. If *unary-expression*'s value is `True`, the result is `False`, and vice versa. The operator `!` is an alternate spelling for `-not`.

This operator is right associative.

Examples:

PowerShell

```
-not $true          # False  
-not -not $false   # False  
-not 0             # True  
-not 1.23          # False  
!"xyz"            # False
```

7.2.3 Bitwise NOT

Syntax:

Syntax

```
bitwise-not-operator:  
    dash bnot  
  
dash: one of  
    - (U+002D)  
        EnDash character (U+2013)  
        EmDash character (U+2014)  
        Horizontal bar character (U+2015)
```

Description:

The operator `-bnot` converts the value designated by *unary-expression* to an integer type ([§6.4](#)), if necessary. If the converted value can be represented in type `int` then that is

the result type. Else, if the converted value can be represented in type `long` then that is the result type. Otherwise, the expression is ill-formed. The resulting value is the ones-complement of the converted value.

This operator is right associative.

Examples:

PowerShell

```
-bnot $true          # int with value 0xFFFFFFFF  
-bnot 10            # int with value 0xFFFFFFFF5  
-bnot 2147483648.1 # long with value 0xFFFFFFFF7FFFFFFF  
-bnot $null          # int with value 0xFFFFFFFF  
-bnot "0abc"         # int with value 0xFFFFF543
```

7.2.4 Unary plus

Description:

An expression of the form `+ unary-expression` is treated as if it were written as `0 + unary-expression` ([§7.7](#)). The integer literal `0` has type `int`.

This operator is right associative.

Examples:

PowerShell

```
+123L      # type long, value 123  
+0.12340D  # type decimal, value 0.12340  
+"0abc"    # type int, value 2748
```

7.2.5 Unary minus

Description:

An expression of the form `- unary-expression` is treated as if it were written as `0 - unary-expression` ([§7.7](#)). The integer literal 0 has type `int`. The minus operator can be any one of the *dash* characters listed in [§7.2](#).

This operator is right associative.

Examples:

PowerShell

```
-$true      # type int, value -1
-123L      # type long, value -123
-0.12340D # type decimal, value -0.12340
```

7.2.6 Prefix increment and decrement operators

Description:

The *unary-expression* must designate a writable location having a value of numeric type ([§4](#)) or the value `$null`. If the value designated by its *unary-expression* is `$null`, *unary-expression*'s value is converted to type int and value zero before the operator is evaluated.

ⓘ Note

The type of the value designated by *unary-expression* may change when the result is stored. See [§7.11](#) for a discussion of type change via assignment.

For the prefix increment operator `++`, the value of *unary-expression* is incremented by `1` of the appropriate type. The result is the new value after incrementing has taken place. The expression `++E` is equivalent to `E += 1` ([§7.11.2](#)).

For the prefix decrement operator `--`, the value of *unary-expression* is decremented by `1` of the appropriate type. The result is the new value after decrementing has taken place. The expression `--E` is equivalent to `E -= 1` ([§7.11.2](#)). The prefix decrement operator can be any of the patterns matching the *dashdash* pattern in [§7.2](#).

These operators are right associative.

Examples:

PowerShell

```
$i = 0          # $i = 0
++$i           # $i is incremented by 1
$j = --$i       # $i is decremented then $j takes on the value of $i

$a = 1,2,3
$b = 9,8,7
$i = 0;
$j = 1
$b[--$j] = $a[++$i] # $j is # decremented, $i incremented, then $b[0]
                     # takes on the value of $a[1]
```

```

$! = 2147483647      # $! holds a value of type int
+$!
# $! now holds a value of type double because
# 2147483648 is too big to fit in type int

[int]$k = 0            # $k is constrained to int
$k = [int]::MinValue  # $k is set to -2147483648
--$k                  # -2147483649 is too small to fit, imp-def behavior

$x = $null             # target is unconstrained, $null goes to [int]0
--$x                  # value treated as int, 0 becomes -1

```

7.2.7 The unary -join operator

Syntax:

Syntax
<pre> join-operator: dash join dash: one of - (U+002D) EnDash character (U+2013) EmDash character (U+2014) Horizontal bar character (U+2015) </pre>

Description:

The unary `-join` operator produces a string that is the concatenation of the value of one or more objects designated by *unary-expression*. (A separator can be inserted by using the binary version of this operator ([§7.8.4.4](#))).

unary-expression can be a scalar value or a collection.

Examples:

PowerShell
<pre> -join (10, 20, 30) # result is "102030" -join (123, \$false, 19.34e17) # result is "123False1.934E+18" -join 12345 # result is "12345" -join \$null # result is "" </pre>

7.2.8 The unary -split operator

Syntax:

Syntax

```
split-operator:  
  dash split  
  
dash: one of  
  - (U+002D)  
    EnDash character (U+2013)  
    EmDash character (U+2014)  
    Horizontal bar character (U+2015)
```

Description:

The unary `-split` operator splits one or more strings designated by *unary-expression*, returning their subparts in a constrained 1-dimensional array of string. It treats any contiguous group of whitespace characters as the delimiter between successive subparts. An explicit delimiter string can be specified by using the binary version of this operator ([§7.8.4.5](#)) or its two variants ([§7.8](#)).

The delimiter text is not included in the resulting strings. Leading and trailing whitespace in the input string is ignored. An input string that is empty or contains whitespace only results in an array of one string, which is empty.

unary-expression can designate a scalar value or an array of strings.

Examples:

PowerShell

```
-split " red`tblue`ngreen " # 3 strings: "red", "blue", "green"  
-split ("yes no", "up down") # 4 strings: "yes", "no", "up", "down"  
-split " " # 1 (empty) string
```

7.2.9 Cast operator

Description:

This operator converts explicitly ([§6](#)) the value designated by *unary-expression* to the type designated by *type-literal* ([§7.1.10](#)). If *type-literal* is other than void, the type of the result is the named type, and the value is the value after conversion. If *type-literal* is void, no object is written to the pipeline and there is no result.

When an expression of any type is cast to that same type, the resulting type and value is the *unary-expression*'s type and value.

This operator is right associative.

Examples:

PowerShell

```
[bool]-10      # a bool with value True
[int]-10.70D   # a decimal with value -10
[int]10.7      # an int with value 11
[long]"+2.3e+3" # a long with value 2300
[char[]]"Hello" # an array of 5 char with values H, e, l, l, and o.
```

7.3 Binary comma operator

Syntax:

Syntax

```
array-literal-expression:
    unary-expression , new-lines~opt~ array-literal-expression
```

Description:

The binary comma operator creates a 1-dimensional array whose elements are the values designated by its operands, in lexical order. The array has unconstrained type.

Examples:

PowerShell

```
2,4,6          # Length 3; values 2,4,6
(2,4),6        # Length 2; values [Object[],int]
(2,4,6),12,(2..4) # Length 3; [Object[],int,[Object[]]]
2,4,6,"red",$null,$true # Length 6
```

The addition of grouping parentheses to certain binary comma expressions does not document the default precedence; instead, it changes the result.

7.4 Range operator

Syntax:

Syntax

```
range-expression:  
    unary-expression .. new-lines~opt~ unary-expression
```

Description:

A *range-expression* creates an unconstrained 1-dimensional array whose elements are the values of the `int` sequence specified by the range bounds. The values designated by the operands are converted to `int`, if necessary ([§6.4](#)). The operand designating the lower value after conversion is the *lower bound*, while the operand designating the higher value after conversion is the *upper bound*. Both bounds may be the same, in which case, the resulting array has length 1. If the left operand designates the lower bound, the sequence is in ascending order. If the left operand designates the upper bound, the sequence is in descending order.

Conceptually, this operator is a shortcut for the corresponding binary comma operator sequence. For example, the range `5..8` can also be generated using `5,6,7,8`. However, if an ascending or descending sequence is needed without having an array, an implementation may avoid generating an actual array. For example, in `foreach ($i in 1..5) { ... }`, no array need be created.

A *range-expression* can be used to specify an array slice ([§9.9](#)).

Examples:

PowerShell

```
1..10      # ascending range 1..10  
-495..-500 # descending range -495..-500  
16..16     # sequence of 1  
  
$x = 1.5  
$x..5.40D # ascending range 2..5  
  
$true..3   # ascending range 1..3  
-2..$null  # ascending range -2..0  
0xf..0xa   # descending range 15..10
```

7.5 Format operator

Syntax:

Syntax

```

format-expression:
    format-specification-string format-operator new-lines~opt~ range-
expression

format-operator:
    dash f

dash:
    - (U+002D)
    EnDash character (U+2013)
    EmDash character (U+2014)
    Horizontal bar character (U+2015)

```

Description:

A *format-expression* formats one or more values designated by *range-expression* according to a *format-specification-string* designated by *format-expression*. The positions of the values designated by *range-expression* are numbered starting at zero and increasing in lexical order. The result has type `string`.

A format specification string may contain zero or more format specifications each having the following form:

```
{N [ ,M ][ : FormatString ]}
```

N represents a (required) *range-expression* value position, *M* represents the (optional) minimum display width, and *FormatString* indicates the (optional) format. If the width of a formatted value exceeds the specified width, the width is increased accordingly. Values whose positions are not referenced in *FormatString* are ignored after being evaluated for any side effects. If *N* refers to a non-existent position, the behavior is implementation defined. Value of type `$null` and `void` are formatted as empty strings. Arrays are formatted as for *sub-expression* (§7.1.6). To include the characters `{` and `}` in a format specification without their being interpreted as format delimiters, write them as `{}{` and `}}{`, respectively.

For a complete definition of format specifications, see the type `System.IFormattable` in [Ecma Technical Report TR/84](#).

Examples:

PowerShell

<code>"__{0,3}__" -f 5</code>	<code># __ 5__</code>
<code>"__{0,-3}__" -f 5</code>	<code># __5__</code>
<code>"__{0,3:000}__" -f 5</code>	<code># __005__</code>
<code>"__{0,5:0.00}__" -f 5.0</code>	<code># __ 5.00__</code>

```

"__{0:C}__" -f 1234567.888          # __$1,234,567.89__
"__{0:C}__" -f -1234.56             # __($1,234.56)__
"__{0,12:e2}__" -f 123.456e2        # __ 1.23e+004__
"__{0,-12:p}__" -f -0.252           # __-25.20 % __

$i = 5; $j = 3
"__{0} + {1} <= {2}__" -f $i,$j,($i+$j) # __5 + 3 <= 8__

$format = "__0x{0:X8}__"
$format -f 65535                      # __0x0000FFFF__

```

In a format specification, if N refers to a non-existent position, a `FormatError` is raised.

7.6 Multiplicative operators

Syntax:

Syntax

```

multiplicative-expression:
    multiplicative-expression * new-lines~opt~ format-expression
    multiplicative-expression / new-lines~opt~ format-expression
    multiplicative-expression % new-lines~opt~ format-expression

```

7.6.1 Multiplication

Description:

The result of the multiplication operator `*` is the product of the values designated by the two operands after the usual arithmetic conversions ([§6.15](#)) have been applied.

This operator is left associative.

Examples:

PowerShell

```

12 * -10L      # long result -120
-10.300D * 12 # decimal result -123.600
10.6 * 12     # double result 127.2
12 * "0xabc"   # int result 32976

```

7.6.2 String replication

Description:

When the left operand designates a string the binary `*` operator creates a new string that contains the one designated by the left operand replicated the number of times designated by the value of the right operand as converted to integer type ([§6.4](#)).

This operator is left associative.

Examples:

PowerShell

```
"red" * "3"      # string replicated 3 times
"red" * 4        # string replicated 4 times
"red" * 0        # results in an empty string
"red" * 2.3450D  # string replicated twice
"red" * 2.7      # string replicated 3 times
```

7.6.3 Array replication

Description:

When the left operand designates an array the binary `*` operator creates a new unconstrained 1-dimensional array that contains the value designated by the left operand replicated the number of times designated by the value of the right operand as converted to integer type ([§6.4](#)). A replication count of zero results in an array of length 1. If the left operand designates a multidimensional array, it is flattened ([§9.12](#)) before being used.

This operator is left associative.

Examples:

PowerShell

```
$a = [int[]](10,20)          # [int[]], Length 2*1
$a * "3"                    # [Object[]], Length 2*3
$a * 4                      # [Object[]], Length 2*4
$a * 0                      # [Object[]], Length 2*0
$a * 2.3450D                # [Object[]], Length 2*2
$a * 2.7                    # [Object[]], Length 2*3
(New-Object 'float[,]' 2,3) * 2 # [Object[]], Length 2*2
```

7.6.4 Division

Description:

The result of the division operator `/` is the quotient when the value designated by the left operand is divided by the value designated by the right operand after the usual arithmetic conversions ([§6.15](#)) have been applied.

If an attempt is made to perform integer or decimal division by zero, an implementation-defined terminating error is raised.

This operator is left associative.

Examples:

PowerShell

```
10/-10      # int result -1
12/-10      # double result -1.2
12/-10D     # decimal result 1.2
12/10.6     # double result 1.13207547169811
12/"0xabc"  # double result 0.00436681222707424
```

If an attempt is made to perform integer or decimal division by zero, a **RuntimeException** exception is raised.

7.6.5 Remainder

Description:

The result of the remainder operator `%` is the remainder when the value designated by the left operand is divided by the value designated by the right operand after the usual arithmetic conversions ([§6.15](#)) have been applied.

If an attempt is made to perform integer or decimal division by zero, an implementation-defined terminating error is raised.

Examples:

PowerShell

```
10 % 3      # int result 1
10.0 % 0.3   # double result 0.1
10.00D % "0x4" # decimal result 2.00
```

If an attempt is made to perform integer or decimal division by zero, a **RuntimeException** exception is raised.

7.7 Additive operators

Syntax:

```
Syntax

additive-expression:
    primary-expression + new-lines~opt~ expression
    primary-expression dash new-lines~opt~ expression

dash: one of
    - (U+002D)
    EnDash character (U+2013)
    EmDash character (U+2014)
    Horizontal bar character (U+2015)
```

7.7.1 Addition

Description:

The result of the addition operator `+` is the sum of the values designated by the two operands after the usual arithmetic conversions ([§6.15](#)) have been applied.

This operator is left associative.

Examples:

```
PowerShell

12 + -10L      # long result 2
-10.300D + 12  # decimal result 1.700
10.6 + 12      # double result 22.6
12 + "0xabc"   # int result 2760
```

7.7.2 String concatenation

Description:

When the left operand designates a string the binary `+` operator creates a new string that contains the value designated by the left operand followed immediately by the value(s) designated by the right operand as converted to type string ([§6.8](#)).

This operator is left associative.

Examples:

PowerShell

```
"red" + "blue"      # "redblue"  
"red" + "123"       # "red123"  
"red" + 123         # "red123"  
"red" + 123.456e+5 # "red12345600"  
"red" + (20,30,40)  # "red20 30 40"
```

7.7.3 Array concatenation

Description:

When the left operand designates an array the binary `+` operator creates a new unconstrained 1-dimensional array that contains the elements designated by the left operand followed immediately by the value(s) designated by the right operand. Multidimensional arrays present in either operand are flattened ([§9.12](#)) before being used.

This operator is left associative.

Examples:

PowerShell

```
$a = [int[]](10,20)                  # [int[]], Length 2  
$a + "red"                          # [Object[]], Length 3  
$a + 12.5,$true                     # [Object[]], Length 4  
$a + (New-Object 'float[,]' 2,3)    # [Object[]], Length 8  
(New-Object 'float[,]' 2,3) + $a    # [Object[]], Length 8
```

7.7.4 Hashtable concatenation

Description:

When both operands designate Hashtables the binary `+` operator creates a new Hashtable that contains the elements designated by the left operand followed immediately by the elements designated by the right operand.

If the Hashtables contain the same key, an implementation-defined terminating error is raised.

This operator is left associative.

Examples:

PowerShell

```
$h1 = @{ FirstName = "James"; LastName = "Anderson" }
$h2 = @{ Dept = "Personnel" }
$h3 = $h1 + $h2      # new Hashtable, Count = 3
```

If the Hashtables contain the same key, an exception of type **BadOperatorArgument** is raised.

7.7.5 Subtraction

Description:

The result of the subtraction operator `-` is the difference when the value designated by the right operand is subtracted from the value designated by the left operand after the usual arithmetic conversions ([§6.15](#)) have been applied. The subtraction operator can be any one of the *dash* characters listed in [§7.7](#).

This operator is left associative.

Examples:

PowerShell

```
12 - -10L      # long result 22
-10.300D - 12 # decimal result -22.300
10.6 - 12        # double result -1.4
12 - "0xabC"     # int result -2736
```

7.8 Comparison operators

Syntax:

Syntax

```
comparison-expression:
    primary-expression comparison-operator new-lines~opt~ expression

comparison-operator:
    equality-operator
    relational-operator
    containment-operator
    type-operator
    like-operator
    match-operator
```

Description:

The type of the value designated by the left operand determines how the value designated by the right operand is converted ([§6](#)), if necessary, before the comparison is done.

Some comparison operators have two variants, one that is case sensitive (`-c<operator>`), and one that isn't case sensitive (`-i<operator>`). The `-<operator>` version is equivalent to `-i<operator>`. Case sensitivity is meaningful only with comparisons of values of type string. In non-string comparison contexts, the two variants behave the same.

These operators are left associative.

7.8.1 Equality and relational operators

Syntax:

```
Syntax

equality-operator: one of
    dash eq      dash ceq      dash ieq
    dash ne      dash cne      dash ine

dash:
    - (U+002D)
    EnDash character (U+2013)
    EmDash character (U+2014)
    Horizontal bar character (U+2015)

relational-operator: one of
    dash lt      dash clt     dash ilt
    dash le      dash cle     dash ile
    dash gt      dash cgt     dash igt
    dash ge      dash cge     dash ige
```

Description:

There are two equality operators: equality (`-eq`) and inequality (`-ne`); and four relational operators: less-than (`-lt`), less-than-or-equal-to (`-le`), greater-than (`-gt`), and greater-than-or-equal-to (`-ge`). Each of these has two variants ([§7.8](#)).

For two strings to compare equal, they must have the same length and contents, and letter case, if appropriate.

If the value designated by the left operand is not a collection, the result has type `bool`. Otherwise, the result is a possibly empty unconstrained 1-dimensional array containing

the elements of the collection that test True when compared to the value designated by the right operand.

Examples:

PowerShell

```
10 -eq "010"          # True, int comparison
"010" -eq 10          # False, string comparison
"RED" -eq "Red"        # True, case-insensitive comparison
"RED" -ceq "Red"       # False, case-sensitive comparison
"ab" -lt "abc"         # True

10,20,30,20,10 -ne 20 # 10,30,10, Length 3
10,20,30,20,10 -eq 40 # Length 0
10,20,30,20,10 -ne 40 # 10,20,30,20,10, Length 5
10,20,30,20,10 -gt 25 # 30, Length 1
0,1,30 -ne $true      # 0,30, Length 2
0,"00" -eq "0"         # 0 (int), Length 1
```

7.8.2 Containment operators

Syntax:

Syntax

```
containment-operator: one of
    dash contains      dash ccontains      dash icontains
    dash notcontains   dash cnotcontains   dash inotcontains
    dash in            dash cin           dash iin
    dash notin         dash cnotin        dash inotin

dash:
    - (U+002D)
    EnDash character (U+2013)
    EmDash character (U+2014)
    Horizontal bar character (U+2015)
```

Description:

There are four containment operators: contains (-contains), does-not-contain (-notcontains), in (-in) and not-in (-notin). Each of these has two variants ([§7.8](#)).

The containment operators return a result of type bool that indicates whether a value occurs (or does not occur) at least once in the elements of an array. With -contains and -notcontains, the value is designated by the right operand and the array is designated

by the left operand. With `-in` and `-notin`, the operands are reversed. The value is designated by the left operand and the array is designated by the right operand.

For the purposes of these operators, if the array operand has a scalar value, the scalar value is treated as an array of one element.

Examples:

PowerShell

```
10,20,30,20,10 -contains 20      # True
10,20,30,20,10 -contains 42.9    # False
10,20,30 -contains "10"          # True
"10",20,30 -contains 10          # True
"010",20,30 -contains 10          # False
10,20,30,20,10 -notcontains 15    # True
"Red",20,30 -ccontains "RED"      # False
```

7.8.3 Type testing and conversion operators

Syntax:

Syntax

```
type-operator: one of
  dash is
  dash as

dash:
  - (U+002D)
  EnDash character (U+2013)
  EmDash character (U+2014)
  Horizontal bar character (U+2015)
```

Description:

The type operator `-is` tests whether the value designated by the left operand has the type, or is derived from a type that has the type, designated by the right operand. The right operand must designate a type or a value that can be converted to a type (such as a string that names a type). The type of the result is `bool`. The type operator `-isnot` returns the logical negation of the corresponding `-is` form.

The type operator `-as` attempts to convert the value designated by the left operand to the type designated by the right operand. The right operand must designate a type or a value that can be converted to a type (such as a string that names a type). If the

conversion fails, `$null` is returned; otherwise, the converted value is returned and the return type of that result is the runtime type of the converted value.

Examples:

PowerShell

```
$a = 10          # value 10 has type int
$a -is [int]      # True

$t = [int]
$a -isnot $t      # False
$a -is "int"       # True
$a -isnot [double] # True

$x = [int[]](10,20)
$x -is [int[]}     # True

$a = "abcd"        # string is derived from object
$a -is [Object]    # True

$x = [double]
foreach ($t in [int],$x,[decimal],"string") {
    $b = (10.60D -as $t) * 2 # results in int 22, double 21.2
                                # decimal 21.20, and string "10.6010.60"
}
```

7.8.4 Pattern matching and text manipulation operators

7.8.4.1 The -like and -notlike operators

Syntax:

Syntax

```
like-operator: one of
    dash like      dash clike      dash ilike
    dash notlike   dash cnotlike   dash inotlike

dash:
    - (U+002D)
    EnDash character (U+2013)
    EmDash character (U+2014)
    Horizontal bar character (U+2015)
```

Description:

If the left operand does not designate a collection, the result has type `bool`. Otherwise, the result is a possibly empty unconstrained 1-dimensional array containing the

elements of the collection that test True when compared to the value designated by the right operand. The right operand may designate a string that contains wildcard expressions ([§3.15](#)). These operators have two variants ([§7.8](#)).

Examples:

PowerShell

```
"Hello" -like "h*"          # True, starts with h
"Hello" -clike "h*"         # False, does not start with lowercase
h
"Hello" -like "*1*"         # True, has an 1 in it somewhere
"Hello" -like "?1"          # False, no length match

"-abc" -like "[xz]*"        # True, - is not a range separator
#$%^&" -notlike "*[A-Za-z]" # True, does not end with alphabetic
character
"He" -like "h[aeiou]?"     # False, need at least 3 characters
"When" -like "*[?]"         # False, ? is not a wildcard character
"When?" -like "*[?]"        # True, ? is not a wildcard character

"abc","abbcde","abcgh" -like "abc*" # object[2], values
"abc" and "abcgh"
```

7.8.4.2 The `-match` and `-notmatch` operators

Syntax:

Syntax

```
match-operator: one of
    dash match      dash cmatch      dash imatch
    dash notmatch   dash cnotmatch   dash inotmatch

dash:
    - (U+002D)
    EnDash character (U+2013)
    EmDash character (U+2014)
    Horizontal bar character (U+2015)
```

Description:

If the left operand does not designate a collection, the result has type `bool` and if that result is `$true`, the elements of the Hashtable `$Matches` are set to the strings that match (or do-not-match) the value designated by the right operand. Otherwise, the result is a possibly empty unconstrained 1-dimensional array containing the elements of the collection that test True when compared to the value designated by the right operand,

and `$Matches` is not set. The right operand may designate a string that contains regular expressions ([§3.16](#)), in which case, it is referred to as a *pattern*. These operators have two variants ([§7.8](#)).

These operators support submatches ([§7.8.4.6](#)).

Examples:

PowerShell

```
"Hello" -match ".1"                      # True, $Matches key/value is 0/"el"
"Hello" -match '\^h.*o$'                   # True, $Matches key/value is
0/"Hello"
"Hello" -cmatch '\^h.*o$'                  # False, $Matches not set
"abc\^ef" -match ".\\|^e"                 # True, $Matches key/value is
0/"c\^e"

"abc" -notmatch "[A-Za-z]"                # False
"abc" -match "[\^A-Za-z]"                 # False
"He" -match "h[aeiou]."
"abc","abbcde","abcgh" -match "abc.*"    # Length is 2, values "abc", "abcgh"
```

7.8.4.3 The `-replace` operator

Syntax:

Syntax

```
binary-replace-operator: one of
    dash replace      dash creplace     dash ireplace

dash:
    - (U+002D)
    EnDash character (U+2013)
    EmDash character (U+2014)
    Horizontal bar character (U+2015)
```

Description:

The `-replace` operator allows text replacement in one or more strings designated by the left operand using the values designated by the right operand. This operator has two variants ([§7.8](#)). The right operand has one of the following forms:

- The string to be located, which may contain regular expressions ([§3.16](#)). In this case, the replacement string is implicitly "".
- An array of 2 objects containing the string to be located, followed by the replacement string.

If the left operand designates a string, the result has type string. If the left operand designates a 1-dimensional array of string, the result is an unconstrained 1-dimensional array, whose length is the same as for left operand's array, containing the input strings after replacement has completed.

This operator supports submatches ([§7.8.4.6](#)).

Examples:

PowerShell

```
"Analogous","an apple" -replace "a","*"      # "*n*logous","*n *pple"
"Analogous" -creplace "[aeiou]","?"          # An?l?g??s"
"Analogous","an apple" -replace '\^a','%A'    # %%Analogous",%%An apple"
"Analogous" -replace "[aeiou]','$&$&'       # AAnaaloogooous"
```

7.8.4.4 The binary `-join` operator

Syntax:

Syntax

```
binary-join-operator: one of
    dash join

dash:
    - (U+002D)
    EnDash character (U+2013)
    EmDash character (U+2014)
    Horizontal bar character (U+2015)
```

Description:

The binary `-join` operator produces a string that is the concatenation of the value of one or more objects designated by the left operand after having been converted to string ([§6.7](#)), if necessary. The string designated by the right operand is used to separate the (possibly empty) values in the resulting string.

The left operand can be a scalar value or a collection.

Examples:

PowerShell

```
(10, 20, 30) -join "\|"    # result is "10\|20\|30"
12345 -join ","            # result is "12345", no separator needed
```

```
($null,$null) -join "<->" # result is "<->", two zero-length values
```

7.8.4.5 The binary `-split` operator

Syntax:

Syntax

```
binary-split-operator: one of
    dash split      dash csplit     dash isplit

dash:
    - (U+002D)
    EnDash character (U+2013)
    EmDash character (U+2014)
    Horizontal bar character (U+2015)
```

Description:

The binary `-split` operator splits one or more strings designated by the left operand, returning their subparts in a constrained 1-dimensional array of string. This operator has two variants ([§7.8](#)). The left operand can designate a scalar value or an array of strings. The right operand has one of the following forms:

- A *delimiter string*
- An array of 2 objects containing a delimiter string followed by a numeric *split count*
- An array of 3 objects containing a delimiter string, a numeric split count, and an *options string*
- A script block
- An array of 2 objects containing a script block followed by a numeric split count

The delimiter string may contain regular expressions ([§3.16](#)). It is used to locate subparts with the input strings. The delimiter is not included in the resulting strings. If the left operand designates an empty string, that results in an empty string element. If the delimiter string is an empty string, it is found at every character position in the input strings.

By default, all subparts of the input strings are placed into the result as separate elements; however, the split count can be used to modify this behavior. If that count is negative, zero, or greater than or equal to the number of subparts in an input string, each subpart goes into a separate element. If that count is less than the number of subparts in the input string, there are count elements in the result, with the final element containing all of the subparts beyond the first **count - 1** subparts.

An options string contains zero or more *option names* with each adjacent pair separated by a comma. Leading, trailing, and embedded whitespace is ignored. Option names may be in any order and are case-sensitive.

If an options string contains the option name **SimpleMatch**, it may also contain the option name **IgnoreCase**. If an options string contains the option name **RegexMatch** or it does not contain either **RegexMatch** or **SimpleMatch**, it may contain any option name except **SimpleMatch**. However, it must not contain both **Multiline** and **Singleline**.

Here is the set of option names:

[+] Expand table

Option	Description
CultureInvariant	Ignores cultural differences in language when evaluating the delimiter.
ExplicitCapture	Ignores non-named match groups so that only explicit capture groups are returned in the result list.
IgnoreCase	Force case-insensitive matching, even if <code>-csplit</code> is used.
IgnorePatternWhitespace	Ignores unescaped whitespace and comments marked with the number sign (#).
Multiline	This mode recognizes the start and end of lines and strings. The default mode is Singleline .
RegexMatch	Use regular expression matching to evaluate the delimiter. This is the default.
SimpleMatch	Use simple string comparison when evaluating the delimiter.
Singleline	This mode recognizes only the start and end of strings. It is the default mode.

The script block ([§7.1.8](#)) specifies the rules for determining the delimiter, and must evaluate to type bool.

Examples:

PowerShell

```
"one,forty two," -split ","          # 5 strings: "one" "forty two" ""  
"  
"abc","de" -split ""                # 9 strings: "" "a" "b" "c" "" ""  
"d" "e" ""
```

```

"ab,cd","1,5,7,8" -split "," , 2           # 4 strings: "ab" "cd" "1" "5,7,8"

"10X20x30" -csplit "X", 0, "SimpleMatch"  # 2 strings: "10" "20x30"

"analogous" -split "[AEIOU]", 0, "RegexMatch, IgnoreCase"
                                         # 6 strings: "" "n" "l" "g" "" "s"

"analogous" -split { $_ -eq "a" -or $_ -eq "o" }, 4
                                         # 4 strings: "" "n" "l" "gous"

```

7.8.4.6 Submatches

The pattern being matched by `-match`, `-notmatch`, and `-replace` may contain subparts (called *submatches*) delimited by parentheses. Consider the following example:

```
"red" -match "red"
```

The result is `$true` and key 0 of `$Matches` contains "red", that part of the string designated by the left operand that exactly matched the pattern designated by the right operand.

In the following example, the whole pattern is a submatch:

```
"red" -match "(red)"
```

As before, key 0 contains "red"; however, key 1 also contains "red", which is that part of the string designated by the left operand that exactly matched the submatch.

Consider the following, more complex, pattern:

```
"red" -match "((r)e)(d)"
```

This pattern allows submatches of "re", "r", "d", or "red".

Again, key 0 contains "red". Key 1 contains "re", key 2 contains "r", and key 3 contains "d". The key/value pairs are in matching order from left-to-right in the pattern, with longer string matches preceding shorter ones.

In the case of `-replace`, the replacement text can access the submatches via names of the form `$n`, where the first match is `$1`, the second is `$3`, and so on. For example,

PowerShell

```
"Monday morning" -replace '(Monday|Tuesday)(morning|afternoon|evening)', 'the $2 of $1'
```

The resulting string is "the morning of Monday".

Instead of having keys in `$Matches` be zero-based indexes, submatches can be named using the form `?<name*>`. For example, `"((r)e)(d)"` can be written with three named submatches, `m1`, `m2`, and `m3`, as follows: `"(?<m1>(?<m2>r)e)(?<m3>d)"`.

7.8.5 Shift operators

Syntax:

```
Syntax

shift-operator: one of
    dash shl
    dash shr

dash:
    - (U+002D)
    EnDash character (U+2013)
    EmDash character (U+2014)
    Horizontal bar character (U+2015)
```

Description:

The shift left (`-shl`) operator and shift right (`-shr`) operator convert the value designed by the left operand to an integer type and the value designated by the right operand to `int`, if necessary, using the usual arithmetic conversions ([§6.15](#)).

The shift left operator shifts the left operand left by a number of bits computed as described below. The low-order empty bit positions are set to zero.

The shift right operator shifts the left operand right by a number of bits computed as described below. The low-order bits of the left operand are discarded, the remaining bits shifted right. When the left operand is a signed value, the high-order empty bit positions are set to zero if the left operand is non-negative and set to one if the left operand is negative. When the left operand is an unsigned value, the high-order empty bit positions are set to zero.

When the left operand has type `int`, the shift count is given by the low-order five bits of the right operand. When the right operand has type `long`, the shift count is given by the low-order six bits of the right operand.

Examples:

```
PowerShell
```

```
0x0408 -shl 1          # int with value 0x0810
0x0408 -shr 3          # int with value 0x0081
0x100000000 -shr 0xffff81 # long with value 0x80000000
```

7.9 Bitwise operators

Syntax:

Syntax

```
bitwise-expression:
    unary-expression -band new-lines~opt~ unary-expression
    unary-expression -bor new-lines~opt~ unary-expression
    unary-expression -bxor new-lines~opt~ unary-expression
```

Description:

The bitwise AND operator `-band`, the bitwise OR operator `-bor`, and the bitwise XOR operator `-bxor` convert the values designated by their operands to integer types, if necessary, using the usual arithmetic conversions ([§6.15](#)). After conversion, if both values have type int that is the type of the result. Otherwise, if both values have type long, that is the type of the result. If one value has type int and the other has type long, the type of the result is long. Otherwise, the expression is ill formed. The result is the bitwise AND, bitwise OR, or bitwise XOR, respectively, of the possibly converted operand values.

These operators are left associative. They are commutative if neither operand contains a side effect.

Examples:

PowerShell

```
0x0F0F -band 0xFE      # int with value 0xE
0x0F0F -band 0xFEL     # long with value 0xE
0x0F0F -band 14.6       # long with value 0xF

0x0F0F -bor 0xFE       # int with value 0xFFFF
0x0F0F -bor 0xFEL      # long with value 0xFFFF
0x0F0F -bor 14.40D      # long with value 0xF0F

0x0F0F -bxor 0xFE      # int with value 0xFF1
0x0F0F -bxor 0xFEL     # long with value 0xFF1
0x0F0F -bxor 14.40D     # long with value 0xF01
0x0F0F -bxor 14.6       # long with value 0xF00
```

7.10 Logical operators

Syntax:

```
Syntax

logical-expression:
    unary-expression -and new-lines~opt~ unary-expression
    unary-expression -or new-lines~opt~ unary-expression
    unary-expression -xor new-lines~opt~ unary-expression
```

Description:

The logical AND operator `-and` converts the values designated by its operands to `bool`, if necessary ([§6.2](#)). The result is the logical AND of the possibly converted operand values, and has type `bool`. If the left operand evaluates to False the right operand is not evaluated.

The logical OR operator `-or` converts the values designated by its operands to `bool`, if necessary ([§6.2](#)). The result is the logical OR of the possibly converted operand values, and has type `bool`. If the left operand evaluates to True the right operand is not evaluated.

The logical XOR operator `-xor` converts the values designated by its operands to `bool` ([§6.2](#)). The result is the logical XOR of the possibly converted operand values, and has type `bool`.

These operators are left associative.

Examples:

```
PowerShell

$j = 10
$k = 20
($j -gt 5) -and (++$k -lt 15) # True -and False -> False
($j -gt 5) -and ($k -le 21)    # True -and True -> True
($j++ -gt 5) -and ($j -le 10)   # True -and False -> False
($j -eq 5) -and (++$k -gt 15)   # False -and True -> False

$j = 10
$k = 20
($j++ -gt 5) -or (++$k -lt 15) # True -or False -> True
($j -eq 10) -or ($k -gt 15)    # False -or True -> True
($j -eq 10) -or (++$k -le 20)   # False -or False -> False

$j = 10
```

```
$k = 20
($j++ -gt 5) -xor (++$k -lt 15) # True -xor False -> True
($j -eq 10) -xor ($k -gt 15)     # False -xor True -> True
($j -gt 10) -xor (++$k -le 25)   # True -xor True -> False
```

7.11 Assignment operators

Syntax:

```
Syntax

assignment-expression:
    expression assignment-operator statement

assignment-operator: *one of
    =    dash =    +=    *=    /=    %=
```

Description:

An assignment operator stores a value in the writable location designated by *expression*. For a discussion of *assignment-operator* `=` see §7.11.1. For a discussion of all other assignment operators see §7.11.2.

An assignment expression has the value designated by *expression* after the assignment has taken place; however, that assignment expression does not itself designate a writable location. If *expression* is type-constrained (§5.3), the type used in that constraint is the type of the result; otherwise, the type of the result is the type after the usual arithmetic conversions (§6.15) have been applied.

This operator is right associative.

7.11.1 Simple assignment

Description:

In *simple assignment* (`=`), the value designated by *statement* replaces the value stored in the writable location designated by *expression*. However, if *expression* designates a non-existent key in a Hashtable, that key is added to the Hashtable with an associated value of the value designated by *statement*.

As shown by the grammar, *expression* may designate a comma-separated list of writable locations. This is known as *multiple assignment*. *statement* designates a list of one or more comma-separated values. The commas in either operand list are part of the multiple-assignment syntax and do *not* represent the binary comma operator. Values are

taken from the list designated by *statement*, in lexical order, and stored in the corresponding writable location designated by *expression*. If the list designated by *statement* has fewer values than there are *expression* writable locations, the excess locations take on the value `$null`. If the list designated by *statement* has more values than there are *expression* writable locations, all but the right-most *expression* location take on the corresponding *statement* value and the right-most *expression* location becomes an unconstrained 1-dimensional array with all the remaining *statement* values as elements.

For statements that have values ([§8.1.2](#)), *statement* can be a statement.

Examples:

PowerShell

```
$a = 20; $b = $a + 12L          # $b has type long, value 22
$hypot = [Math]::Sqrt(3*3 + 4*4)    # type double, value 5
$a = $b = $c = 10.20D           # all have type decimal, value 10.20
$a = (10,20,30),(1,2)           # type [Object[]], Length 2
[int]$x = 10.6                  # type int, value 11
[long]$x = "0xabc"              # type long, value 0xabc
$a = [float]                     # value type literal [float]
$i,$j,$k = 10,"red",$true       # $i is 10, $j is "red", $k is True
$i,$j = 10,"red",$true          # $i is 10, $j is [Object[]], Length 2
$i,$j = (10,"red"),$true        # $i is [Object[]], Length 2, $j is True
$i,$j,$k = 10                   # $i is 10, $j is $null, $k is $null

$h = @{}
[int] $h.Lower, [int] $h.Upper = -split "10 100"

$h1 = @{ FirstName = "James"; LastName = "Anderson"; IDNum = 123 }
$h1.Dept = "Finance"            # adds element Finance
$h1["City"] = "New York"         # adds element City

[int]$Variable:v = 123.456        # v takes on the value 123
${E:output.txt} = "a"             # write text to the given file
$Env:MyPath = "X:\data\file.txt"  # define the environment variable
$Function:F = { param ($a, $b) "Hello there, $a, $b" }
F 10 "red"                      # define and invoke a function
function Demo { "Hi there from inside Demo" }
$Alias:A = "Demo"                # create alias for function Demo
A                                # invoke function Demo via the alias
```

7.11.2 Compound assignment

Description:

A *compound assignment* has the form `E1 op= E2`, and is equivalent to the simple assignment expression `E1 = E1 op (E2)` except that in the compound assignment case the expression *E1* is evaluated only once. If *expression* is type-constrained (§5.3), the type used in that constraint is the type of the result; otherwise, the type of the result is determined by *op*. For `*=`, see §7.6.1, §7.6.2, §7.6.3; for `/=`, see §7.6.4; for `%=`, see §7.6.5; for `+=`, see §7.7.1, §7.7.2, §7.7.3; for `-=`, see §7.7.5.

ⓘ Note

An operand designating an unconstrained value of numeric type may have its type changed by an assignment operator when the result is stored.

Examples:

PowerShell

```
$a = 1234; $a *= (3 + 2) # type is int, value is 1234 * (3 + 2)
$b = 10,20,30           # $b[1] has type int, value 20
$b[1] /= 6              # $b[1] has type double, value 3.33...

$i = 0
$b = 10,20,30           # side effect evaluated only once
$b[++$i] += 2

[int]$Variable:v = 10    # v takes on the value 10
$Variable:v -= 3         # 3 is subtracted from v

${E:output.txt} = "a"    # write text to the given file
${E:output.txt} += "b"    # append text to the file giving ab
${E:output.txt} *= 4      # replicate ab 4 times giving ababab
```

7.12 Redirection operators

Syntax:

Syntax

```
pipeline:
  expression redirections~opt~ pipeline-tail~opt~
  command verbatim-command-argument~opt~ pipeline-tail~opt~

redirections:
  redirection
  redirections redirection

redirection:
```

```

merging-redirection-operator
file-redirection-operator redirected-file-name

redirected-file-name:
  command-argument
  primary-expression

file-redirection-operator: one of
  >    >>   2>   2>>   3>   3>>   4>   4>>
  5>   5>>   6>   6>>   >    >>    <

merging-redirection-operator: one of
  >&1   2>&1   3>&1   4>&1   5>&1   6>&1
  >&2   1>&2   3>&2   4>&2   5>&2   6>&2

```

Description:

The redirection operator `>` takes the standard output from the pipeline and redirects it to the location designated by *redirected-file-name*, overwriting that location's current contents.

The redirection operator `>>` takes the standard output from the pipeline and redirects it to the location designated by *redirected-file-name*, appending to that location's current contents, if any. If that location does not exist, it is created.

The redirection operator with the form `n>` takes the output of stream *n* from the pipeline and redirects it to the location designated by *redirected-file-name*, overwriting that location's current contents.

The redirection operator with the form `n>>` takes the output of stream *n* from the pipeline and redirects it to the location designated by *redirected-file-name*, appending to that location's current contents, if any. If that location does not exist, it is created.

The redirection operator with the form `m>&n` writes output from stream *m* to the same location as stream *n*.

The following are the valid streams:

[] Expand table

Stream	Description
1	Standard output stream
2	Error output stream
3	Warning output stream

Stream	Description
4	Verbose output stream
5	Debug output stream
*	Standard output, error output, warning output, verbose output, and debug output streams

The redirection operators `1>&2`, `6>`, `6>>` and `<` are reserved for future use.

If on output the value of *redirected-file-name* is `$null`, the output is discarded.

Ordinarily, the value of an expression containing a top-level side effect is not written to the pipeline unless that expression is enclosed in a pair of parentheses. However, if such an expression is the left operand of an operator that redirects standard output, the value is written.

Examples:

PowerShell

```
$i = 200                      # pipeline gets nothing
$i                         # pipeline gets result
$i > output1.txt           # result redirected to named file
++$i >> output1.txt        # result appended to named file
type file1.txt 2> error1.txt # error output redirected to named file
type file2.txt 2>> error1.txt # error output appended to named file
dir -Verbose 4> verbose1.txt # verbose output redirected to named file

# Send all output to output2.txt
dir -Verbose -Debug -WarningAction Continue *> output2.txt

# error output redirected to named file, verbose output redirected
# to the same location as error output
dir -Verbose 4>&2 2> error2.txt
```

8. Statements

Article • 07/15/2024

Editorial note

Important

The *Windows PowerShell Language Specification 3.0* was published in December 2012 and is based on Windows PowerShell 3.0. This specification does not reflect the current state of PowerShell. There is no plan to update this documentation to reflect the current state. This documentation is presented here for historical reference.

The specification document is available as a Microsoft Word document from the Microsoft Download Center at:

<https://www.microsoft.com/download/details.aspx?id=36389> That Word document has been converted for presentation here on Microsoft Learn. During conversion, some editorial changes have been made to accommodate formatting for the Docs platform. Some typos and minor errors have been corrected.

8.1 Statement blocks and lists

Syntax:

Tip

The `~opt~` notation in the syntax definitions indicates that the lexical entity is optional in the syntax.

Syntax

```
statement-block:  
    new-lines~opt~ { statement-list~opt~ new-lines~opt~ }  
  
statement-list:  
    statement  
    statement-list statement  
  
statement:  
    if-statement
```

```
label~opt~ labeled-statement
function-statement
flow-control-statement statement-terminator
trap-statement
try-statement
data-statement
inlinescript-statement
parallel-statement
sequence-statement
pipeline statement-terminator

statement-terminator:
;
new-line-character
```

Description:

A *statement* specifies some sort of action that is to be performed. Unless indicated otherwise within this clause, statements are executed in lexical order.

A *statement-block* allows a set of statements to be grouped into a single syntactic unit.

8.1.1 Labeled statements

Syntax:

Syntax
<pre>labeled-statement: switch-statement foreach-statement for-statement while-statement do-statement</pre>

Description:

An iteration statement ([§8.4](#)) or a switch statement ([§8.6](#)) may optionally be preceded immediately by one statement label, *label*. A statement label is used as the optional target of a break ([§8.5.1](#)) or continue ([§8.5.2](#)) statement. However, a label does not alter the flow of control.

White space is not permitted between the colon (:) and the token that follows it.

Examples:

PowerShell

```

:go_here while ($j -le 100) {
    # ...
}

:labelA
for ($i = 1; $i -le 5; ++$i) {
    :labelB
    for ($j = 1; $j -le 3; ++$j) {
        :labelC
        for ($k = 1; $k -le 2; ++$k) {
            # ...
        }
    }
}

```

8.1.2 Statement values

The value of a statement is the cumulative set of values that it writes to the pipeline. If the statement writes a single scalar value, that is the value of the statement. If the statement writes multiple values, the value of the statement is that set of values stored in elements of an unconstrained 1-dimensional array, in the order in which they were written. Consider the following example:

```
$v = for ($i = 10; $i -le 5; ++$i) { }
```

There are no iterations of the loop and nothing is written to the pipeline. The value of the statement is `$null`.

```
$v = for ($i = 1; $i -le 5; ++$i) { }
```

Although the loop iterates five times nothing is written to the pipeline. The value of the statement is `$null`.

```
$v = for ($i = 1; $i -le 5; ++$i) { $i }
```

The loop iterates five times each time writing to the pipeline the `int` value `$i`. The value of the statement is `object[]` of Length 5.

```
$v = for ($i = 1; $i -le 5; ) { ++$i }
```

Although the loop iterates five times nothing is written to the pipeline. The value of the statement is `$null`.

```
$v = for ($i = 1; $i -le 5; ) { (++$i) }
```

The loop iterates five times with each value being written to the pipeline. The value of the statement is `object[]` of Length 5.

```
$i = 1; $v = while ($i++ -lt 2) { $i }
```

The loop iterates once. The value of the statement is the `int` with value 2.

Here are some other examples:

PowerShell

```
# if $count is not currently defined then define it with int value 10
$count = if ($count -eq $null) { 10 } else { $count }

$i = 1
$v = while ($i -le 5) {
    $i                         # $i is written to the pipeline
    if ($i -band 1) {

        "odd"                  # conditionally written to the pipeline

    }
    ++$i                      # not written to the pipeline
}

# $v is object[], Length 8, value 1,"odd",2,3,"odd",4,5,"odd"
```

8.2 Pipeline statements

Syntax:

Syntax

```
pipeline:
    assignment-expression
    expression redirections~opt~ pipeline-tail~opt~
    command verbatim-command-argument~opt~ pipeline-tail~opt~

assignment-expression:
    expression assignment-operator statement

pipeline-tail:
    | new-lines~opt~ command
    | new-lines~opt~ command pipeline-tail

command:
    command-name command-elements~opt~
    command-invocation-operator command-module~opt~ command-name-expr
    command-elements~opt~
```

```

command-invocation-operator: one of
& .

command-module:
    primary-expression

command-name:
    generic-token
    generic-token-with-subexpr

generic-token-with-subexpr:
    No whitespace is allowed between ) and command-name.
    generic-token-with-subexpr-start statement-list~opt~ )

command-namecommand-name-expr:
    command-name

primary-expressioncommand-elements:
    command-element
    command-elements command-element

command-element:
    command-parameter
    command-argument
    redirection

command-argument:
    command-name-expr

verbatim-command-argument:
    --% verbatim-command-argument-chars

```

Description:

redirections is discussed in [§7.12](#); *assignment-expression* is discussed in [§7.11](#); and the *command-invocation-operator* dot (.) is discussed in [§3.5.5](#). For a discussion of argument-to-parameter mapping in command invocations, see [§8.14](#).

The first command in a *pipeline* is an expression or a command invocation. Typically, a command invocation begins with a *command-name*, which is usually a bare identifier. *command-elements* represents the argument list to the command. A newline or n unescaped semicolon terminates a pipeline.

A command invocation consists of the command's name followed by zero or more arguments. The rules governing arguments are as follows:

- An argument that is not an expression, but which contains arbitrary text without unescaped white space, is treated as though it were double quoted. Letter case is preserved.

- Variable substitution and sub-expression expansion ([§2.3.5.2](#)) takes place inside *expandable-string-literals* and *expandable-here-string-literals*.
- Text inside quotes allows leading, trailing, and embedded white space to be included in the argument's value. [Note: The presence of whitespace in a quoted argument does not turn a single argument into multiple arguments. *end note*]
- Putting parentheses around an argument causes that expression to be evaluated with the result being passed instead of the text of the original expression.
- To pass an argument that looks like a switch parameter ([§2.3.4](#)) but is not intended as such, enclose that argument in quotes.
- When specifying an argument that matches a parameter having the `[switch]` type constraint ([§8.10.5](#)), the presence of the argument name on its own causes that parameter to be set to `$true`. However, the parameter's value can be set explicitly by appending a suffix to the argument. For example, given a type constrained parameter *p*, an argument of `-p:$true` sets *p* to True, while `-p:$false` sets *p* to False.
- An argument of `--` indicates that all arguments following it are to be passed in their actual form as though double quotes were placed around them.
- An argument of `--%` indicates that all arguments following it are to be passed with minimal parsing and processing. This argument is called the verbatim parameter. Arguments after the verbatim parameter are not PowerShell expressions even if they are syntactically valid PowerShell expressions.

If the command type is Application, the parameter `--%` is not passed to the command. The arguments after `--%` have any environment variables (strings surrounded by `%`) expanded. For example:

PowerShell

```
echoargs.exe --% "%path%" # %path% is replaced with the value $Env:path
```

The order of evaluation of arguments is unspecified.

For information about parameter binding see [§8.14](#). For information about name lookup see [§3.8](#).

Once argument processing has been completed, the command is invoked. If the invoked command terminates normally ([§8.5.4](#)), control reverts to the point in the script or function immediately following the command invocation. For a description of the

behavior on abnormal termination see `break` ([§8.5.1](#)), `continue` ([§8.5.2](#)), `throw` ([§8.5.3](#)), `exit` ([§8.5.5](#)), `try` ([§8.7](#)), and `trap` ([§8.8](#)).

Ordinarily, a command is invoked by using its name followed by any arguments. However, the command-invocation operator, `&`, can be used. If the command name contains unescaped white space, it must be quoted and invoked with this operator. As a script block has no name, it too must be invoked with this operator. For example, the following invocations of a command call `Get-Factorial` are equivalent:

PowerShell

```
Get-Factorial 5
& Get-Factorial 5
& "Get-Factorial" 5
```

Direct and indirect recursive function calls are permitted. For example,

PowerShell

```
function Get-Power([int]$x, [int]$y) {
    if ($y -gt 0) { return $x * (Get-Power $x (--$y)) }
    else { return 1 }
}
```

Examples:

PowerShell

```
New-Object 'int[,]' 3,2
New-Object -ArgumentList 3,2 -TypeName 'int[,]'

dir E:\PowerShell\Scripts\*statement*.ps1 | ForEach-Object {$_.Length}

dir E:\PowerShell\Scripts\*.ps1 |
    Select-String -List "catch" |
        Format-Table Path, LineNumber -AutoSize
```

8.3 The if statement

Syntax:

Syntax

```
if-statement:
    if new-lines~opt~ ( new-lines~opt~ pipeline new-lines~opt~ ) statement-
```

```

block
    elseif-clauses~opt~ else-clause~opt~

elseif-clauses:
    elseif-clause
    elseif-clauses elseif-clause

elseif-clause:
    new-lines~opt~ elseif new-lines~opt~ ( new-lines~opt~ pipeline new-
lines~opt~ ) statement-block

else-clause:
    new-lines~opt~ else statement-block

```

Description:

The *pipeline* controlling expressions must have type bool or be implicitly convertible to that type. The *else-clause* is optional. There may be zero or more *elseif-clauses*.

If the top-level *pipeline* tests True, then its *statement-block* is executed and execution of the statement terminates. Otherwise, if an *elseif-clause* is present, if its *pipeline* tests True, then its *statement-block* is executed and execution of the statement terminates. Otherwise, if an *else-clause* is present, its *statement-block* is executed.

Examples:

PowerShell

```

$grade = 92
if ($grade -ge 90) { "Grade A" }
elseif ($grade -ge 80) { "Grade B" }
elseif ($grade -ge 70) { "Grade C" }
elseif ($grade -ge 60) { "Grade D" }
else { "Grade F" }

```

8.4 Iteration statements

8.4.1 The while statement

Syntax:

Syntax

```

while-statement:
    while new-lines~opt~ ( new-lines~opt~ while-condition new-lines~opt~ )
    statement-block

```

```
while-condition:  
    new-lines~opt~ pipeline
```

Description:

The controlling expression *while-condition* must have type bool or be implicitly convertible to that type. The loop body, which consists of *statement-block*, is executed repeatedly until the controlling expression tests False. The controlling expression is evaluated before each execution of the loop body.

Examples:

PowerShell

```
$i = 1  
while ($i -le 5) {  
    "{0,1}`t{1,2}" -f $i, ($i*$i)  
    ++$i  
}
```

8.4.2 The do statement

Syntax:

Syntax

```
do-statement:  
    do statement-block new-lines~opt~ while new-lines~opt~ ( while-condition  
new-lines~opt~ )  
        do statement-block new-lines~opt~ until new-lines~opt~ ( while-condition  
new-lines~opt~ )  
  
while-condition:  
    new-lines~opt~ pipeline
```

Description:

The controlling expression *while-condition* must have type bool or be implicitly convertible to that type. In the while form, the loop body, which consists of *statement-block*, is executed repeatedly while the controlling expression tests True. In the until form, the loop body is executed repeatedly until the controlling expression tests True. The controlling expression is evaluated after each execution of the loop body.

Examples:

PowerShell

```

$i = 1
do {
    "{0,1}`t{1,2}" -f $i, ($i * $i)
}
while (++$i -le 5)                      # loop 5 times

$i = 1
do {
    "{0,1}`t{1,2}" -f $i, ($i * $i)
}
until (++$i -gt 5)                      # loop 5 times

```

8.4.3 The for statement

Syntax:

Syntax

```

for-statement:
    for new-lines~opt~ (
        new-lines~opt~ for-initializer~opt~ statement-terminator
        new-lines~opt~ for-condition~opt~ statement-terminator
        new-lines~opt~ for-iterator~opt~
        new-lines~opt~ ) statement-block

    for new-lines~opt~ (
        new-lines~opt~ for-initializer~opt~ statement-terminator
        new-lines~opt~ for-condition~opt~
        new-lines~opt~ ) statement-block

    for new-lines~opt~ (
        new-lines~opt~ for-initializer~opt~
        new-lines~opt~ ) statement-block

for-initializer:
    pipeline

for-condition:
    pipeline

for-iterator:
    pipeline

```

Description:

The controlling expression *for-condition* must have type bool or be implicitly convertible to that type. The loop body, which consists of *statement-block*, is executed repeatedly while the controlling expression tests True. The controlling expression is evaluated before each execution of the loop body.

Expression *for-initializer* is evaluated before the first evaluation of the controlling expression. Expression *for-initializer* is evaluated for its side effects only; any value it produces is discarded and is not written to the pipeline.

Expression *for-iterator* is evaluated after each execution of the loop body. Expression *for-iterator* is evaluated for its side effects only; any value it produces is discarded and is not written to the pipeline.

If expression *for-condition* is omitted, the controlling expression tests True.

Examples:

PowerShell

```
for ($i = 5; $i -ge 1; --$i) { # loop 5 times
    "{0,1}`t{1,2}" -f $i, ($i * $i)
}

$i = 5
for (; $i -ge 1; ) { # equivalent behavior
    "{0,1}`t{1,2}" -f $i, ($i * $i)
    --$i
}
```

8.4.4 The foreach statement

Syntax:

Syntax

```
foreach-statement:
    foreach new-lines~opt~ foreach-parameter~opt~ new-lines~opt~
        ( new-lines~opt~ variable new-lines~opt~ *in* new-lines~opt~
pipeline
    new-lines~opt~ ) statement-block

foreach-parameter:
    -parallel
```

Description:

The loop body, which consists of *statement-block*, is executed for each element designated by the variable *variable* in the collection designated by *pipeline*. The scope of *variable* is not limited to the foreach statement. As such, it retains its final value after the loop body has finished executing. If *pipeline* designates a scalar (excluding the value

`$null`) instead of a collection, that scalar is treated as a collection of one element. If `pipeline` designates the value `$null`, `pipeline` is treated as a collection of zero elements.

If the *foreach-parameter* `-parallel` is specified, the behavior is implementation defined.

The *foreach-parameter* `-parallel` is only allowed in a workflow ([§8.10.2](#)).

Every foreach statement has its own enumerator, `$foreach` ([§2.3.2.2](#), [§4.5.16](#)), which exists only while that loop is executing.

The objects produced by `pipeline` are collected before *statement-block* begins to execute. However, with the [ForEach-Object cmdlet](#), *statement-block* is executed on each object as it is produced.

Examples:

PowerShell

```
$a = 10, 53, 16, -43
foreach ($e in $a) {
    ...
}
$e # the int value -43

foreach ($e in -5..5) {
    ...
}

foreach ($t in [byte], [int], [long]) {
    $t::MaxValue # get static property
}

foreach ($f in Get-ChildItem *.txt) {
    ...
}

$h1 = @{ FirstName = "James"; LastName = "Anderson"; IDNum = 123 }
foreach ($e in $h1.Keys) {
    "Key is " + $e + ", Value is " + $h1[$e]
}
```

8.5 Flow control statements

Syntax:

Syntax

```
flow-control-statement:
    break label-expression~opt~
    continue label-expression~opt~
    throw pipeline~opt~
    return pipeline~opt~
    exit pipeline~opt~

label-expression:
    simple-name
    unary-expression
```

Description:

A flow-control statement causes an unconditional transfer of control to some other location.

8.5.1 The `break` statement

Description:

A `break` statement with a *label-expression* is referred to as a *labeled break statement*. A `break` statement without a *label-expression* is referred to as an *unlabeled break statement*.

Outside a trap statement, an unlabeled `break` statement directly within an iteration statement ([§8.4](#)) terminates execution of that smallest enclosing iteration statement. An unlabeled `break` statement directly within a switch statement ([§8.6](#)) terminates pattern matching for the current switch's *switch-condition*. See ([§8.8](#)) for details of using `break` from within a trap statement.

An iteration statement or a switch statement may optionally be preceded immediately by one statement label ([§8.1.1](#)). Such a statement label may be used as the target of a labeled `break` statement, in which case, that statement terminates execution of the targeted enclosing iteration statement.

A labeled `break` need not be resolved in any local scope; the search for a matching label may continue up the calling stack even across script and function-call boundaries. If no matching label is found, the current command invocation is terminated.

The name of the label designated by *label-expression* need not have a constant value.

If *label-expression* is a *unary-expression*, it is converted to a string.

Examples:

PowerShell

```
$i = 1
while ($true) { # infinite loop
    if ($i * $i -gt 100) {
        break # break out of current while loop
    }
    ++$i
}

$lab = "go_here"
:go_here
for ($i = 1; ; ++$i) {
    if ($i * $i -gt 50) {
        break $lab # use a string value as target
    }
}

:labelA
for ($i = 1; $i -le 2; $i++) {

    :labelB
    for ($j = 1; $j -le 2; $j++) {

        :labelC
        for ($k = 1; $k -le 3; $k++) {
            if (...) { break labelA }
        }
    }
}
```

8.5.2 The continue statement

Description:

A `continue` statement with a *label-expression* is referred to as a *labeled continue statement*. A `continue` statement without a *label-expression* is referred to as an *unlabeled continue statement*.

The use of `continue` from within a trap statement is discussed in [§8.8](#).

An unlabeled `continue` statement within a loop terminates execution of the current loop and transfers control to the closing brace of the smallest enclosing iteration statement ([§8.4](#)). An unlabeled `continue` statement within a switch terminates execution of the current `switch` iteration and transfers control to the smallest enclosing `switch`'s *switch-condition* ([§8.6](#)).

An iteration statement or a `switch` statement ([§8.6](#)) may optionally be preceded immediately by one statement label ([§8.1.1](#)). Such a statement label may be used as the target of an enclosed labeled `continue` statement, in which case, that statement terminates execution of the current loop or `switch` iteration, and transfers control to the targeted enclosing iteration or `switch` statement label.

A labeled `continue` need not be resolved in any local scope; the search for a matching label may `continue` up the calling stack even across script and function-call boundaries. If no matching label is found, the current command invocation is terminated.

The name of the label designated by *label-expression* need not have a constant value.

If *label-expression* is a *unary-expression*, it is converted to a string.

Examples:

PowerShell

```
$i = 1
while (...) {
    ...
    if (...) {
        continue # start next iteration of current loop
    }
    ...
}

$lab = "go_here"
:go_here
for (...; ...; ...) {
    if (...) {
        continue $lab # start next iteration of labeled loop
    }
}

:labelA
for ($i = 1; $i -le 2; $i++) {

    :labelB
    for ($j = 1; $j -le 2; $j++) {

        :labelC
        for ($k = 1; $k -le 3; $k++) {
            if (...) { continue labelB }
        }
    }
}
```

8.5.3 The throw statement

Description:

An exception is a way of handling a system- or application-level error condition. The `throw` statement raises an exception. (See [§8.7](#) for a discussion of exception handling.)

If *pipeline* is omitted and the `throw` statement is not in a *catch-clause*, the behavior is implementation defined. If *pipeline* is present and the `throw` statement is in a *catch-clause*, the exception that was caught by that *catch-clause* is re-thrown after any *finally-clause* associated with the *catch-clause* is executed.

If *pipeline* is present, the type of the exception thrown is implementation defined.

When an exception is thrown, control is transferred to the first catch clause in an enclosing try statement that can handle the exception. The location at which the exception is thrown initially is called the *throw point*. Once an exception is thrown the steps described in [§8.7](#) are followed repeatedly until a catch clause that matches the exception is found or none can be found.

Examples:

PowerShell

```
throw
throw 100
throw "No such record in file"
```

If *pipeline* is omitted and the `throw` statement is not from within a *catch-clause*, the text "ScriptHalted" is written to the pipeline, and the type of the exception raised is `System.Management.Automation.RuntimeException`.

If *pipeline* is present, the exception raised is wrapped in an object of type `System.Management.Automation.RuntimeException`, which includes information about the exception as a `System.Management.Automation.ErrorRecord` object (accessible via `$_.`).

Example 1: `throw 123` results in an exception of type `RuntimeException`. From within the catch block, `$_.TargetObject` contains the object wrapped inside, in this case, a `System.Int32` with value 123.

Example 2: `throw "xxx"` results in an exception of type `RuntimeException`. From within the catch block, `$_.TargetObject` contains the object wrapped inside, in this case, a `System.String` with value "xxx".

Example 3: `throw 10,20` results in an exception of type **RuntimeException**. From within the catch block, `$_._TargetObject` contains the object wrapped inside, in this case, a `System.Object[]`, an unconstrained array of two elements with the `System.Int32`` values 10 and 20.

8.5.4 The return statement

Description:

The `return` statement writes to the pipeline the value(s) designated by *pipeline*, if any, and returns control to the function or script's caller. A function or script may have zero or more `return` statements.

If execution reaches the closing brace of a function an implied `return` without *pipeline* is assumed.

The `return` statement is a bit of "syntactic sugar" to allow programmers to express themselves as they can in other languages; however, the value returned from a function or script is actually all of the values written to the pipeline by that function or script plus any value(s) specified by *pipeline*. If only a scalar value is written to the pipeline, its type is the type of the value returned; otherwise, the return type is an unconstrained 1-dimensional array containing all the values written to the pipeline.

Examples:

PowerShell

```
function Get-Factorial ($v) {
    if ($v -eq 1) {
        return 1 # return is not optional
    }

    return $v * (Get-Factorial ($v - 1)) # return is optional
}
```

The caller to `Get-Factorial` gets back an `int`.

PowerShell

```
function Test {
    "text1" # "text1" is written to the pipeline
    #
    "text2" # "text2" is written to the pipeline
    #
}
```

```
    return 123 # 123 is written to the pipeline
}
```

The caller to `Test` gets back an unconstrained 1-dimensional array of three elements.

8.5.5 The exit statement

Description:

The `exit` statement terminates the current script and returns control and an *exit code* to the host environment or the calling script. If *pipeline* is provided, the value it designates is converted to `int`, if necessary. If no such conversion exists, or if *pipeline* is omitted, the `int` value zero is returned.

Examples:

PowerShell

```
exit $count # terminate the script with some accumulated count
```

8.6 The switch statement

Syntax:

Syntax

```
switch-statement:
    switch new-lines~opt~ switch-parameters~opt~ switch-condition switch-
body

switch-parameters:
    switch-parameter
    switch-parameters switch-parameter

switch-parameter:
    -Regex
    -Wildcard
    -Exact
    -CaseSensitive
    -Parallel

switch-condition:
    ( new-lines~opt~ pipeline new-lines~opt~ )
    -File new-lines~opt~ switch-filename

switch-filename:
    command-argument
```

```
primary-expression

switch-body:
    new-lines~opt~ { new-lines~opt~ switch-clauses }

switch-clauses:
    switch-clause
    switch-clauses switch-clause

switch-clause:
    switch-clause-condition statement-block statement-terminators~opt~

switch-clause-condition:
    command-argument
    primary-expression
```

Description:

If *switch-condition* designates a single value, control is passed to one or more matching pattern statement blocks. If no patterns match, some default action can be taken.

A switch must contain one or more *switch-clauses*, each starting with a pattern (a *non-default switch clause*), or the keyword `default` (a *default switch clause*). A switch must contain zero or one `default` switch clauses, and zero or more non-default switch clauses. Switch clauses may be written in any order.

Multiple patterns may have the same value. A pattern need not be a literal, and a switch may have patterns with different types.

If the value of *switch-condition* matches a pattern value, that pattern's *statement-block* is executed. If multiple pattern values match the value of *switch-condition*, each matching pattern's *statement-block* is executed, in lexical order, unless any of those *statement-blocks* contains a `break` statement ([§8.5.1](#)).

If the value of *switch-condition* does not match any pattern value, if a `default` switch clause exists, its *statement-block* is executed; otherwise, pattern matching for that *switch-condition* is terminated.

Switches may be nested, with each switch having its own set of switch clauses. In such instances, a switch clause belongs to the innermost switch currently in scope.

On entry to each *statement-block*, `$_` is automatically assigned the value of the *switch-condition* that caused control to go to that *statement-block*. `$_` is also available in that *statement-block's switch-clause-condition*.

Matching of non-strings is done by testing for equality ([§7.8.1](#)).

If the matching involves strings, by default, the comparison is case-insensitive. The presence of the *switch-parameter* `-CaseSensitive` makes the comparison case-sensitive.

A pattern may contain wildcard characters ([§3.15](#)), in which case, wildcard string comparisons are performed, but only if the *switch-parameter* `-Wildcard` is present. By default, the comparison is case-insensitive.

A pattern may contain a regular expression ([§3.16](#)), in which case, regular expression string comparisons are performed, but only if the *switch-parameter* `-Regex` is present. By default, the comparison is case-insensitive. If `-Regex` is present and a pattern is matched, `$Matches` is defined in the *switch-clause statement-block* for that pattern.

A *switch-parameter* may be abbreviated; any distinct leading part of a parameter may be used. For example, `-Regex`, `-Rege`, `-Reg`, `-Re`, and `-R` are equivalent.

If conflicting *switch-parameters* are specified, the lexically final one prevails. The presence of `-Exact` disables `-Regex` and `-Wildcard`; it has no affect on `-Case`, however.

If the *switch-parameter* `-Parallel` is specified, the behavior is implementation defined.

The *switch-parameter* `-Parallel` is only allowed in a workflow ([§8.10.2](#)).

If a pattern is a *script-block-expression*, that block is evaluated and the result is converted to bool, if necessary. If the result has the value `$true`, the corresponding *statement-block* is executed; otherwise, it is not.

If *switch-condition* designates multiple values, the switch is applied to each value in lexical order using the rules described above for a *switch-condition* that designates a single value. Every switch statement has its own enumerator, `$switch` ([§2.3.2.2](#), [§4.5.16](#)), which exists only while that switch is executing.

A switch statement may have a label, and it may contain labeled and unlabeled break ([§8.5.1](#)) and continue ([§8.5.2](#)) statements.

If *switch-condition* is `-File` *switch-filename*, instead of iterating over the values in an expression, the switch iterates over the values in the file designated by *switch-filename*. The file is read a line at a time with each line comprising a value. Line terminator characters are not included in the values.

Examples:

PowerShell

```
$s = "ABC def`nghi`tjkl`fmno @##"  
$charCount = 0; $pageCount = 0; $lineCount = 0; $otherCount = 0
```

```

for ($i = 0; $i -lt $s.Length; ++$i) {
    ++$charCount
    switch ($s[$i]) {
        "`n" { ++$lineCount }
        "`f" { ++$pageCount }
        "`t" { }
        " " { }
        default { ++$otherCount }
    }
}

switch -Wildcard ("abc") {
    a* { "a*, $_" }
    ?B? { "?B?, $_" }
    default { "default, $_" }
}

switch -Regex -CaseSensitive ("abc") {
    ^a* { "a*" }
    ^A* { "A*" }
}

switch (0, 1, 19, 20, 21) {
    { $_ -lt 20 } { "-lt 20" }
    { $_ -band 1 } { "Odd" }
    { $_ -eq 19 } { "-eq 19" }
    default { "default" }
}

```

8.7 The try/finally statement

Syntax:

Syntax

```

try-statement:
    try statement-block catch-clauses
    try statement-block finally-clause
    try statement-block catch-clauses finally-clause

catch-clauses:
    catch-clause
    catch-clauses catch-clause

catch-clause:
    new-lines~opt~ catch catch-type-list~opt~
    statement-block

catch-type-list:
    new-lines~opt~ type-literal
    catch-type-list new-lines~opt~, new-lines~opt~

```

```
type-literalfinally-clause:  
    new-lines~opt~ finally statement-block
```

Description:

The `try` statement provides a mechanism for catching exceptions that occur during execution of a block. The `try` statement also provides the ability to specify a block of code that is always executed when control leaves the `try` statement. The process of raising an exception via the `throw` statement is described in §8.5.3.

A *try block* is the *statement-block* associated with the `try` statement. A *catch block* is the *statement-block* associated with a *catch-clause*. A *finally block* is the *statement-block* associated with a *finally-clause*.

A *catch-clause* without a *catch-type-list* is called a *general catch clause*.

Each *catch-clause* is an *exception handler*, and a *catch-clause* whose *catch-type-list* contains the type of the raised exception is a *matching catch clause*. A general catch clause matches all exception types.

Although *catch-clauses* and *finally-clause* are optional, at least one of them must be present.

The processing of a thrown exception consists of evaluating the following steps repeatedly until a catch clause that matches the exception is found.

- In the current scope, each `try` statement that encloses the throw point is examined. For each `try` statement *S*, starting with the innermost `try` statement and ending with the outermost `try` statement, the following steps are evaluated:
 - If the `try` block of *S* encloses the throw point and if *S* has one or more catch clauses, the catch clauses are examined in lexical order to locate a suitable handler for the exception. The first catch clause that specifies the exception type or a base type of the exception type is considered a match. A general catch clause is considered a match for any exception type. If a matching catch clause is located, the exception processing is completed by transferring control to the block of that catch clause. Within a matching catch clause, the variable `$_` contains a description of the current exception.
 - Otherwise, if the `try` block or a `catch` block of *S* encloses the throw point and if *S* has a `finally` block, control is transferred to the `finally` block. If the `finally` block throws another exception, processing of the current exception is terminated. Otherwise, when control reaches the end of the `finally` block, processing of the current exception is continued.

- If an exception handler was not located in the current scope, the steps above are then repeated for the enclosing scope with a throw point corresponding to the statement from which the current scope was invoked.
- If the exception processing ends up terminating all scopes, indicating that no handler exists for the exception, then the behavior is unspecified.

To prevent unreachable catch clauses in a try block, a catch clause may not specify an exception type that is equal to or derived from a type that was specified in an earlier catch clause within that same try block.

The statements of a `finally` block are always executed when control leaves a `try` statement. This is true whether the control transfer occurs as a result of normal execution, as a result of executing a `break`, `continue`, or `return` statement, or as a result of an exception being thrown out of the `try` statement.

If an exception is thrown during execution of a `finally` block, the exception is thrown out to the next enclosing `try` statement. If another exception was in the process of being handled, that exception is lost. The process of generating an exception is further discussed in the description of the `throw` statement.

`try` statements can co-exist with `trap` statements; see §8.8 for details.

Examples:

```
PowerShell

$a = New-Object 'int[]' 10
$i = 20 # out-of-bounds subscript

while ($true) {
    try {
        $a[$i] = 10
        "Assignment completed without error"
        break
    }

    catch [IndexOutOfRangeException] {
        "Handling out-of-bounds index, >$_<`n"
        $i = 5
    }

    catch {
        "Caught unexpected exception"
    }

    finally {
        # ...
    }
}
```

```
    }  
}
```

Each exception thrown is raised as a `System.Management.Automation.RuntimeException`. If there are type-specific *catch-clauses* in the `try` block, the `InnerException` property of the exception is inspected to try and find a match, such as with the type `System.IndexOutOfRangeException` above.

8.8 The trap statement

Syntax:

Syntax

```
trap-statement:  
*trap* new-lines~opt~ type-literal~opt~ new-lines~opt~ statement-block
```

Description:

A `trap` statement with and without *type-literal* is analogous to a `catch` block ([§8.7](#)) with and without *catch-type-list*, respectively, except that a `trap` statement can trap only one type at a time.

Multiple `trap` statements can be defined in the same *statement-block*, and their order of definition is irrelevant. If two `trap` statements with the same *type-literal* are defined in the same scope, the lexically first one is used to process an exception of matching type.

Unlike a `catch` block, a `trap` statement matches an exception type exactly; no derived type matching is performed.

When an exception occurs, if no matching `trap` statement is present in the current scope, a matching trap statement is searched for in the enclosing scope, which may involve looking in the calling script, function, or filter, and then in its caller, and so on. If the lookup ends up terminating all scopes, indicating that no handler exists for the exception, then the behavior is unspecified.

A `trap` statement's *statement-body* only executes to process the corresponding exception; otherwise, execution passes over it.

If a `trap`'s *statement-body* exits normally, by default, an error object is written to the error stream, the exception is considered handled, and execution continues with the statement immediately following the one in the scope containing the `trap` statement

that made the exception visible. The cause of the exception might be in a command called by the command containing the `trap` statement.

If the final statement executed in a `trap`'s *statement-body* is `continue` ([§8.5.2](#)), the writing of the error object to the error stream is suppressed, and execution continues with the statement immediately following the one in the scope containing the `trap` statement that made the exception visible. If the final statement executed in a `trap`'s *statement-body* is `break` ([§8.5.1](#)), the writing of the error object to the error stream is suppressed, and the exception is re-thrown.

Within a `trap` statement the variable `$_` contains a description of the current error.

Consider the case in which an exception raised from within a `try` block does not have a matching `catch` block, but a matching `trap` statement exists at a higher block level. After the `try` block's `finally` clause is executed, the `trap` statement gets control even if any parent scope has a matching `catch` block. If a `trap` statement is defined within the `try` block itself, and that `try` block has a matching `catch` block, the `trap` statement gets control.

Examples:

In the following example, the error object is written and execution continues with the statement immediately following the one that caused the trap; that is, "Done" is written to the pipeline.

```
PowerShell  
  
$j = 0; $v = 10/$j; "Done"  
trap { $j = 2 }
```

In the following example, the writing of the error object is suppressed and execution continues with the statement immediately following the one that caused the trap; that is, "Done" is written to the pipeline.

```
PowerShell  
  
$j = 0; $v = 10/$j; "Done"  
trap { $j = 2; continue }
```

In the following example, the writing of the error object is suppressed and the exception is re-thrown.

```
PowerShell
```

```
$j = 0; $v = 10/$j; "Done"  
trap { $j = 2; break }
```

In the following example, the trap and exception-generating statements are in the same scope. After the exception is caught and handled, execution resumes with writing 1 to the pipeline.

PowerShell

```
&{trap{}; throw '\...'; 1}
```

In the following example, the trap and exception-generating statements are in different scopes. After the exception is caught and handled, execution resumes with writing 2 (not 1) to the pipeline.

PowerShell

```
trap{} &{throw '\...'; 1}; 2
```

8.9 The data statement

Syntax:

Syntax

```
data-statement:  
    data new-lines~opt~ data-name data-commands-allowed~opt~ statement-block  
  
data-name:  
    simple-name  
  
data-commands-allowed:  
    new-lines~opt~ -SupportedCommand data-commands-list  
  
data-commands-list:  
    new-lines~opt~ data-command  
    data-commands-list , new-lines~opt~ data-command  
  
data-command:  
    command-name-expr
```

Description:

A data statement creates a *data section*, keeping that section's data separate from the code. This separation supports facilities like separate string resource files for text, such as error messages and Help strings. It also helps support internationalization by making it easier to isolate, locate, and process strings that will be translated into different languages.

A script or function can have zero or more data sections.

The *statement-block* of a data section is limited to containing the following PowerShell features only:

- All operators except `-match`
- The `if` statement
- The following automatic variables: `$PSCulture`, `$PSUICulture`, `$true`, `$false`, and `$null`.
- Comments
- Pipelines
- Statements separated by semicolons (`;`)
- Literals
- Calls to the [ConvertFrom-StringData](#) cmdlet
- Any other cmdlets identified via the **SupportedCommand** parameter

If the `ConvertFrom-StringData` cmdlet is used, the key/value pairs can be expressed using any form of string literal. However, *expandable-string-literals* and *expandable-here-string-literals* must not contain any variable substitutions or sub-expression expansions.

Examples:

The **SupportedCommand** parameter indicates that the given cmdlets or functions generate data only. For example, the following data section includes a user-written cmdlet, `ConvertTo-Xml`, which formats data in an XML file:

PowerShell

```
data -SupportedCommand ConvertTo-Xml {
    Format-Xml -Strings string1, string2, string3
}
```

Consider the following example, in which the data section contains a `ConvertFrom-StringData` command that converts the strings into a hash table, whose value is assigned to `$messages`.

PowerShell

```
$messages = data {
    ConvertFrom-StringData -StringData @"
    Greeting = Hello
    Yes = yes
    No = no
'@
}
```

The keys and values of the hash table are accessed using `$messages.Greeting`, `$messages.Yes`, and `$messages.No`, respectively.

Now, this can be saved as an English-language resource. German- and Spanish-language resources can be created in separate files, with the following data sections:

PowerShell

```
$messages = data {
    ConvertFrom-StringData -StringData @@
    Greeting = Guten Tag
    Yes = ja
    No = nein
"@
}

$messagesS = data {
    ConvertFrom-StringData -StringData @@
    Greeting = Buenos días
    Yes = sí
    No = no
"@
}
```

If *dataname* is present, it names the variable (without using a leading \$) into which the value of the data statement is to be stored. Specifically, `$name = data { ... }` is equivalent to `data name { ... }`.

8.10 Function definitions

Syntax:

Syntax

```
function-statement:
    function new-lines~opt~ function-name function-parameter-
declaration~opt~ { script-block }
```

```

    filter new-lines~opt~ function-name function-parameter-declaration~opt~
{ script-block }
    workflow new-lines~opt~ function-name function-parameter-
declaration~opt~ { script-block }

function-name:
    command-argument

command-argument:
    command-name-expr

function-parameter-declaration:
    new-lines~opt~ ( parameter-list new-lines~opt~ )

parameter-list:
    script-parameter
    parameter-list new-lines~opt~ , script-parameter

script-parameter:
    new-lines~opt~ attribute-list~opt~ new-lines~opt~ variable script-
parameter-default~opt~

script-block:
    param-block~opt~ statement-terminators~opt~ script-block-body~opt~

param-block:
    new-lines~opt~ attribute-list~opt~ new-lines~opt~ param new-lines~opt~
    ( parameter-list~opt~ new-lines~opt~ )

parameter-list:
    script-parameter
    parameter-list new-lines~opt~ , script-parameter

script-parameter-default:
    new-lines~opt~ = new-lines~opt~ expression

script-block-body:
    named-block-list
    statement-list

named-block-list:
    named-block
    named-block-list named-block

named-block:
    block-name statement-block statement-terminators~opt~

block-name: one of
    dynamicparam    begin    process    end

```

Description:

A *function definition* specifies the name of the function, filter, or workflow being defined and the names of its parameters, if any. It also contains zero or more statements that are executed to achieve that function's purpose.

Each function is an instance of the class `System.Management.Automation.FunctionInfo`.

8.10.1 Filter functions

Whereas an ordinary function runs once in a pipeline and accesses the input collection via `$input`, a *filter* is a special kind of function that executes once for each object in the input collection. The object currently being processed is available via the variable `$_`.

A filter with no named blocks ([§8.10.7](#)) is equivalent to a function with a process block, but without any begin block or end block.

Consider the following filter function definition and calls:

```
PowerShell

filter Get-Square2 { # make the function a filter
    $_ * $_ # access current object from the collection
}

-3..3 | Get-Square2 # collection has 7 elements
6, 10, -3 | Get-Square2 # collection has 3 elements
```

Each filter is an instance of the class `System.Management.Automation.FilterInfo` ([§4.5.11](#)).

8.10.2 Workflow functions

A workflow function is like an ordinary function with implementation defined semantics. A workflow function is translated to a sequence of Windows Workflow Foundation activities and executed in the Windows Workflow Foundation engine.

8.10.3 Argument processing

Consider the following definition for a function called `Get-Power`:

```
PowerShell

function Get-Power ([long]$Base, [int]$Exponent) {
    $result = 1
    for ($i = 1; $i -le $Exponent; ++$i) {
        $result *= $Base
```

```
    }
    return $result
}
```

This function has two parameters, `$Base` and `$Exponent`. It also contains a set of statements that, for non-negative exponent values, computes `$Base^$Exponent^` and returns the result to `Get-Power`'s caller.

When a script, function, or filter begins execution, each parameter is initialized to its corresponding argument's value. If there is no corresponding argument and a default value ([§8.10.4](#)) is supplied, that value is used; otherwise, the value `$null` is used. As such, each parameter is a new variable just as if it was initialized by assignment at the start of the *script-block*.

If a *script-parameter* contains a type constraint (such as `[long]` and `[int]` above), the value of the corresponding argument is converted to that type, if necessary; otherwise, no conversion occurs.

When a script, function, or filter begins execution, variable `$args` is defined inside it as an unconstrained 1-dimensional array, which contains all arguments not bound by name or position, in lexical order.

Consider the following function definition and calls:

PowerShell

```
function F ($a, $b, $c, $d) { ... }

F -b 3 -d 5 2 4      # $a is 2, $b is 3, $c is 4, $d is 5, $args Length 0
F -a 2 -d 3 4 5      # $a is 2, $b is 4, $c is 5, $d is 3, $args Length 0
F 2 3 4 5 -c 7 -a 1  # $a is 1, $b is 2, $c is 7, $d is 3, $args Length 2
```

For more information about parameter binding see [§8.14](#).

8.10.4 Parameter initializers

The declaration of a parameter *p* may contain an initializer, in which case, that initializer's value is used to initialize *p* provided *p* is not bound to any arguments in the call.

Consider the following function definition and calls:

PowerShell

```
function Find-Str ([string]$Str, [int]$StartPos = 0) { ... }

Find-Str "abcabc" # 2nd argument omitted, 0 used for $StartPos
Find-Str "abcabc" 2 # 2nd argument present, so it is used for $StartPos
```

8.10.5 The [switch] type constraint

When a switch parameter is passed, the corresponding parameter in the command must be constrained by the type switch. Type switch has two values, True and False.

Consider the following function definition and calls:

PowerShell

```
function Process ([switch]$Trace, $P1, $P2) { ... }

Process 10 20          # $Trace is False, $P1 is 10, $P2 is 20
Process 10 -Trace 20    # $Trace is True, $P1 is 10, $P2 is 20
Process 10 20 -Trace    # $Trace is True, $P1 is 10, $P2 is 20
Process 10 20 -Trace:$false # $Trace is False, $P1 is 10, $P2 is 20
Process 10 20 -Trace:$true  # $Trace is True, $P1 is 10, $P2 is 20
```

8.10.6 Pipelines and functions

When a script, function, or filter is used in a pipeline, a collection of values is delivered to that script or function. The script, function, or filter gets access to that collection via the enumerator \$input ([\\$2.3.2.2](#), [\\$4.5.16](#)), which is defined on entry to that script, function, or filter.

Consider the following function definition and calls:

PowerShell

```
function Get-Square1 {
    foreach ($i in $input) {    # iterate over the collection
        $i * $i
    }
}

-3..3 | Get-Square1          # collection has 7 elements
6, 10, -3 | Get-Square1      # collection has 3 elements
```

8.10.7 Named blocks

The statements within a *script-block* can belong to one large unnamed block, or they can be distributed into one or more named blocks. Named blocks allow custom processing of collections coming from pipelines; named blocks can be defined in any order.

The statements in a *begin block* (i.e.; one marked with the keyword begin) are executed once, before the first pipeline object is delivered.

The statements in a *process block* (i.e.; one marked with the keyword process) are executed for each pipeline object delivered. (`$_` provides access to the current object being processed from the input collection coming from the pipeline.) This means that if a collection of zero elements is sent via the pipeline, the process block is not executed at all. However, if the script or function is called outside a pipeline context, this block is executed exactly once, and `$_` is set to `$null`, as there is no current collection object.

The statements in an *end block* (i.e.; one marked with the keyword end) are executed once, after the last pipeline object has been delivered.

8.10.8 dynamicparam block

The subsections of [§8.10](#) thus far deal with *static parameters*, which are defined as part of the source code. It is also possible to define *dynamic parameters* via a *dynamicparam block*, another form of named block ([§8.10.7](#)), which is marked with the keyword `dynamicparam`. Much of this machinery is implementation defined.

Dynamic parameters are parameters of a cmdlet, function, filter, or script that are available under certain conditions only. One such case is the **Encoding** parameter of the `Set-Item` cmdlet.

In the *statement-block*, use an if statement to specify the conditions under which the parameter is available in the function. Use the `New-Object` cmdlet to create an object of an implementation-defined type to represent the parameter, and specify its name. Also, use `New-Object` to create an object of a different implementation-defined type to represent the implementation-defined attributes of the parameter.

The following example shows a function with standard parameters called `Name` and `Path`, and an optional dynamic parameter named `DP1`. The `DP1` parameter is in the `PSet1` parameter set and has a type of `Int32`. The `DP1` parameter is available in the `Sample` function only when the value of the `Path` parameter contains "HKLM:", indicating that it is being used in the `HKEY_LOCAL_MACHINE` registry drive.

```

function Sample {
    param ([string]$Name, [string]$Path)
    dynamicparam {
        if ($Path -match "*HKLM*:") {
            $dynParam1 = New-Object
            System.Management.Automation.RuntimeDefinedParameter("dp1", [int32],
$attributeCollection)

            $attributes = New-Object
            System.Management.Automation.ParameterAttribute
                $attributes.ParameterSetName = 'pset1'
                $attributes.Mandatory = $false

                $attributeCollection = New-Object -Type
            System.Collections.ObjectModel.Collection`1[System.Attribute]
                $attributeCollection.Add($attributes)

                $paramDictionary = New-Object
            System.Management.Automation.RuntimeDefinedParameterDictionary
                $paramDictionary.Add("dp1", $dynParam1)
                return $paramDictionary
        }
    }
}

```

The type used to create an object to represent a dynamic parameter is

`System.Management.Automation.RuntimeDefinedParameter`.

The type used to create an object to represent the attributes of the parameter is

`System.Management.Automation.ParameterAttribute`.

The implementation-defined attributes of the parameter include **Mandatory**, **Position**, and **ValueFromPipeline**.

8.10.9 param block

A *param-block* provides an alternate way of declaring parameters. For example, the following sets of parameter declarations are equivalent:

PowerShell

```

function FindStr1 ([string]$Str, [int]$StartPos = 0) { ... }
function FindStr2 {
    param ([string]$Str, [int]$StartPos = 0) ...
}

```

A *param-block* allows an *attribute-list* on the *param-block* whereas a *function-parameter-declaration* does not.

A script may have a *param-block* but not a *function-parameter-declaration*. A function or filter definition may have a *function-parameter-declaration* or a *param-block*, but not both.

Consider the following example:

PowerShell

```
param ( [Parameter(Mandatory = $true, ValueFromPipeline=$true)]
      [string[]] $ComputerName )
```

The one parameter, `$ComputerName`, has type `string[]`, it is required, and it takes input from the pipeline.

See [§12.3.7](#) for a discussion of the **Parameter** attribute and for more examples.

8.11 The parallel statement

Syntax:

Syntax

```
parallel-statement:
  *parallel* statement-block
```

The parallel statement contains zero or more statements that are executed in an implementation defined manner.

A parallel statement is only allowed in a workflow ([§8.10.2](#)).

8.12 The sequence statement

Syntax:

Syntax

```
sequence-statement:
  *sequence* statement-block
```

The sequence statement contains zero or more statements that are executed in an implementation defined manner.

A sequence statement is only allowed in a workflow ([§8.10.2](#)).

8.13 The inlinescript statement

Syntax:

```
Syntax  
  
inlinescript-statement:  
    inlinescript statement-block
```

The inlinescript statement contains zero or more statements that are executed in an implementation defined manner.

An inlinescript statement is only allowed in a workflow ([§8.10.2](#)).

8.14 Parameter binding

When a script, function, filter, or cmdlet is invoked, each argument can be bound to the corresponding parameter by position, with the first parameter having position zero.

Consider the following definition fragment for a function called `Get-Power`, and the calls to it:

```
PowerShell  
  
function Get-Power ([long]$Base, [int]$Exponent) { ... }  
  
Get-Power 5 3      # argument 5 is bound to parameter $Base in position 0  
                  # argument 3 is bound to parameter $Exponent in position  
1  
                  # no conversion is needed, and the result is 5 to the  
power 3  
  
Get-Power 4.7 3.2  # double argument 4.7 is rounded to int 5, double  
argument          # 3.2 is rounded to int 3, and result is 5 to the power  
3  
  
Get-Power 5        # $Exponent has value $null, which is converted to int 0  
  
Get-Power          # both parameters have value $null, which is converted  
to int 0
```

When a script, function, filter, or cmdlet is invoked, an argument can be bound to the corresponding parameter by name. This is done by using a *parameter with argument*, which is an argument that is the parameter's name with a leading dash (-), followed by the associated value for that argument. The parameter name used can have any case-insensitive spelling and can use any prefix that uniquely designates the corresponding parameter. When choosing parameter names, avoid using the names of the [common parameters](#).

Consider the following calls to function `Get-Power`:

```
PowerShell

Get-Power -Base 5 -Exponent 3 # -Base designates $Base, so 5 is
                                # bound to that, -Exponent designates
                                # $Exponent, so 3 is bound to that

Get-Power -Exp 3 -Bas 5          # $Base takes on 5 and $Exponent takes on 3

Get-Power -E 3 -B 5            # $Base takes on 5 and $Exponent takes on 3
```

On the other hand, calls to the following function

```
PowerShell

function Get-Hypot ([double]$Side1, [double]$Side2) {
    return [Math]::Sqrt($Side1 * $Side1 + $Side2 * $Side2)
}
```

must use parameters `-Side1` and `-Side2`, as there is no prefix that uniquely designates the parameter.

The same parameter name cannot be used multiple times with or without different associated argument values.

Parameters can have attributes (§12). For information about the individual attributes see the sections within [§12.3](#). For information about parameter sets see [§12.3.7](#).

A script, function, filter, or cmdlet can receive arguments via the invocation command line, from the pipeline, or from both. Here are the steps, in order, for resolving parameter binding:

1. Bind all named parameters, then
2. Bind positional parameters, then
3. Bind from the pipeline by value ([§12.3.7](#)) with exact match, then
4. Bind from the pipeline by value ([§12.3.7](#)) with conversion, then

5. Bind from the pipeline by name ([§12.3.7](#)) with exact match, then
6. Bind from the pipeline by name ([§12.3.7](#)) with conversion

Several of these steps involve conversion, as described in [§6](#). However, the set of conversions used in binding is not exactly the same as that used in language conversions. Specifically,

- Although the value `$null` can be cast to `bool`, `$null` cannot be bound to `bool`.
- When the value `$null` is passed to a switch parameter for a cmdlet, it is treated as if `$true` was passed. However, when passed to a switch parameter for a function, it is treated as if `$false` was passed.
- Parameters of type `bool` or `switch` can only bind to numeric or `bool` arguments.
- If the parameter type is not a collection, but the argument is some sort of collection, no conversion is attempted unless the parameter type is `object` or `PsObject`. (The main point of this restriction is to disallow converting a collection to a string parameter.) Otherwise, the usual conversions are attempted.

If the parameter type is `IList` or `ICollection<T>`, only those conversions via `Constructor`, `op_Implicit`, and `op_Explicit` are attempted. If no such conversions exist, a special conversion for parameters of "collection" type is used, which includes `IList`, `ICollection<T>`, and arrays.

Positional parameters prefer to be bound without type conversion, if possible. For example,

PowerShell

```
function Test {
    [CmdletBinding(DefaultParameterSetName = "SetB")]
    param([Parameter(Position = 0, ParameterSetName = "SetA")]
        [decimal]$Dec,
        [Parameter(Position = 0, ParameterSetName = "SetB")]
        [int]$In
    )
    $PSCmdlet.ParameterSetName
}

Test 42d # outputs "SetA"
Test 42 # outputs "SetB"
```

9. Arrays

Article • 01/08/2025

Editorial note

Important

The *Windows PowerShell Language Specification 3.0* was published in December 2012 and is based on Windows PowerShell 3.0. This specification does not reflect the current state of PowerShell. There is no plan to update this documentation to reflect the current state. This documentation is presented here for historical reference.

The specification document is available as a Microsoft Word document from the Microsoft Download Center at:

<https://www.microsoft.com/download/details.aspx?id=36389> That Word document has been converted for presentation here on Microsoft Learn. During conversion, some editorial changes have been made to accommodate formatting for the Docs platform. Some typos and minor errors have been corrected.

9.1 Introduction

PowerShell supports arrays of one or more dimensions with each dimension having zero or more *elements*. Within a dimension, elements are numbered in ascending integer order starting at zero. Any individual element can be accessed via the array subscript operator `[]` ([§7.1.4](#)). The number of dimensions in an array is called its *rank*.

An element can contain a value of any type including an array type. An array having one or more elements whose values are of any array type is called a *jagged array*. A *multidimensional array* has multiple dimensions, in which case, the number of elements in each row of a dimension is the same. An element of a jagged array may contain a multidimensional array, and vice versa.

Multidimensional arrays are stored in row-major order. The number of elements in an array is called that array's *length*, which is fixed when the array is created. As such, the elements in a 1-dimensional array *A* having length *N* can be accessed (i.e., *subscripted*) using the expressions `A[0], A[1], ..., A[N-1]`. The elements in a 2-dimensional array *B* having *M* rows, with each row having *N* columns, can be accessed using the expressions

`B[0,0], B[0,1], ..., B[0,N-1], B[1,0], B[1,1], ..., B[1,N-1], ..., B[M-1,0], B[M-1,1], ..., B[M-1,N-1]`. And so on for arrays with three or more dimensions.

By default, an array is *polymorphic*; i.e., its elements do not need to all have the same type. For example,

PowerShell

```
$items = 10, "blue", 12.54e3, 16.30D # 1-D array of length 4
$items[1] = -2.345
$items[2] = "green"

$a = New-Object 'object[,]' 2,2 # 2-D array of length 4
$a[0,0] = 10
$a[0,1] = $false
$a[1,0] = "red"
$a[1,1] = $null
```

A 1-dimensional array has type `type[]`, a 2-dimensional array has type `type[,]`, a 3-dimensional array has type `type[,,]`, and so on, where `type` is `object` for an unconstrained type array, or the constrained type for a constrained array ([§9.4](#)).

All array types are derived from the type `Array` ([§4.3.2](#)).

9.2 Array creation

An array is created via an *array creation expression*, which has the following forms: unary comma operator ([§7.2.1](#)), *array-expression* ([§7.1.7](#)), binary comma operator ([§7.3](#)), range operator ([§7.4](#)), or `New-Object` cmdlet.

Here are some examples of array creation and usage:

PowerShell

```
$values = 10, 20, 30
for ($i = 0; $i -lt $values.Length; ++$i) {
    "$values[$i] = $($values[$i])"
}

$x = , 10                                # x refers to an array of length 1
$x = @(10)                                 # x refers to an array of length 1
$x = @()                                    # x refers to an array of length 0

$a = New-Object 'object[,]' 2, 2 # create a 2x2 array of anything
$a[0, 0] = 10                            # set to an int value
$a[0, 1] = $false                          # set to a boolean value
$a[1, 0] = "red"                           # set to a string value
$a[1, 1] = 10.50D                         # set to a decimal value
```

```
foreach ($e in $a) {                      # enumerate over the whole array
    $e
}
```

The following is written to the pipeline:

Output

```
$values[0] = 10
$values[1] = 20
$values[2] = 30

10
False
red
10.50
```

The default initial value of any element not explicitly initialized is the default value for that element's type (that is, `$false`, zero, or `$null`).

9.3 Array concatenation

Arrays of arbitrary type and length can be concatenated via the `+` and `+=` operators, both of which result in the creation of a new unconstrained 1-dimensional array. The existing arrays are unchanged. See [§7.7.3](#) for more information, and [§9.4](#) for a discussion of adding to an array of constrained type.

9.4 Constraining element types

A 1-dimensional array can be created so that it is type-constrained by prefixing the array-creation expression with an array type cast. For example,

PowerShell

```
$a = [int[]](1,2,3,4)      # constrained to int
$a[1] = "abc"              # implementation-defined behavior
$a += 1.23                 # new array is unconstrained
```

The syntax for creating a multidimensional array requires the specification of a type, and that type becomes the constraint type for that array. However, by specifying type `object[]`, there really is no constraint as a value of any type can be assigned to an element of an array of that type.

Concatenating two arrays ([§7.7.3](#)) always results in a new array that is unconstrained even if both arrays are constrained by the same type. For example,

PowerShell

```
$a = [int[]](1,2,3)      # constrained to int
$b = [int[]](10,20)      # constrained to int
$c = $a + $b            # constraint not preserved
$c = [int[]]($a + $b)    # result explicitly constrained to int
```

9.5 Arrays as reference types

As array types are reference types, a variable designating an array can be made to refer to any array of any rank, length, and element type. For example,

PowerShell

```
$a = 10,20                  # $a refers to an array of length 2
$a = 10,20,30                # $a refers to a different array, of length 3
$a = "red",10.6              # $a refers to a different array, of length 2
$a = New-Object 'int[,]' 2,3  # $a refers to an array of rank 2
```

Assignment of an array involves a shallow copy; that is, the variable assigned to refers to the same array, no copy of the array is made. For example,

PowerShell

```
$a = 10,20,30
">$a<"                   # $a is a reference to an array of length 3
$b = $a                     # make $b refer to the same array as $a
">$b<"                   # $b is a reference to the same array as $a

$a[0] = 6                  # change value of [0] via $a
">$a<"                   # $a is still a reference to the same array
">$b<"                   # change is reflected in $b

$b += 40                  # make $b refer to a new array
$a[0] = 8                  # change value of [0] via $a
">$a<"                   # $a is still a reference to the same array
">$b<"                   # change is not reflected in $b
```

The following is written to the pipeline:

Output

```
>10 20 30<
>10 20 30<
```

```
>6 20 30<
>6 20 30<
>8 20 30<
>6 20 30 40<
```

9.6 Arrays as array elements

Any element of an array can itself be an array. For example,

PowerShell

```
$colors = "red", "blue", "green"
$list = $colors, (,7), (1.2, "yes") # parens in (,7) are redundant; they
                                    # are intended to aid readability
``$list refers to an array of length $($list.Length)``
">$($list[1][0])<"
```

The following is written to the pipeline:

Output

```
$list refers to an array of length 3
>7<
>yes<
```

`$list[1]` refers to an array of 1 element, the integer 7, which is accessed via `$list[1][0]`, as shown. Compare this with the following subtly different case:

PowerShell

```
$list = $colors, 7, (1.2, "yes") # 7 has no prefix comma
">$($list[1])<"
```

Here, `$list[1]` refers to a scalar, the integer 7, which is accessed via `$list[1]`.

Consider the following example,

PowerShell

```
$x = [string[]]("red", "green")
$y = 12.5, $true, "blue"
$a = New-Object 'object[,]' 2,2
$a[0,0] = $x                      # element is an array of 2 strings
$a[0,1] = 20                        # element is an int
```

```
$a[1,0] = $y          # element is an array of 3 objects
$a[1,1] = [int[]](92,93)  # element is an array of 2 ints
```

9.7 Negative subscripting

This is discussed in [§7.1.4.1](#).

9.8 Bounds checking

This is discussed in [§7.1.4.1](#).

9.9 Array slices

An *array slice* is an unconstrained 1-dimensional array whose elements are copies of zero or more elements from a collection. An array slice is created via the subscript operator `[]` ([§7.1.4.5](#)).

9.10 Copying an array

A contiguous set of elements can be copied from one array to another using the method `[array]::Copy`. For example,

PowerShell

```
$a = [int[]](10,20,30)
$b = [int[]](0,1,2,3,4,5)
[array]::Copy($a, $b, 2)      # $a[0]->$b[0],
$a[1]->$b[1]
[array]::Copy($a, 1, $b, 3, 2) # $a[1]->$b[3],
$a[2]->$b[4]
```

9.11 Enumerating over an array

Although it is possible to loop through an array accessing each of its elements via the subscript operator, we can enumerate over that array's elements using the `foreach` statement. For a multidimensional array, the elements are processed in row-major order. For example,

PowerShell

```

$a = 10, 53, 16, -43
foreach ($elem in $a) {
    # do something with element via $elem
}

foreach ($elem in -5..5) {
    # do something with element via $elem
}

$a = New-Object 'int[,]' 3, 2
foreach ($elem in $a) {
    # do something with element via $elem
}

```

9.12 Multidimensional array flattening

Some operations on a multidimensional array (such as replication ([§7.6.3](#)) and concatenation ([§7.7.3](#))) require that array to be *flattened*; that is, to be turned into a 1-dimensional array of unconstrained type. The resulting array takes on all the elements in row-major order.

Consider the following example:

PowerShell

```

$a = "red",$true
$b = (New-Object 'int[,]' 2,2)
$b[0,0] = 10
$b[0,1] = 20
$b[1,0] = 30
$b[1,1] = 40
$c = $a + $b

```

The array designated by `$c` contains the elements "red", `$true`, 10, 20, 30, and 40.

10. Hashtables

key-expression:  
    simple-name  
    unary-expression
```

```
statement-terminator:  
;  
new-line-character
```

10.1 Introduction

The type `Hashtable` represents a collection of *key/value pair* objects that supports efficient retrieval of a value when indexed by the key. Each key/value pair is an *element*, which is stored in some implementation-defined object type.

An element's key cannot be the null value. There are no restrictions on the type of a key or value. Duplicate keys are not supported.

Given a key/value pair object, the key and associated value can be obtained by using the instance properties `Key` and `Value`, respectively.

Given one or more keys, the corresponding value(s) can be accessed via the `Hashtable` subscript operator `[]` ([§7.1.4.3](#)).

All `Hashtables` have type `Hashtable` ([§4.3.3](#)).

The order of the keys in the collection returned by `Keys` is unspecified; however, it is the same order as the associated values in the collection returned by `Values`.

Here are some examples involving `Hashtables`:

PowerShell

```
$h1 = @{ FirstName = "James"; LastName = "Anderson"; IDNum = 123 }  
$h1.FirstName # designates the key FirstName  
$h1["LastName"] # designates the associated value for key LastName  
$h1.Keys # gets the collection of keys
```

`Hashtable` elements are stored in an object of type `DictionaryEntry`, and the collections returned by `Keys` and `Values` have type `ICollection`.

10.2 Hashtable creation

A `Hashtable` is created via a hash literal ([§7.1.9](#)) or the `New-Object` cmdlet. It can be created with zero or more elements. The `Count` property returns the current element count.

10.3 Adding and removing Hashtable elements

An element can be added to a `Hashtable` by assigning ([\\$7.11.1](#)) a value to a non-existent key name or to a subscript ([\\$7.1.4.3](#)) that uses a non-existent key name. Removal of an element requires the use of the `Remove` method. For example,

PowerShell

```
$h1 = @{ FirstName = "James"; LastName = "Anderson"; IDNum = 123 }
$h1.Dept = "Finance" # adds element Finance
$h1["Salaried"] = $false # adds element Salaried
$h1.Remove("Salaried") # removes element Salaried
```

10.4 Hashtable concatenation

Hashtables can be concatenated via the `+` and `+=` operators, both of which result in the creation of a new `Hashtable`. The existing Hashtables are unchanged. See [\\$7.7.4](#) for more information.

10.5 Hashtables as reference types

As `Hashtable` is a reference type, assignment of a `Hashtable` involves a shallow copy; that is, the variable assigned to refers to the same `Hashtable`; no copy of the `Hashtable` is made. For example,

PowerShell

```
$h1 = @{ FirstName = "James"; LastName = "Anderson"; IDNum = 123 }
$h2 = $h1
$h1.FirstName = "John" # change key's value in $h1
$h2.FirstName # change is reflected in $h2
```

10.6 Enumerating over a Hashtable

To process every pair in a `Hashtable`, use the `Keys` property to retrieve the list of keys as an array, and then enumerate over the elements of that array getting the associated value via the `Value` property or a subscript, as follows

PowerShell

```
$h1 = @{ FirstName = "James"; LastName = "Anderson"; IDNum = 123}
foreach ($e in $h1.Keys) {
    "Key is " + $e + ", Value is " + $h1[$e]
}
```

11. Modules

Article • 01/08/2025

Editorial note

Important

The *Windows PowerShell Language Specification 3.0* was published in December 2012 and is based on Windows PowerShell 3.0. This specification does not reflect the current state of PowerShell. There is no plan to update this documentation to reflect the current state. This documentation is presented here for historical reference.

The specification document is available as a Microsoft Word document from the Microsoft Download Center at:

<https://www.microsoft.com/download/details.aspx?id=36389> That Word document has been converted for presentation here on Microsoft Learn. During conversion, some editorial changes have been made to accommodate formatting for the Docs platform. Some typos and minor errors have been corrected.

11.1 Introduction

As stated in §3.14, a module is a self-contained reusable unit that allows PowerShell code to be partitioned, organized, and abstracted. A module can contain one or more *module members*, which are commands (such as cmdlets and functions) and items (such as variables and aliases). The names of these members can be kept private to the module or they may be *exported* to the session into which the module is *imported*.

There are three different *module types*: manifest, script, and binary. A *manifest module* is a file that contains information about a module, and controls certain aspects of that module's use. A *script module* is a PowerShell script file with a file extension of `.psm1` instead of `.ps1`. A *binary module* contains class types that define cmdlets and providers. Unlike script modules, binary modules are written in compiled languages. Binary modules are not covered by this specification.

A binary module is a .NET assembly (i.e.; a DLL) that was compiled against the PowerShell libraries.

Modules may *nest*; that is, one module may import another module. A module that has associated nested modules is a *root module*.

When a PowerShell session is created, by default, no modules are imported.

When modules are imported, the search path used to locate them is defined by the environment variable **PSModulePath**.

The following cmdlets deal with modules:

- [Get-Module](#): Identifies the modules that have been, or can be imported
- [Import-Module](#): Adds one or more modules to the current session (see [§11.4](#))
- [Export-ModuleMember](#): Identifies the module members that are to be exported
- [Remove-Module](#): Removes one or more modules from the current session (see [§11.5](#))
- [New-Module](#): Creates a dynamic module (see [§11.7](#))

11.2 Writing a script module

A script module is a script file. Consider the following script module:

```
PowerShell

function Convert-CentigradeToFahrenheit ([double]$tempC) {
    return ($tempC * (9.0 / 5.0)) + 32.0
}
New-Alias c2f Convert-CentigradeToFahrenheit

function Convert-FahrenheitToCentigrade ([double]$tempF) {
    return ($tempF - 32.0) * (5.0 / 9.0)
}
New-Alias f2c Convert-FahrenheitToCentigrade

Export-ModuleMember -Function Convert-CentigradeToFahrenheit
Export-ModuleMember -Function Convert-FahrenheitToCentigrade
Export-ModuleMember -Alias c2f, f2c
```

This module contains two functions, each of which has an alias. By default, all function names, and only function names are exported. However, once the cmdlet `Export-ModuleMember` has been used to export anything, then only those things exported explicitly will be exported. A series of commands and items can be exported in one call or a number of calls to this cmdlet; such calls are cumulative for the current session.

11.3 Installing a script module

A script module is defined in a script file, and modules can be stored in any directory. The environment variable PSModulePath points to a set of directories to be searched when module-related cmdlets look for modules whose names do not include a fully qualified path. Additional lookup paths can be provided; for example,

```
$Env:PSModulePath = $Env:PSModulePath + ";<additional-path>"
```

Any additional paths added affect the current session only.

Alternatively, a fully qualified path can be specified when a module is imported.

11.4 Importing a script module

Before the resources in a module can be used, that module must be imported into the current session, using the cmdlet `Import-Module`. `Import-Module` can restrict the resources that it actually imports.

When a module is imported, its script file is executed. That process can be configured by defining one or more parameters in the script file, and passing in corresponding arguments via the `ArgumentList` parameter of `Import-Module`.

Consider the following script that uses these functions and aliases defined in §11.2:

```
Import-Module "E:\Scripts\Modules\PSTest_Temperature" -Verbose
```

PowerShell

```
"0 degrees C is " + (Convert-CentigradeToFahrenheit 0) + " degrees F"
"100 degrees C is " + (c2f 100) + " degrees F"
"32 degrees F is " + (Convert-FahrenheitToCentigrade 32) + " degrees C"
"212 degrees F is " + (f2c 212) + " degrees C"
```

Importing a module causes a name conflict when commands or items in the module have the same names as commands or items in the session. A name conflict results in a name being hidden or replaced. The `Prefix` parameter of `Import-Module` can be used to avoid naming conflicts. Also, the `Alias`, `Cmdlet`, `Function`, and `Variable` parameters can limit the selection of commands to be imported, thereby reducing the chances of name conflict.

Even if a command is hidden, it can be run by qualifying its name with the name of the module in which it originated. For example, `& M\F 100` invokes the function `F` in module `M`, and passes it the argument 100.

When the session includes commands of the same kind with the same name, such as two cmdlets with the same name, by default it runs the most recently added command.

See [§3.5.6](#) for a discussion of scope as it relates to modules.

11.5 Removing a script module

One or more modules can be removed from a session via the cmdlet `Remove-Module`.

Removing a module does not uninstall the module.

In a script module, it is possible to specify code that is to be executed prior to that module's removal, as follows:

```
$MyInvocation.MyCommand.ScriptBlock.Module.OnRemove = { *on-removal-code* }
```

11.6 Module manifests

As stated in [§11.1](#), a manifest module is a file that contains information about a module, and controls certain aspects of that module's use.

A module need not have a corresponding manifest, but if it does, that manifest has the same name as the module it describes, but with a `.psd1` file extension.

A manifest contains a limited subset of PowerShell script, which returns a Hashtable containing a set of keys. These keys and their values specify the *manifest elements* for that module. That is, they describe the contents and attributes of the module, define any prerequisites, and determine how the components are processed.

Essentially, a manifest is a data file; however, it can contain references to data types, the if statement, and the arithmetic and comparison operators. (Assignments, function definitions and loops are not permitted.) A manifest also has read access to environment variables and it can contain calls to the cmdlet `Join-Path`, so paths can be constructed.

ⓘ Note

Editor's Note: The original document contains a list of keys allowed in a module manifest file. That list is outdated and incomplete. For a complete list of keys in a module manifest, see [New-ModuleManifest](#).

The only key that is required is `ModuleVersion`.

Here is an example of a simple manifest:

PowerShell

```
@{
    ModuleVersion = '1.0'
    Author = 'John Doe'
    RequiredModules = @()
    FunctionsToExport = 'Set*', 'Get*', 'Process*'
}
```

The key **GUID** has a `string` value. This specifies a Globally Unique Identifier (GUID) for the module. The **GUID** can be used to distinguish among modules having the same name. To create a new GUID, call the method `[guid]::NewGuid()`.

11.7 Dynamic modules

A *dynamic module* is a module that is created in memory at runtime by the cmdlet `New-Module`; it is not loaded from disk. Consider the following example:

PowerShell

```
$sb = {
    function Convert-CentigradeToFahrenheit ([double]$tempC) {
        return ($tempC * (9.0 / 5.0)) + 32.0
    }

    New-Alias c2f Convert-CentigradeToFahrenheit

    function Convert-FahrenheitToCentigrade ([double]$tempF) {
        return ($tempF - 32.0) * (5.0 / 9.0)
    }

    New-Alias f2c Convert-FahrenheitToCentigrade

    Export-ModuleMember -Function Convert-CentigradeToFahrenheit
    Export-ModuleMember -Function Convert-FahrenheitToCentigrade
    Export-ModuleMember -Alias c2f, f2c
}

New-Module -Name MyDynMod -ScriptBlock $sb
Convert-CentigradeToFahrenheit 100
c2f 100
```

The script block `$sb` defines the contents of the module, in this case, two functions and two aliases to those functions. As with an on-disk module, only functions are exported

by default, so `Export-ModuleMember` cmdlets calls exist to export both the functions and the aliases.

Once `New-Module` runs, the four names exported are available for use in the session, as is shown by the calls to the `Convert-CentigradeToFahrenheit` and `c2f`.

Like all modules, the members of dynamic modules run in a private module scope that is a child of the global scope. `Get-Module` cannot get a dynamic module, but `Get-Command` can get the exported members.

To make a dynamic module available to `Get-Module`, pipe a `New-Module` command to `Import-Module`, or pipe the module object that `New-Module` returns, to `Import-Module`. This action adds the dynamic module to the `Get-Module` list, but it does not save the module to disk or make it persistent.

11.8 Closures

A dynamic module can be used to create a *closure*, a function with attached data. Consider the following example:

PowerShell

```
function Get-NextID ([int]$StartValue = 1) {
    $nextID = $StartValue
    {
        ($Script:nextID++)
    }.GetNewClosure()
}

$v1 = Get-NextID      # get a scriptblock with $StartValue of 0
& $v1                 # invoke Get-NextID getting back 1
& $v1                 # invoke Get-NextID getting back 2

$v2 = Get-NextID 100  # get a scriptblock with $StartValue of 100
& $v2                 # invoke Get-NextID getting back 100
& $v2                 # invoke Get-NextID getting back 101
```

The intent here is that `Get-NextID` return the next ID in a sequence whose start value can be specified. However, multiple sequences must be supported, each with its own `$StartValue` and `$nextID` context. This is achieved by the call to the method `[scriptblock]::GetNewClosure` ([\\$4.3.7](#)).

Each time a new closure is created by `GetNewClosure`, a new dynamic module is created, and the variables in the caller's scope (in this case, the script block containing the increment) are copied into this new module. To ensure that the `nextId` defined inside the

parent function (but outside the script block) is incremented, the explicit Script: scope prefix is needed.

Of course, the script block need not be a named function; for example:

PowerShell

```
$v3 = & {      # get a scriptblock with $StartValue of 200
    param ([int]$StartValue = 1)
    $nextID = $StartValue
    {
        ($Script:nextID++)
        }.GetNewClosure()
} 200

& $v3          # invoke script getting back 200
& $v3          # invoke script getting back 201
```

12. Attributes

Article • 03/24/2025

Editorial note

Important

The *Windows PowerShell Language Specification 3.0* was published in December 2012 and is based on Windows PowerShell 3.0. This specification does not reflect the current state of PowerShell. There is no plan to update this documentation to reflect the current state. This documentation is presented here for historical reference.

The specification document is available as a Microsoft Word document from the Microsoft Download Center at:

<https://www.microsoft.com/download/details.aspx?id=36389> That Word document has been converted for presentation here on Microsoft Learn. During conversion, some editorial changes have been made to accommodate formatting for the Docs platform. Some typos and minor errors have been corrected.

An *attribute* object associates predefined system information with a *target element*, which can be a param block or a parameter ([§8.10](#)). Each attribute object has an *attribute type*.

Information provided by an attribute is also known as *metadata*. Metadata can be examined by the command or the execution environment to control how the command processes data or before run time by external tools to control how the command itself is processed or maintained.

Multiple attributes can be applied to the same target element.

12.1 Attribute specification

Tip

The `~opt~` notation in the syntax definitions indicates that the lexical entity is optional in the syntax.

Syntax

```
attribute-list:  
    attribute  
    attribute-list new-lines~opt~ attribute  
  
attribute:  
    [ new-lines~opt~ attribute-name ( attribute-arguments new-lines~opt~ )  
new-lines~opt~ ]  
    type-literal  
  
attribute-name:  
    type-spec  
  
attribute-arguments:  
    attribute-argument  
    attribute-argument new-lines~opt~,  
    attribute-arguments  
  
attribute-argument:  
    new-lines~opt~ expression  
    new-lines~opt~ simple-name  
    new-lines~opt~ simple-name = new-lines~opt~ expression
```

An attribute consists of an *attribute-name* and an optional list of positional and named arguments. The positional arguments (if any) precede the named arguments. A named argument consists of a *simple-name*, optionally followed by an equal sign and followed by an *expression*. If the expression is omitted, the value `$true` is assumed.

The *attribute-name* is a reserved attribute type ([§12.3](#)) or some implementation-defined attribute type.

12.2 Attribute instances

An attribute instance is an object of an attribute type. The instance represents an attribute at run-time.

To create an object of some attribute type *A*, use the notation `A()`. An attribute is declared by enclosing its instance inside `[]`, as in `[A()]`. Some attribute types have positional and named parameters ([§8.14](#)), just like functions and cmdlets. For example,

```
[A(10,IgnoreCase=$true)]
```

shows an instance of type *A* being created using a positional parameter whose argument value is 10, and a named parameter, `IgnoreCase`, whose argument value is `$true`.

12.3 Reserved attributes

The attributes described in the following sections can be used to augment or modify the behavior of PowerShell functions, filters, scripts, and cmdlets.

12.3.1 The Alias attribute

This attribute is used in a *script-parameter* to specify an alternate name for a parameter. A parameter may have multiple aliases, and each alias name must be unique within a *parameter-list*. One possible use is to have different names for a parameter in different parameter sets (see **ParameterSetName**).

The attribute argument has type `string[]`.

Consider a function call `Test1` that has the following param block, and which is called as shown:

```
PowerShell

param (
    [Parameter(Mandatory = $true)]
    [Alias("CN")]
    [Alias("Name", "System")]
    [string[]] $ComputerName
)

Test1 "Mars", "Saturn"          # pass argument by position
Test1 -ComputerName "Mars", "Saturn" # pass argument by name
Test1 -CN "Mars", "Saturn"       # pass argument using first alias
Test1 -Name "Mars", "Saturn"     # pass argument using second alias
Test1 -Sys "Mars", "Saturn"      # pass argument using third alias
```

Consider a function call `Test2` that has the following param block, and which is called as shown:

```
PowerShell

param (
    [Parameter(Mandatory = $true, ValueFromPipelineByPropertyName = $true)]
    [Alias('PSPPath')]
    [string] $LiteralPath
)

Get-ChildItem "E:\*.txt" | Test2 -LiteralPath { $_ ; "`n`t";
    $_.FullName + ".bak" }
Get-ChildItem "E:\*.txt" | Test2
```

Cmdlet `Get-ChildItem` (alias `dir`) adds to the object it returns a new `NoteProperty` of type `string`, called `PSPPath`.

12.3.2 The AllowEmptyCollection attribute

This attribute is used in a *script-parameter* to allow an empty collection as the argument of a mandatory parameter.

Consider a function call `Test` that has the following param block, and which is called as shown:

```
PowerShell

param (
    [Parameter(Mandatory = $true)]
    [AllowEmptyCollection()]
    [string[]] $ComputerName
)

Test "Red", "Green" # $ComputerName has Length 2
Test "Red" # $ComputerName has Length 1
Test -Comp @() # $ComputerName has Length 0
```

12.3.3 The AllowEmptyString attribute

This attribute is used in a *script-parameter* to allow an empty string as the argument of a mandatory parameter.

Consider a function call `Test` that has the following param block, and which is called as shown:

```
PowerShell

param (
    [Parameter(Mandatory = $true)]
    [AllowEmptyString()]
    [string] $ComputerName
)

Test "Red" # $ComputerName is "Red"
Test "" # empty string is permitted
Test -Comp "" # empty string is permitted
```

12.3.4 The AllowNull attribute

This attribute is used in a *script-parameter* to allow `$null` as the argument of a mandatory parameter for which no implicit conversion is available.

Consider a function call `Test` that has the following param block, and which is called as shown:

```
PowerShell

param (
    [Parameter(Mandatory = $true)]
    [AllowNull()]
    [int[]] $Values
)

Test 10, 20, 30      # $values has Length 3, values 10, 20, 30
Test 10, $null, 30   # $values has Length 3, values 10, 0, 30
Test -Val $null       # $values has value $null
```

Note that the second case above does not need this attribute; there is already an implicit conversion from `$null` to int.

12.3.5 The `CmdletBinding` attribute

This attribute is used in the *attribute-list* of *param-block* of a function to indicate that function acts similar to a cmdlet. Specifically, it allows functions to access a number of methods and properties through the `$PSCmdlet` variable by using begin, process, and end named blocks ([§8.10.7](#)).

When this attribute is present, positional arguments that have no matching positional parameters cause parameter binding to fail and `$args` is not defined. (Without this attribute `$args` would take on any unmatched positional argument values.)

The following arguments are used to define the characteristics of the parameter:

[] Expand table

Parameter Name	Purpose
SupportsShouldProcess (named)	Type: bool; Default value: \$false Specifies whether the function supports calls to the <code>ShouldProcess</code> method, which is used to prompt the user for feedback before the function makes a change to the system. A value of <code>\$true</code> indicates that it does. A value of <code>\$false</code> indicates that it doesn't.
ConfirmImpact (named)	Type: string; Default value: "Medium"

Parameter Name	Purpose
	<p>Specifies the impact level of the action performed. The call to the ShouldProcess method displays a confirmation prompt only when the ConfirmImpact argument is greater than or equal to the value of the \$ConfirmPreference preference variable.</p> <p>The possible values of this argument are:</p> <ul style="list-style-type: none"> None: Suppress all requests for confirmation. Low: The action performed has a low risk of losing data. Medium: The action performed has a medium risk of losing data. High: The action performed has a high risk of losing data. <p>The value of \$ConfirmPreference can be set so that only cmdlets with an equal or higher impact level can request confirmation before they perform their operation. For example, if \$ConfirmPreference is set to Medium, cmdlets with a Medium or High impact level can request confirmation. Requests from cmdlets with a low impact level are suppressed.</p>
DefaultParameterSetName (named)	<p>Type: string; Default value: "__AllParameterSets"</p> <p>Specifies the parameter set to use if that cannot be determined from the arguments. See the named argument ParameterSetName in the attribute Parameter ([§12.3.7][§12.3.7]).</p>
PositionalBinding (named)	<p>Type: bool; Default value: \$true</p> <p>Specifies whether positional binding is supported or not. The value of this argument is ignored if any parameters specify non-default values for either the named argument Position or the named argument ParameterSetName in the attribute Parameter ([§12.3.7][§12.3.7]). Otherwise, if the argument is \$false then no parameters are positional, otherwise parameters are assigned a position based on the order the parameters are specified.</p>

Here's is an example of the framework for using this attribute:

```

PowerShell

[CmdletBinding(SupportsShouldProcess = $true, ConfirmImpact = "Low")]
param ( ... )

begin { ... }
Get-process { ... }
end { ... }

```

12.3.6 The OutputType attribute

This attribute is used in the *attribute-list* of *param-block* to specify the types returned. The following arguments are used to define the characteristics of the parameter:

[+] Expand table

Parameter Name	Purpose
Type (position 0)	Type: string[] or array of type literals A list of the types of the values that are returned.
ParameterSetName (named)	Type: string[] Specifies the parameter sets that return the types indicated by the corresponding elements of the Type parameter.

Here are several examples of this attribute's use:

PowerShell

```
[OutputType([int])] param ( ... )
[OutputType("double")] param ( ... )
[OutputType("string","string")] param ( ... )
```

12.3.7 The Parameter attribute

This attribute is used in a *script-parameter*. The following named arguments are used to define the characteristics of the parameter:

[+] Expand table

Parameter	Purpose
HelpMessage (named)	Type: string This argument specifies a message that is intended to contain a short description of the parameter. This message is used in an implementation-defined manner when the function or cmdlet is run yet a mandatory parameter having a HelpMessage does not have a corresponding argument. The following example shows a parameter declaration that provides a description of the parameter.

Parameter	Purpose
	<pre data-bbox="653 159 1257 278">param ([Parameter(Mandatory = \$true, HelpMessage = "An array of computer names.")] [string[]] \$ComputerName)</pre> <p data-bbox="653 316 1353 474">Windows PowerShell: If a required parameter is not provided the runtime prompts the user for a parameter value. The prompt dialog box includes the HelpMessage text.</p>
Mandatory (named)	<p data-bbox="653 519 1050 553">Type: bool; Default value: \$false</p> <p data-bbox="653 591 1380 748">This argument specifies whether the parameter is required within the given parameter set (see ParameterSetName argument below). A value of \$true indicates that it is. A value of \$false indicates that it isn't.</p> <pre data-bbox="653 789 1157 863">param ([Parameter(Mandatory = \$true)] [string[]] \$ComputerName)</pre> <p data-bbox="653 901 1353 1058">Windows PowerShell: If a required parameter is not provided the runtime prompts the user for a parameter value. The prompt dialog box includes the HelpMessage text, if any.</p>
ParameterSetName (named)	<p data-bbox="653 1108 1241 1141">Type: string; Default value: "__AllParameterSets"</p> <p data-bbox="653 1180 1396 1382">It is possible to write a single function or cmdlet that can perform different actions for different scenarios. It does this by exposing different groups of parameters depending on the action it wants to take. Such parameter groupings are called <i>parameter sets</i>.</p> <p data-bbox="653 1420 1400 1578">The argument ParameterSetName specifies the parameter set to which a parameter belongs. This behavior means that each parameter set must have one unique parameter that is not a member of any other parameter set.</p> <p data-bbox="653 1618 1391 1775">For parameters that belong to multiple parameter sets, add a Parameter attribute for each parameter set. This allows the parameter to be defined differently for each parameter set.</p> <p data-bbox="653 1814 1359 1971">A parameter set that contains multiple positional parameters must define unique positions for each parameter. No two positional parameters can specify the same position.</p> <p data-bbox="653 2009 1294 2083">If no parameter set is specified for a parameter, the parameter belongs to all parameter sets.</p>

Parameter	Purpose
	<p>When multiple parameter sets are defined, the named argument <code>DefaultParameterSetName</code> of the attribute <code>CmdletBinding ([§12.3.5][§12.3.5])</code> is used to specify the default parameter set. The runtime uses the default parameter set if it cannot determine the parameter set to use based on the information provided by the command, or raises an exception if no default parameter set has been specified.</p> <p>The following example shows a function <code>Test</code> with a parameter declaration of two parameters that belong to two different parameter sets, and a third parameter that belongs to both sets:</p> <pre>param ([Parameter(Mandatory = \$true, ParameterSetName = "Computer")] [string[]] \$ComputerName, [Parameter(Mandatory = \$true, ParameterSetName = "User")] [string[]] \$UserName, [Parameter(Mandatory = \$true, ParameterSetName = "Computer")] [Parameter(ParameterSetName = "User")] [int] \$SharedParam = 5) if (\$PSCmdlet.ParameterSetName -eq "Computer") { # handle "Computer" parameter set } elseif (\$PSCmdlet.ParameterSetName -eq "User") { # handle "User" parameter set } ... }</pre> <p><code>Test -ComputerName "Mars","Venus" -SharedParam 10</code> <code>Test -UserName "Mary","Jack"</code> <code>Test -UserName "Mary","Jack" -SharedParam 20</code></p>
Position (named)	<p>Type: int</p> <p>This argument specifies the position of the parameter in the argument list. If this argument is not specified, the parameter name or its alias must be specified explicitly when the parameter is set. If none of the parameters of a</p>

Parameter	Purpose
	<p>function has positions, positions are assigned to each parameter based on the order in which they are received.</p> <p>The following example shows the declaration of a parameter whose value must be specified as the first argument when the function is called.</p> <pre data-bbox="653 429 1066 508">param ([Parameter(Position = 0)] [string[]] \$ComputerName)</pre>
ValueFromPipeline (named)	<p>Type: bool; Default value: \$false</p> <p>This argument specifies whether the parameter accepts input from a pipeline object. A value of \$true indicates that it does. A value of \$false indicates that it does not.</p> <p>Specify \$true if the function or cmdlet accesses the complete object, not just a property of the object.</p> <p>Only one parameter in a parameter set can declare ValueFromPipeline as \$true.</p> <p>The following example shows the parameter declaration of a mandatory parameter, \$ComputerName, that accepts the input object that is passed to the function from the pipeline.</p> <pre data-bbox="653 1204 1146 1328">param ([Parameter(Mandatory = \$true, ValueFromPipeline=\$true)] [string[]] \$ComputerName)</pre> <p>For an example of using this parameter in conjunction with the Alias attribute see [§12.3.1][§12.3.1].</p>
ValueFromPipelineByPropertyName (named)	<p>Type: bool; Default value: \$false</p> <p>This argument specifies whether the parameter takes its value from a property of a pipeline object that has either the same name or the same alias as this parameter. A value of \$true indicates that it does. A value of \$false indicates that it does not.</p> <p>Specify \$true if the following conditions are true: the parameter accesses a property of the piped object, and the property has the same name as the parameter, or the property has the same alias as the parameter.</p> <p>A parameter having ValueFromPipelineByPropertyName set to \$true need not have a parameter in the same set with ValueFromPipeline set to \$true.</p>

Parameter	Purpose
	<p>If a function has a parameter \$ComputerName, and the piped object has a ComputerName property, the value of the ComputerName property is assigned to the \$ComputerName parameter of the Function:</p> <pre data-bbox="653 361 1214 474">param ([Parameter(Mandatory = \$true, ValueFromPipelineByPropertyName = \$true)] [string[]] \$ComputerName)</pre> <p>Multiple parameters in a parameter set can define the ValueFromPipelineByPropertyName as \$true. Although, a single input object cannot be bound to multiple parameters, different properties in that input object may be bound to different parameters.</p> <p>When binding a parameter with a property of an input object, the runtime environment first looks for a property with the same name as the parameter. If such a property does not exist, the runtime environment looks for aliases to that parameter, in their declaration order, picking the first such alias for which a property exists.</p> <pre data-bbox="653 1036 1341 1643">function Process-Date { param([Parameter(ValueFromPipelineByPropertyName=\$true)] [int]\$Year, [Parameter(ValueFromPipelineByPropertyName=\$true)] [int]\$Month, [Parameter(ValueFromPipelineByPropertyName=\$true)] [int]\$Day) process { ... } }</pre> <p>Get-Date Process-Date</p>
ValueFromRemainingArguments (named)	<p>Type: bool; Default value: \$false</p> <p>This argument specifies whether the parameter accepts all of the remaining arguments that are not bound to the parameters of the function. A value of \$true indicates that it does. A value of \$false indicates that it does not.</p> <p>The following example shows a parameter \$Others that accepts all the remaining arguments of the input object that is passed to the function Test:</p>

Parameter	Purpose
	<pre>param ([Parameter(Mandatory = \$true)][int] \$p1, [Parameter(Mandatory = \$true)][int] \$p2, [Parameter(ValueFromRemainingArguments = \$true)] [string[]] \$Others)</pre> <p>Test 10 20 # \$Others has Length 0 Test 10 20 30 40 # \$Others has Length 2, value 30,40</p>

An implementation may define other attributes as well.

The following attributes are provided as well:

- **HelpMessageBaseName**: Specifies the location where resource identifiers reside. For example, this parameter could specify a resource assembly that contains Help messages that are to be localized.
- **HelpMessageResourceId**: Specifies the resource identifier for a Help message.

12.3.8 The PSDefaultValue attribute

This attribute is used in a *script-parameter* to provide additional information about the parameter. The attribute is used in an implementation defined manner. The following arguments are used to define the characteristics of the parameter:

[Expand table](#)

Parameter	Purpose
Name	
Help (named)	<p>Type: string</p> <p>This argument specifies a message that is intended to contain a short description of the default value of a parameter. This message is used in an implementation-defined manner.</p> <p>Windows PowerShell: The message is used as part of the description of the parameter for the help topic displayed by the [Get-Help](xref:Microsoft.PowerShell.Core.Get-Help) cmdlet.</p>
Value (named)	<p>Type: object</p> <p>This argument specifies a value that is intended to be the default value of a parameter. The value is used in an implementation-defined manner.</p> <p>Windows PowerShell: The value is used as part of the description of the parameter for the help topic displayed by the [Get-Help](xref:Microsoft.PowerShell.Core.Get-Help) cmdlet when the Help property is not specified.</p>

12.3.9 The SupportsWildcards attribute

This attribute is used in a *script-parameter* to provide additional information about the parameter. The attribute is used in an implementation defined manner.

This attribute is used as part of the description of the parameter for the help topic displayed by the [Get-Help](#) cmdlet.

12.3.10 The ValidateCount attribute

This attribute is used in a *script-parameter* to specify the minimum and maximum number of argument values that the parameter can accept. The following arguments are used to define the characteristics of the parameter:

[] [Expand table](#)

Parameter Name	Purpose
MinLength (position 0)	Type: int This argument specifies the minimum number of argument values allowed.
MaxLength (position 1)	Type: int This argument specifies the maximum number of argument values allowed.

In the absence of this attribute, the parameter's corresponding argument value list can be of any length.

Consider a function call `Test` that has the following param block, and which is called as shown:

```
PowerShell

param (
    [ValidateCount(2, 5)]
    [int[]] $Values
)

Temp 10, 20, 30
Temp 10          # too few argument values
Temp 10, 20, 30, 40, 50, 60      # too many argument values

[ValidateCount(3, 4)]$Array = 1..3
```

```
$Array = 10                      # too few argument values  
$Array = 1..100                    # too many argument values
```

12.3.11 The ValidateLength attribute

This attribute is used in a *script-parameter* or *variable* to specify the minimum and maximum length of the parameter's argument, which must have type string. The following arguments are used to define the characteristics of the parameter:

[\[+\] Expand table](#)

Parameter Name	Purpose
MinLength (position 0)	Type: int This argument specifies the minimum number of characters allowed.
MaxLength (position 1)	Type: int This argument specifies the maximum number of characters allowed.

In the absence of this attribute, the parameter's corresponding argument can be of any length.

Consider a function call `Test` that has the following param block, and which is called as shown:

```
PowerShell  
  
param ( [Parameter(Mandatory = $true)]  
[ValidateLength(3,6)]  
[string[]] $ComputerName )  
  
Test "Thor", "Mars"      # length is ok  
Test "Io", "Mars"        # "Io" is too short  
Test "Thor", "Jupiter"   # "Jupiter" is too long
```

12.3.12 The ValidateNotNull attribute

This attribute is used in a *script-parameter* or *variable* to specify that the argument of the parameter cannot be `$null` or be a collection containing a null-valued element.

Consider a function call `Test` that has the following param block, and which is called as shown:

PowerShell

```
param (
    [ValidateNotNull()]  
    [string[]] $Names  
)  
  
Test "Jack", "Jill"      # ok  
Test "Jane", $null        # $null array element value not allowed  
Test $null                # null array not allowed  
  
[ValidateNotNull()]$Name = "Jack" # ok  
$Name = $null              # null value not allowed
```

12.3.13 The ValidateNotNullOrEmpty attribute

This attribute is used in a *script-parameter* or *variable* to specify that the argument if the parameter cannot be \$null, an empty string, or an empty array, or be a collection containing a \$null-valued or empty string element.

Consider a function call `Test` that has the following param block, and which is called as shown:

PowerShell

```
param (  
    [ValidateNotNullOrEmpty()]  
    [string[]] $Names  
)  
  
Test "Jack", "Jill"      # ok  
Test "Mary", ""           # empty string not allowed  
Test "Jane", $null        # $null array element value not allowed  
Test $null                # null array not allowed  
Test @()                  # empty array not allowed  
  
[ValidateNotNullOrEmpty()]$Name = "Jack" # ok  
$Name = ""                 # empty string not allowed  
$Name = $null              # null value not allowed
```

12.3.14 The ValidatePattern attribute

This attribute is used in a *script-parameter* or *variable* to specify a regular expression for matching the pattern of the parameter's argument. The following arguments are used to define the characteristics of the parameter:

Parameter Name	Purpose
RegexString (position 0)	Type: String A regular expression that is used to validate the parameter's argument
Options (named)	Type: Regular-Expression-Option See [§4.2.6.4][§4.2.6.4] for the allowed values.

If the argument is a collection, each element in the collection must match the pattern.

Consider a function call `Test` that has the following param block, and which is called as shown:

```
PowerShell

param (
    [ValidatePattern('^\[A-Z\]\[1-5\]\[0-9\]$')]
    [string] $Code,

    [ValidatePattern('^\(0x|0X\)(\[A-F\]|\[a-f\]|\[0-9\])(\[A-F\]|\[a-f\]|\[0-9\])$')]
    [string] $HexNum,

    [ValidatePattern('^\[+|-?\[1-9\]$')]
    [int] $Minimum
)

Test -C A12 # matches pattern
Test -C A63 # does not match pattern

Test -H 0x4f # matches pattern
Test -H "0XB2" # matches pattern
Test -H 0xK3 # does not match pattern

Test -M -4 # matches pattern
Test -M "+7" # matches pattern
Test -M -12 # matches pattern, but is too long

[ValidatePattern('^\[a-z\]\[a-z0-9\]\*$')]$ident = "abc"
$ident = "123" # does not match pattern
```

12.3.15 The ValidateRange attribute

This attribute is used in a *script-parameter* or *variable* to specify the minimum and maximum values of the parameter's argument. The following arguments are used to define the characteristics of the parameter:

Parameter Name	Purpose
MinRange (position 0)	Type: object This argument specifies the minimum value allowed.
MaxRange (position 1)	Type: object This argument specifies the maximum value allowed.

In the absence of this attribute, there is no range restriction.

Consider a function call `Test1` that has the following param block, and which is called as shown:

PowerShell

```
param (
    [Parameter(Mandatory = $true)]
    [ValidateRange(1, 10)]
    [int] $StartValue
)

Test1 2
Test1 -St 7
Test1 -3 # value is too small
Test1 12 # value is too large
```

Consider a function call `Test2` that has the following param block and calls:

PowerShell

```
param (
    [Parameter(Mandatory = $true)]
    [ValidateRange("b", "f")]
    [string] $Name
)

Test2 "Bravo" # ok
Test2 "Alpha" # value compares less than the minimum
Test2 "Hotel" # value compares greater than the maximum
```

Consider a function call `Test3` that has the following param block, and which is called as shown:

PowerShell

```

param (
    [Parameter(Mandatory = $true)]
    [ValidateRange(0.002, 0.003)]
    [double] $Distance
)

Test3 0.002
Test3 0.0019    # value is too small
Test3 "0.005"   # value is too large

[ValidateRange(13, 19)]$teenager = 15
$teenager = 20  # value is too large

```

12.3.16 The ValidateScript attribute

This attribute is used in a *script-parameter* or *variable* to specify a script that is to be used to validate the parameter's argument.

The argument in position 1 is a *script-block-expression*.

Consider a function call `Test` that has the following param block, and which is called as shown:

PowerShell

```

param (
    [Parameter(Mandatory = $true)]
    [ValidateScript( { ($_. -ge 1 -and $_ -le 3) -or ($_. -ge 20) })]
    [int] $Count
)

Test 2 # ok, valid value
Test 25 # ok, valid value
Test 5 # invalid value
Test 0 # invalid value

[ValidateScript({$.Length --gt 7})]$password = "password" # ok
$password = "abc123" # invalid value

```

12.3.17 The ValidateSet attribute

This attribute is used in a *script-parameter* or *variable* to specify a set of valid values for the argument of the parameter. The following arguments are used to define the characteristics of the parameter:

Parameter Name	Purpose
ValidValues (position 0)	Type: string[] The set of valid values.
IgnoreCase (named)	Type: bool; Default value: \$true Specifies whether case should be ignored for parameters of type string.

If the parameter has an array type, every element of the corresponding argument array must match an element of the value set.

Consider a function call `Test` that has the following param block, and which is called as shown:

PowerShell

```
param ( [ValidateSet("Red", "Green", "Blue")]
    [string] $Color,
    [ValidateSet("up", "down", "left", "right", IgnoreCase =
        $false)]
    [string] $Direction
)

Test -Col "RED"      # case is ignored, is a member of the set
Test -Col "white"   # case is ignored, is not a member of the set

Test -Dir "up"       # case is not ignored, is a member of the set
Test -Dir "Up"       # case is not ignored, is not a member of the set

[ValidateSet(("Red", "Green", "Blue"))]$color = "RED" # ok, case is ignored
$color = "Purple"  # case is ignored, is not a member of the set
```

13. Cmdlets

Article • 01/08/2025

Editorial note

Important

The *Windows PowerShell Language Specification 3.0* was published in December 2012 and is based on Windows PowerShell 3.0. This specification does not reflect the current state of PowerShell. There is no plan to update this documentation to reflect the current state. This documentation is presented here for historical reference.

The specification document is available as a Microsoft Word document from the Microsoft Download Center at:

<https://www.microsoft.com/download/details.aspx?id=36389> That Word document has been converted for presentation here on Microsoft Learn. During conversion, some editorial changes have been made to accommodate formatting for the Docs platform. Some typos and minor errors have been corrected.

A cmdlet is a single-feature command that manipulates objects in PowerShell. Cmdlets can be recognized by their name format, a verb and noun separated by a dash (-), such as `Get-Help`, `Get-Process`, and `Start-Service`. A *verb pattern* is a verb expressed using wildcards, as in `w*`. A *noun pattern* is a noun expressed using wildcards, as in `event`.

Cmdlets should be simple and be designed to be used in combination with other cmdlets. For example, **Get** cmdlets should only retrieve data, **Set** cmdlets should only establish or change data, **Format** cmdlets should only format data, and **Out** cmdlets should only direct the output to a specified destination.

For each cmdlet, provide a help file that can be accessed by typing:

```
Get-Help *cmdlet-name* -Detailed
```

The detailed view of the cmdlet help file should include a description of the cmdlet, the command syntax, descriptions of the parameters, and an example that demonstrate the use of that cmdlet.

Cmdlets are used similarly to operating system commands and utilities. PowerShell commands are not case-sensitive.

Note

Editor's note: The original document contains a list of cmdlet with descriptions, syntax diagrams, parameter definitions, and examples. This information is incomplete and out dated. For current information about cmdlet, consult the [Reference section of the PowerShell documentation](#).

13.1 Common parameters

The *common parameters* are a set of cmdlet parameters that can be used with any cmdlet. They are implemented by the PowerShell runtime environment itself, not by the cmdlet developer, and they are automatically available to any cmdlet or function that uses the [Parameter attribute](#) ([§12.3.7](#)) or [CmdletBinding attribute](#) ([§12.3.5](#)).

Although the common parameters are accepted by any cmdlet, they might not have any semantics for that cmdlet. For example, if a cmdlet does not generate any verbose output, using the **Verbose** common parameter has no effect.

Several common parameters override system defaults or preferences that can be set via preference variables ([§2.3.2.3](#)). Unlike the preference variables, the common parameters affect only the commands in which they are used.

Note

Editor's note: The original document contains a list of the Common Parameters. This information is incomplete and out dated. For current information see [about_CommonParameters](#).

A. Comment-Based Help

Article • 01/08/2025

Editorial note

Important

The *Windows PowerShell Language Specification 3.0* was published in December 2012 and is based on Windows PowerShell 3.0. This specification does not reflect the current state of PowerShell. There is no plan to update this documentation to reflect the current state. This documentation is presented here for historical reference.

The specification document is available as a Microsoft Word document from the Microsoft Download Center at:

<https://www.microsoft.com/download/details.aspx?id=36389> That Word document has been converted for presentation here on Microsoft Learn. During conversion, some editorial changes have been made to accommodate formatting for the Docs platform. Some typos and minor errors have been corrected.

PowerShell provides a mechanism for programmers to document their scripts using special comment directives. Comments using such syntax are called *help comments*. The cmdlet [Get-Help](#) generates documentation from these directives.

A.1 Introduction

A help comment contains a *help directive* of the form `.name` followed on one or more subsequent lines by the help content text. The help comment can be made up of a series of *single-line-comments* or a *delimited-comment* ([§2.2.3](#)). The set of comments comprising the documentation for a single entity is called a *help topic*.

For example,

PowerShell

```
# <help-directive-1>
# <help-content-1>
...

```

```
# <help-directive-n>
# <help-content-n>
```

or

PowerShell

```
<#
<help-directive-1>
<help-content-1>
...
<help-directive-n>
<help-content-n>
#>
```

All of the lines in a help topic must be contiguous. If a help topic follows a comment that is not part of that topic, there must be at least one blank line between the two.

The directives can appear in any order, and some of the directives may appear multiple times.

Directive names are not case-sensitive.

When documenting a function, help topics may appear in one of three locations:

- Immediately before the function definition with no more than one blank line between the last line of the function help and the line containing the function statement.
- Inside the function's body immediately following the opening curly bracket.
- Inside the function's body immediately preceding the closing curly bracket.

When documenting a script file, help topics may appear in one of two locations:

- At the beginning of the script file, optionally preceded by comments and blank lines only. If the first item in the script after the help is a function definition, there must be at least two blank lines between the end of the script help and that function declaration. Otherwise, the help will be interpreted as applying to the function instead of the script file.
- At the end of the script file.

A.2 Help directives

A.2.1 .DESCRIPTION

Syntax:

```
Syntax  
.DESCRIPTION
```

Description:

This directive allows for a detailed description of the function or script. (The `.SYNOPSIS` directive ([§A.2.11](#)) is intended for a brief description.) This directive can be used only once in each topic.

Examples:

```
PowerShell  
<#  
.DESCRIPTION  
Computes Base to the power Exponent. Supports non-negative integer  
powers only.  
#>
```

A.2.2 .EXAMPLE

Syntax:

```
Syntax  
.EXAMPLE
```

Description:

This directive allows an example of command usage to be shown.

If this directive occurs multiple times, each associated help content block is displayed as a separate example.

Examples:

```
PowerShell  
<#  
.EXAMPLE  
Get-Power 3 4  
81
```

```
.EXAMPLE  
Get-Power -Base 3 -Exponent 4  
81  
#>
```

A.2.3 .EXTERNALHELP

Syntax:

```
Syntax  
.EXTERNALHELP <XMLHelpFilePath>
```

Description:

This directive specifies the path to an XML-based help file for the script or function.

Although comment-based help is easier to implement, XML-based Help is required if more precise control is needed over help content or if help topics are to be translated into multiple languages. The details of XML-based help are not defined by this specification.

Examples:

```
PowerShell  
<#  
.EXTERNALHELP C:\MyScripts\Update-Month-Help.xml  
#>
```

A.2.4 .FORWARDHELPCATEGORY

Syntax:

```
Syntax  
.FORWARDHELPCATEGORY <Category>
```

Description:

Specifies the help category of the item in **ForwardHelpTargetName** ([§A.2.5](#)). Valid values are **Alias**, **All**, **Cmdlet**, **ExternalScript**, **FAQ**, **Filter**, **Function**, **General**, **Glossary**, **HelpFile**, **Provider**, and **ScriptCommand**. Use this directive to avoid conflicts when there are commands with the same name.

Examples:

See §A.2.5.

A.2.5 .FORWARDHELPTARGETNAME

Syntax:

Syntax

```
.FORWARDHELPTARGETNAME <Command-Name>
```

Description:

Redirects to the help topic specified by `<Command-Name>`.

Examples:

PowerShell

```
function Help {
    #
    .FORWARDHELPTARGETNAME Get-Help
    .FORWARDHELPCATEGORY Cmdlet
    #
    ...
}
```

The command `Get-Help help` is treated as if it were `Get-Help Get-Help` instead.

A.2.6 .INPUTS

Syntax:

Syntax

```
.INPUTS
```

Description:

The pipeline can be used to pipe one or more objects to a script or function. This directive is used to describe such objects and their types.

If this directive occurs multiple times, each associated help content block is collected in the one documentation entry, in the directives' lexical order.

Examples:

PowerShell

```
<#
.INPUTS
None. You cannot pipe objects to Get-Power.

.INPUTS
For the Value parameter, one or more objects of any kind can be written
to the pipeline. However, the object is converted to a string before it
is added to the item.
#>
function Process-Thing {
    param (
        [Parameter(ValueFromPipeline=$true)]
        [Object[]]$Value,
        ...
    )
    ...
}
```

A.2.7 .LINK

Syntax:

Syntax

```
.LINK
```

Description:

This directive specifies the name of a related topic.

If this directive occurs multiple times, each associated help content block is collected in the one documentation entry, in the directives' lexical order.

The Link directive content can also include a URI to an online version of the same help topic. The online version is opens when Get-Help is invoked with the Online parameter. The URI must begin with "http" or "https".

Examples:

PowerShell

```
<#
.INPUTS
None. You cannot pipe objects to Get-Power.

.INPUTS
For the Value parameter, one or more objects of any kind can be written
to the pipeline. However, the object is converted to a string before it
is added to the item.
#>
function Process-Thing {
    param (
        [Parameter(ValueFromPipeline=$true)]
        [Object[]]$Value,
        ...
    )
    ...
}

#>
#>
#>
```

```
.LINK  
Set-ProcedureName  
#>
```

A.2.8 .NOTES

Syntax:

```
Syntax
```

```
.NOTES
```

Description:

This directive allows additional information about the function or script to be provided.
This directive can be used only once in each topic.

Examples:

```
PowerShell
```

```
<#  
.NOTES  
*arbitrary text goes here*  
#>
```

A.2.9 .OUTPUTS

Syntax:

```
Syntax
```

```
.OUTPUTS
```

Description:

This directive is used to describe the objects output by a command.

If this directive occurs multiple times, each associated help content block is collected in the one documentation entry, in the directives' lexical order.

Examples:

PowerShell

```
<#
.OBJECTS
double - Get-Power returns Base to the power Exponent.

.OBJECTS
None unless the -PassThru switch parameter is used.
#>
```

A.2.10 .PARAMETER

Syntax:

Syntax

```
.PARAMETER <Parameter-Name>
```

Description:

This directive allows for a detailed description of the given parameter. This directive can be used once for each parameter. Parameter directives can appear in any order in the comment block; however, the order in which their corresponding parameters are actually defined in the source determines the order in which the parameters and their descriptions appear in the resulting documentation.

An alternate format involves placing a parameter description comment immediately before the declaration of the corresponding parameter variable's name. If the source contains both a parameter description comment and a Parameter directive, the description associated with the Parameter directive is used.

Examples:

PowerShell

```
<#
.PARAMETER Base
The integer value to be raised to the Exponent-th power.

.PARAMETER Exponent
The integer exponent to which Base is to be raised.
#>

function Get-Power {
    param ([long]$Base, [int]$Exponent)
    ...
}
```

```
function Get-Power {
    param ([long]
        # The integer value to be raised to the Exponent-th power.
        $Base,
        [int]
        # The integer exponent to which Base is to be raised.
        $Exponent
    )
    ...
}
```

A.2.11 .SYNOPSIS

Syntax:

```
PowerShell
```

```
.SYNOPSIS
```

Description:

This directive allows for a brief description of the function or script. (The `.DESCRIPTION` directive ([§A.2.1](#)) is intended for a detailed description.) This directive can be used only once in each topic.

Examples:

```
PowerShell
```

```
<#
.SYNOPSIS
Computes Base to the power Exponent.
#>
```

B. Grammar

Article • 01/08/2025

Editorial note

Important

The *Windows PowerShell Language Specification 3.0* was published in December 2012 and is based on Windows PowerShell 3.0. This specification does not reflect the current state of PowerShell. There is no plan to update this documentation to reflect the current state. This documentation is presented here for historical reference.

The specification document is available as a Microsoft Word document from the Microsoft Download Center at:

<https://www.microsoft.com/download/details.aspx?id=36389> That Word document has been converted for presentation here on Microsoft Learn. During conversion, some editorial changes have been made to accommodate formatting for the Docs platform. Some typos and minor errors have been corrected.

This appendix contains summaries of the lexical and syntactic grammars found in the main document.

Tip

The `~opt~` notation in the syntax definitions indicates that the lexical entity is optional in the syntax.

B.1 Lexical grammar

Syntax

```
input:  
    input-elements~opt~ signature-block~opt~  
  
input-elements:  
    input-element  
    input-elements input-element  
  
input-element:
```

```
whitespace
comment
token

signature-block:
    signature-begin signature signature-end

signature-begin:
    new-line-character # SIG # Begin signature block new-line-character

signature:
    base64 encoded signature blob in multiple single-line-comments

signature-end:
    new-line-character # SIG # End signature block new-line-character
```

B.1.1 Line terminators

Syntax

```
new-line-character:
    Carriage return character (U+000D)
    Line feed character (U+000A)
    Carriage return character (U+000D) followed by line feed character
(U+000A)

new-lines:
    new-line-character
    new-lines new-line-character
```

B.1.2 Comments

Syntax

```
comment:
    single-line-comment
    requires-comment
    delimited-comment

single-line-comment:
    # input-characters~opt~

input-characters:
    input-character
    input-characters input-character

input-character:
    Any Unicode character except a new-line-character
```

```

requires-comment:
    #Requires whitespace command-arguments

dash:
    - (U+002D)
    EnDash character (U+2013)
    EmDash character (U+2014)
    Horizontal bar character (U+2015)

dashdash:
    dash dash

delimited-comment:
    <# delimited-comment-text~opt~ hashes >

delimited-comment-text:
    delimited-comment-section
    delimited-comment-text delimited-comment-section

delimited-comment-section:
    >
    hashes~opt~ not-greater-than-or-hash

hashes:
    #
    hashes #

not-greater-than-or-hash:
    Any Unicode character except > or #

```

B.1.3 White space

Syntax

```

whitespace:
    Any character with Unicode class Zs, Zl, or Zp
    Horizontal tab character (U+0009)
    Vertical tab character (U+000B)
    Form feed character (U+000C)
    ` (The backtick character U+0060) followed by new-line-character

```

B.1.4 Tokens

Syntax

```

token:
    keyword
    variable
    command

```

```
command-parameter
command-argument-token
integer-literal
real-literal
string-literal
type-literal
operator-or-punctuator
```

B.1.5 Keywords

Syntax

```
keyword: one of
begin      break      catch      class
continue    data       define     do
dynamicparam else      elseif     end
exit        filter     finally   for
foreach     from      function  if
in          inlinescript parallel param
process    return     switch    throw
trap       try       until     using
var        while     workflow
```

B.1.6 Variables

Syntax

```
variable:
$$
$?
$^
$  variable-scope~opt~  variable-characters
@  variable-scope~opt~  variable-characters
braced-variable

braced-variable:
${  variable-scope~opt~  braced-variable-characters  }

variable-scope:
Global:
Local:
Private:
Script:
Using:
Workflow:
variable-namespace

variable-namespace:
```

```

variable-characters  :

variable-characters:
    variable-character
    variable-characters  variable-character

variable-character:
    A Unicode character of classes Lu, Ll, Lt, Lm, Lo, or Nd
    _   (The underscore character U+005F)
    ?

braced-variable-characters:
    braced-variable-character
    braced-variable-characters  braced-variable-character

braced-variable-character:
    Any Unicode character except
        }   (The closing curly brace character U+007D)
        `   (The backtick character U+0060)
    escaped-character

escaped-character:
    `   (The backtick character U+0060) followed by any Unicode character

```

B.1.7 Commands

Syntax

```

generic-token:
    generic-token-parts

generic-token-parts:
    generic-token-part
    generic-token-parts generic-token-part

generic-token-part:
    expandable-string-literal
    verbatim-here-string-literal
    variable
    generic-token-char

generic-token-char:
    Any Unicode character except
        {   }   (   )   ;   ,   |   &   $
        `   (The backtick character U+0060)
    double-quote-character

```

B.1.8 Parameters

Syntax

```
command-parameter:  
    dash first-parameter-char parameter-chars colon~opt~  
  
first-parameter-char:  
    A Unicode character of classes Lu, Ll, Lt, Lm, or Lo  
    _ (The underscore character U+005F)  
    ?  
  
parameter-chars:  
    parameter-char  
    parameter-chars parameter-char  
  
parameter-char:  
    Any Unicode character except  
        { } ( ) ; , | & . [  
    colon  
    whitespace  
    new-line-character  
  
colon:  
    : (The colon character U+003A)  
  
verbatim-command-argument-chars:  
    verbatim-command-argument-part  
    verbatim-command-argument-chars verbatim-command-argument-part  
  
verbatim-command-argument-part:  
    verbatim-command-string  
    & non-ampersand-character  
    Any Unicode character except  
        |  
    new-line-character  
  
non-ampersand-character:  
    Any Unicode character except &  
  
verbatim-command-string:  
    double-quote-character non-double-quote-chars  
    double-quote-character  
  
non-double-quote-chars:  
    non-double-quote-char  
    non-double-quote-chars non-double-quote-char  
  
non-double-quote-char:
```

Any Unicode character except
double-quote-character

B.1.9 Literals

Syntax

```
literal:  
    integer-literal  
    real-literal  
    string-literal
```

B.1.9.1 Integer Literals

Syntax

```
integer-literal:  
    decimal-integer-literal  
    hexadecimal-integer-literal

decimal-integer-literal:  
    decimal-digits numeric-type-suffix~opt~ numeric-multiplier~opt~

decimal-digits:  
    decimal-digit  
    decimal-digit decimal-digits

decimal-digit: one of  
    0 1 2 3 4 5 6 7 8 9

numeric-type-suffix:  
    long-type-suffix  
    decimal-type-suffix

hexadecimal-integer-literal:  
    0x hexadecimal-digits long-type-suffix~opt~  
    numeric-multiplier~opt~

hexadecimal-digits:  
    hexadecimal-digit  
    hexadecimal-digit decimal-digits

hexadecimal-digit: one of  
    0 1 2 3 4 5 6 7 8 9 a b c d e f

long-type-suffix:  
    l
```

```
numeric-multiplier: one of
  kb mb gb tb pb
```

B.1.9.2 Real Literals

Syntax

```
real-literal:
  decimal-digits . decimal-digits exponent-part~opt~ decimal-type-
suffix~opt~ numeric-multiplier~opt~
  . decimal-digits exponent-part~opt~ decimal-type-suffix~opt~ numeric-
multiplier~opt~
  decimal-digits exponent-part decimal-type-suffix~opt~ numeric-
multiplier~opt~

exponent-part:
  e sign~opt~ decimal-digits

sign: one of
  +
  dash

decimal-type-suffix:
  d
  l
```

B.1.9.3 String Literals

Syntax

```
string-literal:
  expandable-string-literal
  expandable-here-string-literal
  verbatim-string-literal
  verbatim-here-string-literal

expandable-string-literal:
  double-quote-character expandable-string-characters~opt~ dollars~opt~
double-quote-character

double-quote-character:
  " (U+0022)
  Left double quotation mark (U+201C)
  Right double quotation mark (U+201D)
  Double low-9 quotation mark (U+201E)

expandable-string-characters:
  expandable-string-part
  expandable-string-characters
```

```
expandable-string-part

expandable-string-part:
    Any Unicode character except
        $
        double-quote-character
        ` (The backtick character U+0060)
    braced-variable
    $ Any Unicode character except
        (
        {
        double-quote-character
        ` (The backtick character U+0060)*
    $ escaped-character
    escaped-character
    double-quote-character double-quote-character

dollars:
    $
    dollars $

expandable-here-string-literal:
    @ double-quote-character whitespace~opt~ new-line-character
        expandable-here-string-characters~opt~ new-line-character double-

    new-line-character single-quote-character Any Unicode character except
    @

```

B.1.10 Simple Names

Syntax

```

simple-name:
    simple-name-first-char simple-name-chars

simple-name-first-char:
    A Unicode character of classes Lu, Ll, Lt, Lm, or Lo
    _ (The underscore character U+005F)

simple-name-chars:
    simple-name-char
    simple-name-chars simple-name-char

simple-name-char:

```

A Unicode character of classes Lu, Ll, Lt, Lm, Lo, or Nd
_ (The underscore character U+005F)

B.1.11 Type Names

Syntax

```
type-name:  
    type-identifier  
    type-name . type-identifier  
  
type-identifier:  
    type-characters  
  
type-characters:  
    type-character  
    type-characters type-character  
  
type-character:  
    A Unicode character of classes Lu, Ll, Lt, Lm, Lo, or Nd  
    _ (The underscore character U+005F)  
  
array-type-name:  
    type-name [  
  
generic-type-name:  
    type-name [
```

B.1.12 Operators and punctuators

Syntax

```
operator-or-punctuator: one of  
    { } [ ] ( ) @  
    && || & | , ++ .. :: .  
    ! * / % +  
    dash dashdash  
    dash and dash band dash bnot dash bor  
    dash bxor dash not dash or dash xor  
    assignment-operator  
    merging-redirection-operator  
    file-redirection-operator  
    comparison-operator  
    format-operator  
  
assignment-operator: one of  
    = dash = += *= /= %=  
  
file-redirection-operator: one of
```

```

>  >>  2>  2>>  3>  3>>  4>  4>>
5>  5>>  6>  6>>  *>  *>>  <

merging-redirection-operator: one of
  *>&1  2>&1  3>&1  4>&1  5>&1  6>&1
  *>&2  1>&2  3>&2  4>&2  5>&2  6>&2

comparison-operator: one of
  dash as           dash ccontains      dash ceq
  dash cge          dash cgt          dash cle
  dash clike         dash clt          dash cmatch
  dash cne          dash cnotcontains  dash cnotlike
  dash cnotmatch    dash contains      dash creplace
  dash csplit        dash eq           dash ge
  dash gt            dash icontains   dash ieq
  dash ige           dash igt          dash ile
  dash ilike         dash ilt          dash imatch
  dash in             dash ine          dash inotcontains
  dash inotlike      dash inotmatch   dash ireplace
  dash is             dash isnot         dash isplit

Windows PowerShell

Article • 09/17/2021

Updated: July 8, 2013

Windows PowerShell® is a task-based command-line shell and scripting language designed especially for system administration. Built on the .NET Framework, Windows PowerShell® helps IT professionals and power users control and automate the administration of the Windows operating system and applications that run on Windows.

The documents published here are written primarily for cmdlet, provider, and host application developers who require reference information about the APIs provided by Windows PowerShell. However, system administrators might also find the information provided by these documents useful.

For the basic information needed to start using Windows PowerShell, see [Getting Started with Windows PowerShell](#).

Windows PowerShell Documents

- [Installing the Windows PowerShell SDK](#) Provides information about how to install the Windows PowerShell SDK.
- [Writing a Windows PowerShell Module](#) Provides information for administrators, script developers, and cmdlet developers who need to package and distribute their Windows PowerShell solutions.
- [Writing a Windows PowerShell Cmdlet](#) Provides information for designing and implementing cmdlets.
- [Writing a Windows PowerShell Provider](#) Provides information for designing and implementing Windows PowerShell providers. It will help you understand how Windows PowerShell providers work, and it provides sample code that you can use to start designing or writing your own providers.
- [Writing a Windows PowerShell Host Application](#) Provides information that can be used by program managers who are designing host applications and by developers who are implementing them. The host application can define the runspace where commands are run, open sessions on a local or remote computer, and invoke the commands either synchronously or asynchronously based on the needs of the application.

- [Writing a PowerShell Formatting File](#) Provides information for the authoring of formatting files, which control the display format for the objects that are returned by commands (cmdlets, functions, and scripts).
- [Windows PowerShell Reference](#) Provides reference content for the APIs used in writing cmdlets, providers, and host applications, as well as other supporting APIs.

Installing the Windows PowerShell SDK

Article • 10/23/2023

Applies To: Windows PowerShell 2.0, Windows PowerShell 3.0

The following topic describes how to install the PowerShell SDK on different versions of Windows.

Installing Windows PowerShell 3.0 SDK for Windows 8 and Windows Server 2012

Windows PowerShell 3.0 is automatically installed with Windows 8 and Windows Server 2012. In addition, you can download and install the reference assemblies for Windows PowerShell 3.0 as part of the Windows 8 SDK. These assemblies allow you to write cmdlets, providers, and host programs for Windows PowerShell 3.0. When you install the Windows SDK for Windows 8, the Windows PowerShell assemblies are automatically installed in the reference assembly folder, in `\Program Files (x86)\Reference Assemblies\Microsoft\WindowsPowerShell\3.0`. For more information, see the Windows 8 SDK download site. Windows PowerShell code samples are also available in the [powershell-sdk-samples](#) repository.

Reference assemblies

Reference assemblies are installed in the following location by default: `C:\Program Files\Reference Assemblies\Microsoft\WindowsPowerShell\V1.0`.

Note

Code that is compiled against the Windows PowerShell 2.0 assemblies cannot be loaded into Windows PowerShell 1.0 installations. However, code that is compiled against the Windows PowerShell 1.0 assemblies can be loaded into Windows PowerShell 2.0 installations.

Samples

Code samples are installed in the following location by default: `C:\Program Files\Microsoft SDKs\Windows\v7.0\Samples\sysmgmt\WindowsPowerShell\`. The following sections provide a brief description of what each sample does.

Cmdlet samples

- GetProcessSample01 - Shows how to write a simple cmdlet that gets all the processes on the local computer.
- GetProcessSample02 - Shows how to add parameters to the cmdlet. The cmdlet takes one or more process names and returns the matching processes.
- GetProcessSample03 - Shows how to add parameters that accept input from the pipeline.
- GetProcessSample04 - Shows how to handle non-terminating errors.
- GetProcessSample05 - Shows how to display a list of specified processes.
- SelectObject - Shows how to write a filter to select only certain objects.
- SelectString - Shows how to search files for specified patterns.
- StopProcessSample01 - Shows how to implement a PassThru parameter, and how to request user feedback by calls to the ShouldProcess and ShouldContinue methods. Users specify the PassThru parameter when they want to force the cmdlet to return an object,
- StopProcessSample02 - Shows how to stop a specific process.
- StopProcessSample03 - Shows how to declare aliases for parameters and how to support wildcards.
- StopProcessSample04 - Shows how to declare parameter sets, the object that the cmdlet takes as input, and how to specify the default parameter set to use.

Remoting samples

- RemoteRunspace01 - Shows how to create a remote runspace that is used to establish a remote connection.
- RemoteRunspacePool01 - Shows how to construct a remote runspace pool and how to run multiple commands concurrently by using this pool.
- Serialization01 - Shows how to look at an existing .NET class and make sure that information from selected public properties of this class is preserved across serialization/deserialization.
- Serialization02 - Shows how to look at an existing .NET class and make sure that information from instance of this class is preserved across serialization/deserialization when the information is not available in public properties of the class.
- Serialization03 - Shows how to look at an existing .NET class and make sure that instances of this class and of derived classes are deserialized (rehydrated) into live .NET objects.

Event samples

- Event01 - Shows how to create a cmdlet for event registration by deriving from ObjectEventRegistrationBase.
- Event02 - Shows how to receive notifications of Windows PowerShell events that are generated on remote computers. It uses the PSEventReceived event exposed through the Runspace class.

Hosting application samples

- Runspace01 - Shows how to use the PowerShell class to run the `Get-Process` cmdlet synchronously. The `Get-Process` cmdlet returns Process objects for each process running on the local computer.
- Runspace02 - Shows how to use the PowerShell class to run the `Get-Process` and `Sort-Object` cmdlets synchronously. The `Get-Process` cmdlet returns Process objects for each process running on the local computer, and the `Sort-Object` sorts the objects based on their Id property. The results of these commands is displayed by using a DataGridView control.
- Runspace03 - Shows how to use the PowerShell class to run a script synchronously, and how to handle non-terminating errors. The script receives a list of process names and then retrieves those processes. The results of the script, including any non-terminating errors that were generated when running the script, are displayed in a console window.
- Runspace04 - Shows how to use the PowerShell class to run commands, and how to catch terminating errors that are thrown when running the commands. Two commands are run, and the last command is passed a parameter argument that is not valid. As a result, no objects are returned and a terminating error is thrown.
- Runspace05 - Shows how to add a snap-in to an InitialSessionState object so that the cmdlet of the snap-in is available when the runspace is opened. The snap-in provides a Get-Proc cmdlet (defined by the GetProcessSample01 Sample) that is run synchronously using a PowerShell object.
- Runspace06 - Shows how to add a module to an InitialSessionState object so that the module is loaded when the runspace is opened. The module provides a Get-Proc cmdlet (defined by the GetProcessSample02 Sample) that is run synchronously using a PowerShell object.
- Runspace07 - Shows how to create a runspace, and then use that runspace to run two cmdlets synchronously using a PowerShell object.
- Runspace08 - Shows how to add commands and arguments to the pipeline of a PowerShell object and how to run the commands synchronously.
- Runspace09 - Shows how to add a script to the pipeline of a PowerShell object and how to run the script asynchronously. Events are used to handle the output of the script.

- Runspace10 - Shows how to create a default initial session state, how to add a cmdlet to the InitialSessionState, how to create a runspace that uses the initial session state, and how to run the command using a PowerShell object.
- Runspace11 - Shows how to use the ProxyCommand class to create a proxy command that calls an existing cmdlet, but restricts the set of available parameters. The proxy command is then added to an initial session state that is used to create a constrained runspace. This means that the user can access the functionality of the cmdlet only through the proxy command.
- PowerShell01 - Shows how to create a constrained runspace using an InitialSessionState object.
- PowerShell02 - Shows how to use a runspace pool to run multiple commands concurrently.

Host samples

- Host01 - Shows how to implement a host application that uses a custom host. In this sample a runspace is created that uses the custom host, and then the PowerShell API is used to run a script that calls `exit`. The host application then looks at the output of the script and prints out the results.
- Host02 - Shows how to write a host application that uses the Windows PowerShell runtime along with a custom host implementation. The host application sets the host culture to German, runs the `Get-Process` cmdlet and displays the results as you would see them by using `pwrsh.exe`, and then prints out the current data and time in German.
- Host03 - Shows how to build an interactive console-based host application that reads commands from the command line, executes the commands, and then displays the results to the console.
- Host04 - Shows how to build an interactive console-based host application that reads commands from the command line, executes the commands, and then displays the results to the console. This host application also supports displaying prompts that allow the user to specify multiple choices.
- Host05 - Shows how to build an interactive console-based host application that reads commands from the command line, executes the commands, and then displays the results to the console. This host application also supports calls to remote computers by using the `Enter-PSSession` and `Exit-PSSession` cmdlets.
- Host06 - Shows how to build an interactive console-based host application that reads commands from the command line, executes the commands, and then displays the results to the console. In addition, this sample uses the Tokenizer APIs to specify the color of the text that is entered by the user.

Provider samples

- AccessDBProviderSample01 - Shows how to declare a provider class that derives directly from the CmdletProvider class. It is included here only for completeness.
- AccessDBProviderSample02 - Shows how to overwrite the NewDrive and RemoveDrive methods to support calls to the `New-PSDrive` and `Remove-PSDrive` cmdlets. The provider class in this sample derives from the DriveCmdletProvider class.
- AccessDBProviderSample03 - Shows how to overwrite the GetItem and SetItem methods to support calls to the `Get-Item` and `Set-Item` cmdlets. The provider class in this sample derives from the ItemCmdletProvider class.
- AccessDBProviderSample04 - Shows how to overwrite container methods to support calls to the `Copy-Item`, `Get-ChildItem`, `New-Item`, and `Remove-Item` cmdlets. These methods should be implemented when the data store contains items that are containers. A container is a group of child items under a common parent item. The provider class in this sample derives from the ItemCmdletProvider class.
- AccessDBProviderSample05 - Shows how to overwrite container methods to support calls to the `Move-Item` and `Join-Path` cmdlets. These methods should be implemented when the user needs to move items within a container and if the data store contains nested containers. The provider class in this sample derives from the NavigationCmdletProvider class.
- AccessDBProviderSample06 - Shows how to overwrite content methods to support calls to the `Clear-Content`, `Get-Content`, and `Set-Content` cmdlets. These methods should be implemented when the user needs to manage the content of the items in the data store. The provider class in this sample derives from the NavigationCmdletProvider class, and it implements the `IContentCmdletProvider` interface.

Windows PowerShell Reference

Article • 09/17/2021

Windows PowerShell is a Microsoft .NET Framework-connected environment designed for administrative automation. Windows PowerShell provides a new approach to building commands, composing solutions, and creating graphical user interface-based management tools.

Windows PowerShell enables a system administrator to automate the administration of system resources by the execution of commands either directly or through scripts.

Developer Audience

The Windows PowerShell Software Development Kit (SDK) is written for command developers who require reference information about the APIs provided by Windows PowerShell. Command developers use Windows PowerShell to create both commands and providers that extend the tasks that can be performed by Windows PowerShell.

Windows PowerShell Resources

In addition to the Windows PowerShell SDK, the following resources provide more information.

[Getting Started with Windows PowerShell](#) Provides an introduction to Windows PowerShell: the language, the cmdlets, the providers, and the use of objects.

[Writing a Windows PowerShell Module](#) Provides information and examples for administrators, script developers, and cmdlet developers who need to package and distribute their Windows PowerShell solutions using Windows PowerShell modules.

[Writing a Windows PowerShell Cmdlet](#) Provides information and code examples for program managers who are designing cmdlets and for developers who are implementing cmdlet code.

[Windows PowerShell Team Blog ↗](#) The best resource for learning from and collaborating with other Windows PowerShell users. Read the Windows PowerShell Team blog, and then join the Windows PowerShell User Forum (microsoft.public.windows.powershell). Use Windows Live Search to find other Windows PowerShell blogs and resources. Then, as you develop your expertise, freely contribute your ideas.

[PowerShell module browser](#) Provides the latest versions of the command-line Help topics.

Class Libraries

[System.Management.Automation](#) This namespace is the root namespace for Windows PowerShell. It contains the classes, enumerations, and interfaces required to implement custom cmdlets. In particular, the [System.Management.Automation.Cmdlet](#) class is the base class from which all cmdlet classes must be derived. For more information about cmdlets, see.

[System.Management.Automation.Provider](#) This namespace contains the classes, enumerations, and interfaces required to implement a Windows PowerShell provider. In particular, the [System.Management.Automation.Provider.CmdletProvider](#) class is the base class from which all Windows PowerShell provider classes must be derived.

[Microsoft.PowerShell.Commands](#) This namespace contains the classes for the cmdlets and providers implemented by Windows PowerShell. Similarly, it is recommended that you create a *YourName.Commands* namespace for those cmdlets that you implement.

[System.Management.Automation.Host](#) This namespace contains the classes, enumerations, and interfaces that the cmdlet uses to define the interaction between the user and Windows PowerShell.

[System.Management.Automation.Internal](#) This namespace contains the base classes used by other namespace classes. For example, the [System.Management.Automation.Internal.CmdletMetadataAttribute](#) class is the base class for the [System.Management.CmdletAttribute](#) class.

[System.Management.Automation.Runspaces](#) This namespace contains the classes, enumerations, and interfaces used to create a Windows PowerShell runspace. In this context, the Windows PowerShell runspace is the context in which one or more Windows PowerShell pipelines invoke cmdlets. That is, cmdlets work within the context of a Windows PowerShell runspace. For more information about Windows PowerShell runspaces, see [Windows PowerShell Runspaces](#).

What's New

Article • 09/17/2021

Windows PowerShell 2.0 provides the following new features for use when writing cmdlets, providers, and host applications.

Modules

You can now package and distribute Windows PowerShell solutions by using modules. Modules allow you to partition, organize, and abstract your Windows PowerShell code into self-contained, reusable units. For more information about modules, see [Writing a Windows PowerShell Module](#).

The PowerShell class

The `PowerShell` class provides a simpler solution for creating applications, referred to as host applications, that programmatically run commands. This class allows you to create a pipeline of commands, specify the runspace that is used to run the commands, and specify invoking the commands synchronously or asynchronously.

The RunspacePool class

Runspace pools allow you to create multiple runspaces by using a single call. The `CreateRunspacePool` method provides several overloads that can be used to create runspace that have the same features, such as the same host, initial session state, and connection information.

The InitialSessionState class

The `InitialSessionState` class allows you to create a session state configuration that is used when a runspace is opened. You can create a custom configuration, a default configuration that includes the commands provided by `mshshort`, and a configuration whose commands are restricted based on the capabilities of the session.

Remote runspaces

You can now create runspace that can be opened on remote computers, allowing you to run commands on the remote machine and collect the results locally. To create a

remote runspace, you must specify information about the remote connection when creating the runspace. See the `CreateRunspace` and `CreateRunspacePool` methods for examples. The connection information is defined by the `RunspaceConnectionInfo` class.

Private runspace elements

You can now create runspaces whose elements are public or private. This allows you to create runspaces whose elements are available to the runspace, but are not available to the user. See the `ConstrainedSessionStateEntry` class to find out which elements of the runspace can be made private.

Runspace threading modes and apartment state

You can now specify how threads are created and used when running commands in a runspace. See the `System.Management.Automation.Runspaces.Runspace.ThreadOptions` and `System.Management.Automation.Runspaces.RunspacePool.ThreadOptions` properties.

You can now get the apartment state of the threads that are used to run commands in a runspace. See the `System.Management.Automation.Runspaces.Runspace.ApartmentState` and `System.Management.Automation.Runspaces.RunspacePool.ApartmentState` properties.

Transaction cmdlets

You can now create cmdlets that can be used within a transaction. When a cmdlet is used in a transaction, its actions are temporary, and they can be accepted or rejected by the transaction cmdlets provided by Windows PowerShell.

For more information about transactions, see [How to Support Transactions](#).

Transaction provider

You can now create providers that can be used within a transaction. Similar to cmdlets, when a provider is used in a transaction, its actions are temporary, and they can be accepted or rejected by the transaction cmdlets provided by Windows PowerShell.

For more information about specifying support for transaction within a provider class, see the

`System.Management.Automation.Provider.CmdletProviderAttribute.ProviderCapabilities` property.

Job cmdlets

You can now write cmdlets that can perform their action as a job. These jobs are run in the background without interacting with the current session. For more information about how Windows PowerShell supports jobs, see [Background Jobs](#).

Cmdlet output types

You can now specify the .NET Framework types that are returned by your cmdlets by declaring the `OutputType` attribute when writing your cmdlets. This will allow others to determine what type of objects are returned by a cmdlet by looking at the `OutputType` property of the cmdlet.

Event support

You can now write cmdlets that add and consume events. See the `PSEvent` class.

Proxy commands

You can now write proxy commands that can be used to run another command. A proxy command allows you to control what functionality of the source cmdlet is available to the user. For example, you can create a proxy command that removes a parameter that is supplied by the source command. See the `ProxyCommand` class.

Multiple choice prompts

You can now write applications that can provide prompts that allow the user to select multiple choices. See the `IHostUISupportsMultipleChoiceSelection` interface

Interactive sessions

You can now write applications that can start and stop an interactive session on a remote computer. See the `IHostSupportsInteractiveSession` interface.

Custom Cmdlet Help for Providers

You can now create customized Help topics for the provider cmdlets. Custom cmdlet help topics can explain how the cmdlet works in the provider path and document special features, including the dynamic parameters that the provider adds to the cmdlet.

Cmdlet Overview

Article • 09/17/2021

A cmdlet is a lightweight command that is used in the PowerShell environment. The PowerShell runtime invokes these cmdlets within the context of automation scripts that are provided at the command line. The PowerShell runtime also invokes them programmatically through PowerShell APIs.

Cmdlets

Cmdlets perform an action and typically return a Microsoft .NET object to the next command in the pipeline. A cmdlet is a single command that participates in the pipeline semantics of PowerShell. This includes binary (C#) cmdlets, advanced script functions, CDXML, and Workflows.

This SDK documentation describes how to create binary cmdlets written in C#. For information about script-based cmdlets, see:

- [about_Functions_Advanced](#)
- [about_Functions_CmdletBindingAttribute](#)
- [about_Functions_Advanced_Methods](#)

To create a binary cmdlet, you must implement a cmdlet class that derives from one of two specialized cmdlet base classes. The derived class must:

- Declare an attribute that identifies the derived class as a cmdlet.
- Define public properties that are decorated with attributes that identify the public properties as cmdlet parameters.
- Override one or more of the input processing methods to process records.

You can load the assembly that contains the class directly by using the [Import-Module](#) cmdlet, or you can create a host application that loads the assembly by using the [System.Management.Automation.Runspaces.InitialSessionState](#) API. Both methods provide programmatic and command-line access to the functionality of the cmdlet.

Cmdlet Terms

The following terms are used frequently in the PowerShell cmdlet documentation:

Cmdlet attribute

A .NET attribute that is used to declare a cmdlet class as a cmdlet. Although PowerShell uses several other attributes that are optional, the Cmdlet attribute is required. For more information about this attribute, see [Cmdlet Attribute Declaration](#).

Cmdlet parameter

The public properties that define the parameters that are available to the user or to the application that is running the cmdlet. Cmdlets can have required, named, positional, and *switch* parameters. Switch parameters allow you to define parameters that are evaluated only if the parameters are specified in the call. For more information about the different types of parameters, see [Cmdlet Parameters](#).

Parameter set

A group of parameters that can be used in the same command to perform a specific action. A cmdlet can have multiple parameter sets, but each parameter set must have at least one parameter that is unique. Good cmdlet design strongly suggests that the unique parameter also be a required parameter. For more information about parameter sets, see [Cmdlet Parameter Sets](#).

Dynamic parameter

A parameter that is added to the cmdlet at runtime. Typically, the dynamic parameters are added to the cmdlet when another parameter is set to a specific value. For more information about dynamic parameters, see [Cmdlet Dynamic Parameters](#).

Input processing methods

The [System.Management.Automation.Cmdlet](#) class provides the following virtual methods that are used to process records. All the derived cmdlet classes must override one or more of the first three methods:

- [System.Management.Automation.Cmdlet.BeginProcessing](#): Used to provide optional one-time, pre-processing functionality for the cmdlet.
- [System.Management.Automation.Cmdlet.ProcessRecord](#): Used to provide record-by-record processing functionality for the cmdlet. The [System.Management.Automation.Cmdlet.ProcessRecord](#) method might be called any number of times, or not at all, depending on the input of the cmdlet.
- [System.Management.Automation.Cmdlet.EndProcessing](#): Used to provide optional one-time, post-processing functionality for the cmdlet.

- [System.Management.Automation.Cmdlet.StopProcessing](#): Used to stop processing when the user stops the cmdlet asynchronously (for example, by pressing **CTRL + C**).

For more information about these methods, see [Cmdlet Input Processing Methods](#).

When you implement a cmdlet, you must override at least one of these input processing methods. Typically, the **ProcessRecord()** is the method that you override because it is called for every record that the cmdlet processes. In contrast, the **BeginProcessing()** method and the **EndProcessing()** method are called one time to perform pre-processing or post-processing of the records. For more information about these methods, see [Input Processing Methods](#).

ShouldProcess feature

PowerShell allows you to create cmdlets that prompt the user for feedback before the cmdlet makes a change to the system. To use this feature, the cmdlet must declare that it supports the **ShouldProcess** feature when you declare the Cmdlet attribute, and the cmdlet must call the [System.Management.Automation.Cmdlet.ShouldProcess](#) and [System.Management.Automation.Cmdlet.ShouldContinue](#) methods from within an input processing method. For more information about how to support the **ShouldProcess** functionality, see [Requesting Confirmation](#).

Transaction

A logical group of commands that are treated as a single task. The task automatically fails if any command in the group fails, and the user has the choice to accept or reject the actions performed within the transaction. To participate in a transaction, the cmdlet must declare that it supports transactions when the Cmdlet attribute is declared. Support for transactions was introduced in Windows PowerShell 2.0. For more information about transactions, see [How to Support Transactions](#).

How Cmdlets Differ from Commands

Cmdlets differ from commands in other command-shell environments in the following ways:

- Cmdlets are instances of .NET classes; they are not stand-alone executables.
- Cmdlets can be created from as few as a dozen lines of code.
- Cmdlets do not generally do their own parsing, error presentation, or output formatting. Parsing, error presentation, and output formatting are handled by the

PowerShell runtime.

- Cmdlets process input objects from the pipeline rather than from streams of text, and cmdlets typically deliver objects as output to the pipeline.
- Cmdlets are record-oriented because they process a single object at a time.

Cmdlet Base Classes

Windows PowerShell supports cmdlets that are derived from the following two base classes.

- Most cmdlets are based on .NET classes that derive from the [System.Management.Automation.Cmdlet](#) base class. Deriving from this class allows a cmdlet to use the minimum set of dependencies on the Windows PowerShell runtime. This has two benefits. The first benefit is that the cmdlet objects are smaller, and you are less likely to be affected by changes to the PowerShell runtime. The second benefit is that, if you have to, you can directly create an instance of the cmdlet object and then invoke it directly instead of invoking it through the PowerShell runtime.
- The more-complex cmdlets are based on .NET classes that derive from the [System.Management.Automation.PSCmdlet](#) base class. Deriving from this class gives you much more access to the PowerShell runtime. This access allows your cmdlet to call scripts, to access providers, and to access the current session state. (To access the current session state, you get and set session variables and preferences.) However, deriving from this class increases the size of the cmdlet object, and it means that your cmdlet is more tightly coupled to the current version of the PowerShell runtime.

In general, unless you need the extended access to the PowerShell runtime, you should derive from the [System.Management.Automation.Cmdlet](#) class. However, the PowerShell runtime has extensive logging capabilities for the execution of cmdlets. If your auditing model depends on this logging, you can prevent the execution of your cmdlet from within another cmdlet by deriving from the [System.Management.Automation.PSCmdlet](#) class.

Cmdlet Attributes

PowerShell defines several .NET attributes that are used to manage cmdlets and to specify common functionality that is provided by PowerShell and that might be required by the cmdlet. For example, attributes are used to designate a class as a cmdlet, to specify the parameters of the cmdlet, and to request the validation of input so that

cmdlet developers do not have to implement that functionality in their cmdlet code. For more information about attributes, see [PowerShell Attributes](#).

Cmdlet Names

PowerShell uses a verb-and-noun name pair to name cmdlets. For example, the `Get-Command` cmdlet included in PowerShell is used to get all the cmdlets that are registered in the command shell. The verb identifies the action that the cmdlet performs, and the noun identifies the resource on which the cmdlet performs its action.

These names are specified when the .NET class is declared as a cmdlet. For more information about how to declare a .NET class as a cmdlet, see [Cmdlet Attribute Declaration](#).

Writing Cmdlet Code

This document provides two ways to discover how cmdlet code is written. If you prefer to see the code without much explanation, see [Examples of Cmdlet Code](#). If you prefer more explanation about the code, see the [GetProc Tutorial](#), [StopProc Tutorial](#), or [SelectStr Tutorial](#) topics.

For more information about the guidelines for writing cmdlets, see [Cmdlet Development Guidelines](#).

Windows PowerShell Cmdlet Concepts

Article • 09/17/2021

This section describes how cmdlets work.

In This Section

This section includes the following topics.

[Cmdlet Development Guidelines](#) This topic provides development guidelines that can be used to produce well-formed cmdlets.

[Cmdlet Class Declaration](#) This topic describes cmdlet class declaration.

[Approved Verbs for Windows PowerShell Commands](#) This topic lists the predefined cmdlet verbs that you can use when you declare a cmdlet class.

[Cmdlet Input Processing Methods](#) This topic describes the methods that allow a cmdlet to perform preprocessing operations, input processing operations, and post processing operations.

[Cmdlet Parameters](#) This section describes the different types of parameters that you can add to cmdlets.

[Cmdlet Attributes](#) This section describes the attributes that are used to declare .NET Framework classes as cmdlets, to declare fields as cmdlet parameters, and to declare input validation rules for parameters.

[Cmdlet Aliases](#) This topic describes cmdlet aliases.

[Cmdlet Output](#) This section describes the type of output that cmdlets can return and how to define and display the objects that are returned by cmdlets.

[Registering Cmdlets](#) This section describes how to register cmdlets by using modules and snap-ins.

[Requesting Confirmation](#) This section describes how cmdlets request confirmation from a user before they make a change to the system.

[Windows PowerShell Error Reporting](#) This section describes how cmdlets report terminating errors and non-terminating errors, and it describes how to interpret error records.

[Background Jobs](#) This topic describes how cmdlets can perform their work within background jobs that do not interfere with the commands that are executing in the current session.

[Invoking Cmdlets and Scripts Within a Cmdlet](#) This topic describes how cmdlets can invoke other cmdlets and scripts from within their input processing methods.

[Cmdlet Sets](#) This topic describes using base classes to create sets of cmdlets.

[Windows PowerShell Session State](#) This topic describes Windows PowerShell session state.

Cmdlet Development Guidelines

Article • 09/17/2021

The topics in this section provide development guidelines that you can use to produce well-formed cmdlets. By leveraging the common functionality provided by the Windows PowerShell runtime and by following these guidelines, you can develop robust cmdlets with minimal effort and provide the user with a consistent experience. Additionally, you will reduce the test burden because common functionality does not require retesting.

In This Section

- [Required Development Guidelines](#)
- [Strongly Encouraged Development Guidelines](#)
- [Advisory Development Guidelines](#)

Required Development Guidelines

Article • 09/17/2021

The following guidelines must be followed when you write your cmdlets. They are separated into guidelines for designing cmdlets and guidelines for writing your cmdlet code. If you do not follow these guidelines, your cmdlets could fail, and your users might have a poor experience when they use your cmdlets.

In this Topic

Design Guidelines

- [Use Only Approved Verbs \(RD01\)](#)
- [Cmdlet Names: Characters that cannot be Used \(RD02\)](#)
- [Parameters Names that cannot be Used \(RD03\)](#)
- [Support Confirmation Requests \(RD04\)](#)
- [Support Force Parameter for Interactive Sessions \(RD05\)](#)
- [Document Output Objects \(RD06\)](#)

Code Guidelines

- [Derive from the Cmdlet or PSCmdlet Classes \(RC01\)](#)
- [Specify the Cmdlet Attribute \(RC02\)](#)
- [Override an Input Processing Method \(RC03\)](#)
- [Specify the OutputType Attribute \(RC04\)](#)
