- [Do Not Retain Handles to Output Objects \(RC05\)](#)
- [Handle Errors Robustly \(RC06\)](#)
- [Use a Windows PowerShell Module to Deploy your Cmdlets \(RC07\)](#)

Design Guidelines

The following guidelines must be followed when designing cmdlets to ensure a consistent user experience between using your cmdlets and other cmdlets. When you find a Design guideline that applies to your situation, be sure to look at the Code guidelines for similar guidelines.

Use Only Approved Verbs (RD01)

The verb specified in the Cmdlet attribute must come from the recognized set of verbs provided by Windows PowerShell. It must not be one of the prohibited synonyms. Use the constant strings that are defined by the following enumerations to specify cmdlet verbs:

- [System.Management.Automation.VerbsCommon](#)
- [System.Management.Automation.VerbsCommunications](#)
- [System.Management.Automation.VerbsData](#)
- [System.Management.Automation.VerbsDiagnostic](#)
- [System.Management.Automation.VerbsLifecycle](#)
- [System.Management.Automation.VerbsSecurity](#)
- [System.Management.Automation.VerbsOther](#)

For more information about the approved verb names, see [Cmdlet Verbs](#).

Users need a set of discoverable and expected cmdlet names. Use the appropriate verb so that the user can make a quick assessment of what a cmdlet does and to easily discover the capabilities of the system. For example, the following command-line command gets a list of all the commands on the system whose names begin with "Start": `Get-Command Start-*`. Use the nouns in your cmdlets to differentiate your cmdlets from other cmdlets. The noun indicates the resource on which the operation will be performed. The operation itself is represented by the verb.

Cmdlet Names: Characters that cannot be Used (RD02)

When you name cmdlets, do not use any of the following special characters.

[+] [Expand table](#)

Character	Name
#	number sign
,	comma
()	parentheses
{}	braces
[]	brackets
&	ampersand
-	hyphen Note: The hyphen can be used to separate the verb from the noun, but it cannot be used within the noun or within the verb.
/	slash mark
\	backslash
\$	dollar sign
^	caret
;	semicolon
:	colon
"	double quotation mark
'	single quotation mark
<>	angle brackets
	vertical bar
?	question mark
@	at sign
`	back tick (grave accent)
*	asterisk
%	percent sign
+	plus sign
=	equals sign
~	tilde

Parameters Names that cannot be Used (RD03)

Windows PowerShell provides a common set of parameters to all cmdlets plus additional parameters that are added in specific situations. When designing your own cmdlets you cannot use the following names: Confirm, Debug, ErrorAction, ErrorVariable, OutBuffer, OutVariable, WarningAction, WarningVariable, WhatIf, UseTransaction, and Verbose. For more information about these parameters, see [Common Parameter Names](#).

Support Confirmation Requests (RD04)

For cmdlets that perform an operation that modifies the system, they should call the [System.Management.Automation.Cmdlet.ShouldProcess*](#) method to request confirmation, and in special cases call the [System.Management.Automation.Cmdlet.ShouldContinue*](#) method. (The [System.Management.Automation.Cmdlet.ShouldContinue*](#) method should be called only after the [System.Management.Automation.Cmdlet.ShouldProcess*](#) method is called.)

To make these calls the cmdlet must specify that it supports confirmation requests by setting the `SupportsShouldProcess` keyword of the Cmdlet attribute. For more information about setting this attribute, see [Cmdlet Attribute Declaration](#).

Note

If the Cmdlet attribute of the cmdlet class indicates that the cmdlet supports calls to the [System.Management.Automation.Cmdlet.ShouldProcess*](#) method, and the cmdlet fails to make the call to the [System.Management.Automation.Cmdlet.ShouldProcess*](#) method, the user could modify the system unexpectedly.

Use the [System.Management.Automation.Cmdlet.ShouldProcess*](#) method for any system modification. A user preference and the `WhatIf` parameter control the [System.Management.Automation.Cmdlet.ShouldProcess*](#) method. In contrast, the [System.Management.Automation.Cmdlet.ShouldContinue*](#) call performs an additional check for potentially dangerous modifications. This method is not controlled by any user preference or the `WhatIf` parameter. If your cmdlet calls the [System.Management.Automation.Cmdlet.ShouldContinue*](#) method, it should have a `Force` parameter that bypasses the calls to these two methods and that proceeds with the operation. This is important because it allows your cmdlet to be used in non-interactive scripts and hosts.

If your cmdlets support these calls, the user can determine whether the action should actually be performed. For example, the [Stop-Process](#) cmdlet calls the [System.Management.Automation.Cmdlet.ShouldContinue*](#) method before it stops a set of critical processes, including the System, Winlogon, and Spoolsv processes.

For more information about supporting these methods, see [Requesting Confirmation](#).

Support Force Parameter for Interactive Sessions (RD05)

If your cmdlet is used interactively, always provide a Force parameter to override the interactive actions, such as prompts or reading lines of input). This is important because it allows your cmdlet to be used in non-interactive scripts and hosts. The following methods can be implemented by an interactive host.

- [System.Management.Automation.Host.PSHostUserInterface.Prompt*](#)
- [System.Management.Automation.Host.PSHostUserInterface.PromptForChoice](#)
- [System.Management.Automation.Host.IHostUISupportsMultipleChoiceSelection.PromptForChoice](#)
- [System.Management.Automation.Host.PSHostUserInterface.PromptForCredential*](#)
- [System.Management.Automation.Host.PSHostUserInterface.ReadLine*](#)
- [System.Management.Automation.Host.PSHostUserInterface.ReadLineAsSecureString*](#)

Document Output Objects (RD06)

Windows PowerShell uses the objects that are written to the pipeline. In order for users to take advantage of the objects that are returned by each cmdlet, you must document the objects that are returned, and you must document what the members of those returned objects are used for.

Code Guidelines

The following guidelines must be followed when writing cmdlet code. When you find a Code guideline that applies to your situation, be sure to look at the Design guidelines for similar guidelines.

Derive from the Cmdlet or PSCmdlet Classes (RC01)

A cmdlet must derive from either the [System.Management.Automation.Cmdlet](#) or [System.Management.Automation.PSCmdlet](#) base class. Cmdlets that derive from the [System.Management.Automation.Cmdlet](#) class do not depend on the Windows PowerShell runtime. They can be called directly from any Microsoft .NET Framework language. Cmdlets that derive from the [System.Management.Automation.PSCmdlet](#) class depend on the Windows PowerShell runtime. Therefore, they execute within a runspace.

All cmdlet classes that you implement must be public classes. For more information about these cmdlet classes, see [Cmdlet Overview](#).

Specify the Cmdlet Attribute (RC02)

For a cmdlet to be recognized by Windows PowerShell, its .NET Framework class must be decorated with the `Cmdlet` attribute. This attribute specifies the following features of the cmdlet.

- The verb-and-noun pair that identifies the cmdlet.
- The default parameter set that is used when multiple parameter sets are specified. The default parameter set is used when Windows PowerShell does not have enough information to determine which parameter set to use.
- Indicates if the cmdlet supports calls to the [System.Management.Automation.Cmdlet.ShouldProcess](#)* method. This method displays a confirmation message to the user before the cmdlet makes a change to the system. For more information about how confirmation requests are made, see [Requesting Confirmation](#).
- Indicate the impact level (or severity) of the action associated with the confirmation message. In most cases, the default value of Medium should be used. For more information about how the impact level affects the confirmation requests that are displayed to the user, see [Requesting Confirmation](#).

For more information about how to declare the cmdlet attribute, see [CmdletAttribute Declaration](#).

Override an Input Processing Method (RC03)

For the cmdlet to participate in the Windows PowerShell environment, it must override at least one of the following *input processing methods*.

[System.Management.Automation.Cmdlet.BeginProcessing](#) This method is called one time, and it is used to provide pre-processing functionality.

[System.Management.Automation.Cmdlet.ProcessRecord](#) This method is called multiple times, and it is used to provide record-by-record functionality.

[System.Management.Automation.Cmdlet.EndProcessing](#) This method is called one time, and it is used to provide post-processing functionality.

Specify the OutputType Attribute (RC04)

The `OutputType` attribute (introduced in Windows PowerShell 2.0) specifies the .NET Framework type that your cmdlet returns to the pipeline. By specifying the output type of your cmdlets you make the objects returned by your cmdlet more discoverable by other cmdlets. For more information about decorating the cmdlet class with this attribute, see [OutputType Attribute Declaration](#).

Do Not Retain Handles to Output Objects (RC05)

Your cmdlet should not retain any handles to the objects that are passed to the [System.Management.Automation.Cmdlet.WriteObject*](#) method. These objects are passed to the next cmdlet in the pipeline, or they are used by a script. If you retain the handles to the objects, two entities will own each object, which causes errors.

Handle Errors Robustly (RC06)

An administration environment inherently detects and makes important changes to the system that you are administering. Therefore, it is vital that cmdlets handle errors correctly. For more information about error records, see [Windows PowerShell Error Reporting](#).

- When an error prevents a cmdlet from continuing to process any more records, it is a terminating error. The cmdlet must call the [System.Management.Automation.Cmdlet.ThrowTerminatingError*](#) method that references an [System.Management.Automation.ErrorRecord](#) object. If an exception is not caught by the cmdlet, the Windows PowerShell runtime itself throws a terminating error that contains less information.
- For a non-terminating error that does not stop operation on the next record that is coming from the pipeline (for example, a record produced by a different process), the cmdlet must call the [System.Management.Automation.Cmdlet.WriteError*](#) method that references an [System.Management.Automation.ErrorRecord](#) object.

An example of a non-terminating error is the error that occurs if a particular process fails to stop. Calling the [System.Management.Automation.Cmdlet.WriteError](#)* method allows the user to consistently perform the actions requested and to retain the information for particular actions that fail. Your cmdlet should handle each record as independently as possible.

- The [System.Management.Automation.ErrorRecord](#) object that is referenced by the [System.Management.Automation.Cmdlet.ThrowTerminatingError](#)* and [System.Management.Automation.Cmdlet.WriteError](#)* methods requires an exception at its core. Follow the .NET Framework design guidelines when you determine the exception to use. If the error is semantically the same as an existing exception, use that exception or derive from that exception. Otherwise, derive a new exception or exception hierarchy directly from the [System.Exception](#) type.

An [System.Management.Automation.ErrorRecord](#) object also requires an error category that groups errors for the user. The user can view errors based on the category by setting the value of the `$ErrorView` shell variable to CategoryView. The possible categories are defined by the [System.Management.Automation.ErrorCategory](#) enumeration.

- If a cmdlet creates a new thread, and if the code that is running in that thread throws an unhandled exception, Windows PowerShell will not catch the error and will terminate the process.
- If an object has code in its destructor that causes an unhandled exception, Windows PowerShell will not catch the error and will terminate the process. This also occurs if an object calls Dispose methods that cause an unhandled exception.

Use a Windows PowerShell Module to Deploy your Cmdlets (RC07)

Create a Windows PowerShell module to package and deploy your cmdlets. Support for modules is introduced in Windows PowerShell 2.0. You can use the assemblies that contain your cmdlet classes directly as binary module files (this is very useful when testing your cmdlets), or you can create a module manifest that references the cmdlet assemblies. (You can also add existing snap-in assemblies when using modules.) For more information about modules, see [Writing a Windows PowerShell Module](#).

[Writing a Windows PowerShell Cmdlet](#)

Strongly Encouraged Development Guidelines

Article • 04/11/2024

This section describes guidelines that you should follow when you write your cmdlets. They are separated into guidelines for designing cmdlets and guidelines for writing your cmdlet code. You might find that these guidelines are not applicable for every scenario. However, if they do apply and you do not follow these guidelines, your users might have a poor experience when they use your cmdlets.

Design Guidelines

The following guidelines should be followed when designing cmdlets to ensure a consistent user experience between using your cmdlets and other cmdlets. When you find a Design guideline that applies to your situation, be sure to look at the Code guidelines for similar guidelines.

Use a Specific Noun for a Cmdlet Name (SD01)

Nouns used in cmdlet naming need to be very specific so that the user can discover your cmdlets. Prefix generic nouns such as "server" with a shortened version of the product name. For example, if a noun refers to a server that is running an instance of Microsoft SQL Server, use a noun such as "SQLServer". The combination of specific nouns and the short list of approved verbs enable the user to quickly discover and anticipate functionality while avoiding duplication among cmdlet names.

To enhance the user experience, the noun that you choose for a cmdlet name should be singular. For example, use the name `Get-Process` instead of `Get-Processes`. It is best to follow this rule for all cmdlet names, even when a cmdlet is likely to act upon more than one item.

Use Pascal Case for Cmdlet Names (SD02)

Use Pascal case for parameter names. In other words, capitalize the first letter of verb and all terms used in the noun. For example, "`Clear-ItemProperty`".

Parameter Design Guidelines (SD03)

A cmdlet needs parameters that receive the data on which it must operate, and parameters that indicate information that is used to determine the characteristics of the operation. For example, a cmdlet might have a `Name` parameter that receives data from the pipeline, and the cmdlet might have a `Force` parameter to indicate that the cmdlet can be forced to perform its operation. There is no limit to the number of parameters that a cmdlet can define.

Use Standard Parameter Names

Your cmdlet should use standard parameter names so that the user can quickly determine what a particular parameter means. If a more specific name is required, use a standard parameter name, and then specify a more specific name as an alias. For example, the `Get-Service` cmdlet has a parameter that has a generic name (`Name`) and a more specific alias (`ServiceName`). Both terms can be used to specify the parameter.

For more information about parameter names and their data types, see [Cmdlet Parameter Name and Functionality Guidelines](#).

Use Singular Parameter Names

Avoid using plural names for parameters whose value is a single element. This includes parameters that take arrays or lists because the user might supply an array or list with only one element.

Plural parameter names should be used only in those cases where the value of the parameter is always a multiple-element value. In these cases, the cmdlet should verify that multiple elements are supplied, and the cmdlet should display a warning to the user if multiple elements are not supplied.

Use Pascal Case for Parameter Names

Use Pascal case for parameter names. In other words, capitalize the first letter of each word in the parameter name, including the first letter of the name. For example, the parameter name `ErrorAction` uses the correct capitalization. The following parameter names use incorrect capitalization:

- `errorAction`
- `erroraction`

Parameters That Take a List of Options

There are two ways to create a parameter whose value can be selected from a set of options.

- Define an enumeration type (or use an existing enumeration type) that specifies the valid values. Then, use the enumeration type to create a parameter of that type.
- Add the **ValidateSet** attribute to the parameter declaration. For more information about this attribute, see [ValidateSet Attribute Declaration](#).

Use Standard Types for Parameters

To ensure consistency with other cmdlets, use standard types for parameters wherever possible. For more information about the types that should be used for different parameters, see [Standard Cmdlet Parameter Names and Types](#). This topic provides links to several topics that describe the names and .NET Framework types for groups of standard parameters, such as the "activity parameters".

Use Strongly-Typed .NET Framework Types

Parameters should be defined as .NET Framework types to provide better parameter validation. For example, parameters that are restricted to one value from a set of values should be defined as an enumeration type. To support a Uniform Resource Identifier (URI) value, define the parameter as a [System.Uri](#) type. Avoid basic string parameters for all but free-form text properties.

Use Consistent Parameter Types

When the same parameter is used by multiple cmdlets, always use the same parameter type. For example, if the `Process` parameter is a [System.Int16](#) type for one cmdlet, do not make the `Process` parameter for another cmdlet a [System.UInt16](#) type.

Parameters That Take True and False

If your parameter takes only `true` and `false`, define the parameter as type [System.Management.Automation.SwitchParameter](#). A switch parameter is treated as `true` when it is specified in a command. If the parameter is not included in a command, Windows PowerShell considers the value of the parameter to be `false`. Do not define Boolean parameters.

If your parameter needs to differentiate between 3 values: \$true, \$false and "unspecified", then define a parameter of type Nullable<bool>. The need for a 3rd, "unspecified" value typically occurs when the cmdlet can modify a Boolean property of an object. In this case "unspecified" means to not change the current value of the property.

Support Arrays for Parameters

Frequently, users must perform the same operation against multiple arguments. For these users, a cmdlet should accept an array as parameter input so that a user can pass the arguments into the parameter as a Windows PowerShell variable. For example, the [Get-Process](#) cmdlet uses an array for the strings that identify the names of the processes to retrieve.

Support the PassThru Parameter

By default, many cmdlets that modify the system, such as the [Stop-Process](#) cmdlet, act as "sinks" for objects and do not return a result. These cmdlet should implement the `PassThru` parameter to force the cmdlet to return an object. When the `PassThru` parameter is specified, the cmdlet returns an object by using a call to the [System.Management.Automation.Cmdlet.WriteObject](#) method. For example, the following command stops the Calc (CalculatorApp.exe) and passes the resultant process to the pipeline.

```
PowerShell
```

```
Stop-Process -Name CalculatorApp -PassThru
```

In most cases, Add, Set, and New cmdlets should support a `PassThru` parameter.

Support Parameter Sets

A cmdlet is intended to accomplish a single purpose. However, there is frequently more than one way to describe the operation or the operation target. For example, a process might be identified by its name, by its identifier, or by a process object. The cmdlet should support all the reasonable representations of its targets. Normally, the cmdlet satisfies this requirement by specifying sets of parameters (referred to as parameter sets) that operate together. A single parameter can belong to any number of parameter sets. For more information about parameter sets, see [Cmdlet Parameter Sets](#).

When you specify parameter sets, set only one parameter in the set to `ValueFromPipeline`. For more information about how to declare the `Parameter` attribute, see [ParameterAttribute Declaration](#).

When parameter sets are used, the default parameter set is defined by the `Cmdlet` attribute. The default parameter set should include the parameters most likely to be used in an interactive Windows PowerShell session. For more information about how to declare the `Cmdlet` attribute, see [CmdletAttribute Declaration](#).

Provide Feedback to the User (SD04)

Use the guidelines in this section to provide feedback to the user. This feedback allows the user to be aware of what is occurring in the system and to make better administrative decisions.

The Windows PowerShell runtime allows a user to specify how to handle output from each call to the `Write` method by setting a preference variable. The user can set several preference variables, including a variable that determines whether the system should display information and a variable that determines whether the system should query the user before taking further action.

Support the `WriteWarning`, `WriteVerbose`, and `WriteDebug` Methods

A cmdlet should call the [System.Management.Automation.Cmdlet.WriteWarning](#) method when the cmdlet is about to perform an operation that might have an unintended result. For example, a cmdlet should call this method if the cmdlet is about to overwrite a read-only file.

A cmdlet should call the [System.Management.Automation.Cmdlet.WriteVerbose](#) method when the user requires some detail about what the cmdlet is doing. For example, a cmdlet should call this information if the cmdlet author feels that there are scenarios that might require more information about what the cmdlet is doing.

The cmdlet should call the [System.Management.Automation.Cmdlet.WriteDebug](#) method when a developer or product support engineer must understand what has corrupted the cmdlet operation. It is not necessary for the cmdlet to call the [System.Management.Automation.Cmdlet.WriteDebug](#) method in the same code that calls the [System.Management.Automation.Cmdlet.WriteVerbose](#) method because the `Debug` parameter presents both sets of information.

Support WriteProgress for Operations that take a Long Time

Cmdlet operations that take a long time to complete and that cannot run in the background should support progress reporting through periodic calls to the [System.Management.Automation.Cmdlet.WriteProgress](#) method.

Use the Host Interfaces

Occasionally, a cmdlet must communicate directly with the user instead of by using the various Write or Should methods supported by the [System.Management.Automation.Cmdlet](#) class. In this case, the cmdlet should derive from the [System.Management.Automation.PSCmdlet](#) class and use the [System.Management.Automation.PSCmdlet.Host*](#) property. This property supports different levels of communication type, including the PromptForChoice, Prompt, and WriteLine/ReadLine types. At the most specific level, it also provides ways to read and write individual keys and to deal with buffers.

Unless a cmdlet is specifically designed to generate a graphical user interface (GUI), it should not bypass the host by using the [System.Management.Automation.PSCmdlet.Host*](#) property. An example of a cmdlet that is designed to generate a GUI is the [Out-GridView](#) cmdlet.

 **Note**

Cmdlets should not use the [System.Console](#) API.

Create a Cmdlet Help File (SD05)

For each cmdlet assembly, create a Help.xml file that contains information about the cmdlet. This information includes a description of the cmdlet, descriptions of the cmdlet's parameters, examples of the cmdlet's use, and more.

Code Guidelines

The following guidelines should be followed when coding cmdlets to ensure a consistent user experience between using your cmdlets and other cmdlets. When you find a Code guideline that applies to your situation, be sure to look at the Design guidelines for similar guidelines.

Coding Parameters (SC01)

Define a parameter by declaring a public property of the cmdlet class that is decorated with the **Parameter** attribute. Parameters do not have to be static members of the derived .NET Framework class for the cmdlet. For more information about how to declare the **Parameter** attribute, see [Parameter Attribute Declaration](#).

Support Windows PowerShell Paths

The Windows PowerShell path is the mechanism for normalizing access to namespaces. When you assign a Windows PowerShell path to a parameter in the cmdlet, the user can define a custom "drive" that acts as a shortcut to a specific path. When a user designates such a drive, stored data, such as data in the Registry, can be used in a consistent way.

If your cmdlet allows the user to specify a file or a data source, it should define a parameter of type [System.String](#). If more than one drive is supported, the type should be an array. The name of the parameter should be `Path`, with an alias of `PSPath`. Additionally, the `Path` parameter should support wildcard characters. If support for wildcard characters is not required, define a `LiteralPath` parameter.

If the data that the cmdlet reads or writes has to be a file, the cmdlet should accept Windows PowerShell path input, and the cmdlet should use the [System.Management.Automation.SessionState.Path](#) property to translate the Windows PowerShell paths into paths that the file system recognizes. The specific mechanisms include the following methods:

- [System.Management.Automation.PSCmdlet.GetResolvedProviderPathFromPSPath](#)
- [System.Management.Automation.PSCmdlet.GetUnresolvedProviderPathFromPSPat h](#)
- [System.Management.Automation.PathIntrinsics.GetResolvedProviderPathFromPSPath](#)
- [System.Management.Automation.PathIntrinsics.GetUnresolvedProviderPathFromPS Path](#)

If the data that the cmdlet reads or writes is only a set of strings instead of a file, the cmdlet should use the provider content information (`Content` member) to read and write. This information is obtained from the [System.Management.Automation.Provider.CmdletProvider.InvokeProvider](#) property. These mechanisms allow other data stores to participate in the reading and writing of data.

Support Wildcard Characters

A cmdlet should support wildcard characters if possible. Support for wildcard characters occurs in many places in a cmdlet (especially when a parameter takes a string to identify one object from a set of objects). For example, the sample `Stop-Proc` cmdlet from the [StopProc Tutorial](#) defines a `Name` parameter to handle strings that represent process names. This parameter supports wildcard characters so that the user can easily specify the processes to stop.

When support for wildcard characters is available, a cmdlet operation usually produces an array. Occasionally, it does not make sense to support an array because the user might use only a single item at a time. For example, the `Set-Location` cmdlet does not need to support an array because the user is setting only a single location. In this instance, the cmdlet still supports wildcard characters, but it forces resolution to a single location.

For more information about wildcard-character patterns, see [Supporting Wildcard Characters in Cmdlet Parameters](#).

Defining Objects

This section contains guidelines for defining objects for cmdlets and for extending existing objects.

Define Standard Members

Define standard members to extend an object type in a custom `Types.ps1xml` file (use the Windows PowerShell `Types.ps1xml` file as a template). Standard members are defined by a node with the name `PSStandardMembers`. These definitions allow other cmdlets and the Windows PowerShell runtime to work with your object in a consistent way.

Define ObjectMembers to Be Used as Parameters

If you are designing an object for a cmdlet, ensure that its members map directly to the parameters of the cmdlets that will use it. This mapping allows the object to be easily sent to the pipeline and to be passed from one cmdlet to another.

Preeexisting .NET Framework objects that are returned by cmdlets are frequently missing some important or convenient members that are needed by the script developer or user. These missing members can be particularly important for display and for creating the correct member names so that the object can be correctly passed to the pipeline. Create a custom `Types.ps1xml` file to document these required members. When you

create this file, we recommend the following naming convention:

<Your_Product_Name>.Types.ps1xml.

For example, you could add a `Mode` script property to the `System.IO.FileInfo` type to display the attributes of a file more clearly. Additionally, you could add a `Count` alias property to the `System.Array` type to allow the consistent use of that property name (instead of `Length`).

Implement the `IComparable` Interface

Implement a `System.IComparable` interface on all output objects. This allows the output objects to be easily piped to various sorting and analysis cmdlets.

Update Display Information

If the display for an object does not provide the expected results, create a custom <*YourProductName*>.Format.ps1xml file for that object.

Support Well Defined Pipeline Input (SC02)

Implement for the Middle of a Pipeline

Implement a cmdlet assuming that it will be called from the middle of a pipeline (that is, other cmdlets will produce its input or consume its output). For example, you might assume that the `Get-Process` cmdlet, because it generates data, is used only as the first cmdlet in a pipeline. However, because this cmdlet is designed for the middle of a pipeline, this cmdlet allows previous cmdlets or data in the pipeline to specify the processes to retrieve.

Support Input from the Pipeline

In each parameter set for a cmdlet, include at least one parameter that supports input from the pipeline. Support for pipeline input allows the user to retrieve data or objects, to send them to the correct parameter set, and to pass the results directly to a cmdlet.

A parameter accepts input from the pipeline if the `Parameter` attribute includes the `ValueFromPipeline` keyword, the `ValueFromPipelineByPropertyName` keyword attribute, or both keywords in its declaration. If none of the parameters in a parameter set support the `ValueFromPipeline` or `ValueFromPipelineByPropertyName` keywords, the cmdlet

cannot meaningfully be placed after another cmdlet because it will ignore any pipeline input.

Support the ProcessRecord Method

To accept all the records from the preceding cmdlet in the pipeline, your cmdlet must implement the [System.Management.Automation.Cmdlet.ProcessRecord](#) method. Windows PowerShell calls this method multiple times, once for every record that is sent to your cmdlet.

Write Single Records to the Pipeline (SC03)

When a cmdlet returns objects, the cmdlet should write the objects immediately as they are generated. The cmdlet should not hold them in order to buffer them into a combined array. The cmdlets that receive the objects as input will then be able to process, display, or process and display the output objects without delay. A cmdlet that generates output objects one at a time should call the [System.Management.Automation.Cmdlet.WriteObject](#) method. A cmdlet that generates output objects in batches (for example, because an underlying API returns an array of output objects) should call the [System.Management.Automation.Cmdlet.WriteObject](#) Method with its second parameter set to `true`.

Make Cmdlets Case-Insensitive and Case-Preserving (SC04)

By default, Windows PowerShell itself is case-insensitive. However, because it deals with many preexisting systems, Windows PowerShell does preserve case for ease of operation and compatibility. In other words, if a character is supplied in uppercase letters, Windows PowerShell keeps it in uppercase letters. For systems to work well, a cmdlet needs to follow this convention. If possible, it should operate in a case-insensitive way. It should, however, preserve the original case for cmdlets that occur later in a command or in the pipeline.

[Required Development Guidelines](#)

[Advisory Development Guidelines](#)

[Writing a Windows PowerShell Cmdlet](#)

Advisory Development Guidelines

Article • 05/22/2025

This section describes guidelines that you should consider to ensure good development and user experiences. Sometimes they might apply, and sometimes they might not.

Design Guidelines

The following guidelines should be considered when designing cmdlets. When you find a Design guideline that applies to your situation, be sure to look at the Code guidelines for similar guidelines.

Support an InputObject Parameter (AD01)

Because Windows PowerShell works directly with Microsoft .NET Framework objects, a .NET Framework object is often available that exactly matches the type the user needs to perform a particular operation. `InputObject` is the standard name for a parameter that takes such an object as input. For example, the sample `Stop-Proc` cmdlet in the [StopProc Tutorial](#) defines an `InputObject` parameter of type `Process` that supports the input from the pipeline. The user can get a set of process objects, manipulate them to select the exact objects to stop, and then pass them to the `Stop-Proc` cmdlet directly.

Support the Force Parameter (AD02)

Occasionally, a cmdlet needs to protect the user from performing a requested operation. Such a cmdlet should support a `Force` parameter to allow the user to override that protection if the user has permissions to perform the operation.

For example, the `Remove-Item` cmdlet doesn't normally remove a read-only file. However, this cmdlet supports a `Force` parameter so a user can force removal of a read-only file. If the user already has permission to modify the read-only attribute, and the user removes the file, use of the `Force` parameter simplifies the operation. However, if the user doesn't have permission to remove the file, the `Force` parameter has no effect.

Handle Credentials Through Windows PowerShell (AD03)

A cmdlet should define a `Credential` parameter to represent credentials. This parameter must be of type `System.Management.Automation.PSCredential` and must be defined using a Credential attribute declaration. This support automatically prompts the user for the user

name, for the password, or for both when a full credential isn't supplied directly. For more information about the Credential attribute, see [Credential Attribute Declaration](#).

Support Encoding Parameters (AD04)

If your cmdlet reads or writes text to or from a binary form, such as writing to or reading from a file in a filesystem, then your cmdlet has to have Encoding parameter that specifies how the text is encoded in the binary form.

Test Cmdlets Should Return a Boolean (AD05)

Cmdlets that perform tests against their resources should return a [System.Boolean](#) type to the pipeline so that they can be used in conditional expressions.

Code Guidelines

The following guidelines should be considered when writing cmdlet code. When you find a guideline that applies to your situation, be sure to look at the Design guidelines for similar guidelines.

Follow Cmdlet Class Naming Conventions (AC01)

By following standard naming conventions, you make your cmdlets more discoverable, and you help the user understand exactly what the cmdlets do. This practice is particularly important for other developers using Windows PowerShell because cmdlets are public types.

Define a Cmdlet in the Correct Namespace

You normally define the class for a cmdlet in a .NET Framework namespace that appends `.Commands` to the namespace that represents the product in which the cmdlet runs. For example, cmdlets that are included with Windows PowerShell are defined in the `Microsoft.PowerShell.Commands` namespace.

Name the Cmdlet Class to Match the Cmdlet Name

When you name the .NET Framework class that implements a cmdlet, name the class `<Verb>` `<Noun>Command`, where you replace the `<Verb>` and `<Noun>` placeholders with the verb and noun used for the cmdlet name. For example, the [Get-Process](#) cmdlet is implemented by a class called `GetProcessCommand`.

If No Pipeline Input Override the BeginProcessing Method (AC02)

If your cmdlet doesn't accept input from the pipeline, processing should be implemented in the [System.Management.Automation.Cmdlet.BeginProcessing](#) method. Use of this method allows Windows PowerShell to maintain ordering between cmdlets. The first cmdlet in the pipeline always returns its objects before the remaining cmdlets in the pipeline get a chance to start their processing.

To Handle Stop Requests Override the StopProcessing Method (AC03)

Override the [System.Management.Automation.Cmdlet.StopProcessing](#) method so that your cmdlet can handle stop signal. Some cmdlets take a long time to complete their operation, and they let a long time pass between calls to the Windows PowerShell runtime, such as when the cmdlet blocks the thread in long-running RPC calls. This includes cmdlets that make calls to the [System.Management.Automation.Cmdlet.WriteObject](#) method, to the [System.Management.Automation.Cmdlet.LogError](#) method, and to other feedback mechanisms that may take a long time to complete. For these cases the user might need to send a stop signal to these cmdlets.

Implement the IDisposable Interface (AC04)

If your cmdlet has objects that aren't disposed of (written to the pipeline) by the [System.Management.Automation.Cmdlet.ProcessRecord](#) method, your cmdlet might require additional object disposal. For example, if your cmdlet opens a file handle in its [System.Management.Automation.Cmdlet.BeginProcessing](#) method and keeps the handle open for use by the [System.Management.Automation.Cmdlet.ProcessRecord](#) method, this handle has to be closed at the end of processing.

The Windows PowerShell runtime doesn't always call the [System.Management.Automation.Cmdlet.EndProcessing](#) method. For example, the [System.Management.Automation.Cmdlet.EndProcessing](#) method might not be called if the cmdlet is canceled midway through its operation or if a terminating error occurs in any part of the cmdlet. Therefore, the .NET Framework class for a cmdlet that requires object cleanup should implement the complete [System.IDisposable](#) interface pattern, including the finalizer, so that the Windows PowerShell runtime can call both the [System.Management.Automation.Cmdlet.EndProcessing](#) and [System.IDisposable.Dispose*](#) methods at the end of processing.

Use Serialization-friendly Parameter Types (AC05)

To support running your cmdlet on remote computers, use types that can be serialized on the client computer and then rehydrated on the server computer. The following types are serialization-friendly.

Primitive types:

- Byte, SByte, Decimal, Single, Double, Int16, Int32, Int64, UInt16, UInt32, and UInt64.
- Boolean, Guid, Byte[], TimeSpan, DateTime, Uri, and Version.
- Char, String, XmlDocument.

Built-in rehydratable types:

- PSPrimitiveDictionary
- SwitchParameter
- PSListModifier
- PSCredential
- IPAddress, MailAddress
- CultureInfo
- X509Certificate2, X500DistinguishedName
- DirectorySecurity, FileSecurity, RegistrySecurity

Other types:

- SecureString
- Containers (lists and dictionaries of the above type)

Use SecureString for Sensitive Data (AC06)

When handling sensitive data always use the [System.Security.SecureString](#) data type. This could include pipeline input to parameters, as well as returning sensitive data to the pipeline.

While .NET recommends against using **SecureString** for new development, PowerShell continues to support the **SecureString** class for backward compatibility. Using a **SecureString** is still more secure than using a plain text string. PowerShell still relies on the **SecureString** type to avoid accidentally exposing the contents to the console or in logs. Use **SecureString** carefully, because it can be easily converted to a plain text string. For a full discussion about using **SecureString**, see the [System.Security.SecureString class](#) documentation.

Writing a Windows PowerShell Cmdlet

Cmdlet Class Declaration

Article • 09/17/2021

A Microsoft .NET Framework class is declared as a cmdlet by specifying the **Cmdlet** attribute as metadata for the class. (The **Cmdlet** attribute is the only required attribute for all cmdlets). When you specify the **Cmdlet** attribute, you must specify the verb-and-noun pair that identifies the cmdlet to the user. And, you must describe the Windows PowerShell functionality that the cmdlet supports. For more information about the declaration syntax that is used to specify the **Cmdlet** attribute, see [Cmdlet Attribute Declaration](#).

ⓘ Note

The **Cmdlet** attribute is defined by the **System.Management.Automation.CmdletAttribute** class. The properties of this class correspond to the declaration parameters that are used when you declare the attribute.

Nouns

The noun of the cmdlet specifies the resources upon which the cmdlet acts. The noun differentiates your cmdlets from other cmdlets.

Nouns in cmdlet names must be specific, and in the case of generic nouns, such as *server*, it is best to add a short prefix that differentiates your resource from other similar resources. For example, a cmdlet name that includes a noun with a prefix is `Get-SQLServer`. The combination of a specific noun with a more general verb enables the user to quickly locate the cmdlet by its action and then identify the cmdlet by its resource while avoiding unnecessary cmdlet name duplication.

For a list of special characters that cannot be used in cmdlet names, see [Required Development Guidelines](#).

Verbs

When you specify a verb, the development guidelines require you to use one of the predefined verbs provided by Windows PowerShell. By using one of these predefined verbs, you will ensure consistency between the cmdlets that you write and the cmdlets

that are written by Microsoft and by others. For example, the "Get" verb is used for cmdlets that retrieve data.

For more information about guidelines for verbs, see [Cmdlet Verb Names](#). For a list of special characters that cannot be used in cmdlet names, see [Required Development Guidelines](#).

Supporting Windows PowerShell Functionality

The **Cmdlet** attribute also allows you to specify that your cmdlet supports some of the common functionality that is provided by Windows PowerShell. This includes support for common functionality such as user feedback confirmation (referred to as support for the `ShouldProcess` feature) and support for transactions. (Support for transactions was introduced in Windows PowerShell 2.0).

For more information about the declaration syntax that is used to specify the **Cmdlet** attribute, see [Cmdlet Attribute Declaration](#).

Cmdlet Class Definition

The following code is the definition for a `GetProc` cmdlet class. Notice that Pascal casing is used and that the name of the class includes the verb and noun of the cmdlet.

```
C#  
  
[Cmdlet(VerbsCommon.Get, "Proc")]
public class GetProcCommand : Cmdlet
```

Pascal Casing

When you name cmdlets, use Pascal casing. For example, the `Get-Item` and `Get-ItemProperty` cmdlets show the correct way to use capitalization when you are naming cmdlets.

Approved Verbs for PowerShell Commands

Article • 04/29/2025

PowerShell uses a verb-noun pair for the names of cmdlets and for their derived .NET classes. The verb part of the name identifies the action that the cmdlet performs. The noun part of the name identifies the entity on which the action is performed. For example, the `Get-Command` cmdlet retrieves all the commands that are registered in PowerShell.

ⓘ Note

PowerShell uses the term *verb* to describe a word that implies an action even if that word isn't a standard verb in the English language. For example, the term `New` is a valid PowerShell verb name because it implies an action even though it isn't a verb in the English language.

Each approved verb has a corresponding *alias prefix* defined. We use this alias prefix in aliases for commands using that verb. For example, the alias prefix for `Import` is `ip` and, accordingly, the alias for `Import-Module` is `ipmo`. This is a recommendation but not a rule; in particular, it need not be respected for command aliases mimicking well known commands from other environments.

Verb Naming Recommendations

The following recommendations help you choose an appropriate verb for your cmdlet, to ensure consistency between the cmdlets that you create, the cmdlets that are provided by PowerShell, and the cmdlets that are designed by others.

- Use one of the predefined verb names provided by PowerShell
- Use the verb to describe the general scope of the action, and use parameters to further refine the action of the cmdlet.
- Don't use a synonym of an approved verb. For example, always use `Remove`, never use `Delete` or `Eliminate`.
- Use only the form of each verb that's listed in this topic. For example, use `Get`, but don't use `Getting` or `Gets`.
- Don't use the following reserved verbs or aliases. The PowerShell language and a rare few cmdlets use these verbs under exceptional circumstances.
 - `ForEach` (`foreach`)
 - `Ping` (`pi`)
 - `Sort` (`sr`)

- o `Tee` (`te`)
- o `Where` (`wh`)

You may get a complete list of verbs using the `Get-Verb` cmdlet.

Similar Verbs for Different Actions

The following similar verbs represent different actions.

`New` VS. `Add`

Use the `New` verb to create a new resource. Use the `Add` to add something to an existing container or resource. For example, `Add-Content` adds output to an existing file.

`New` VS. `Set`

Use the `New` verb to create a new resource. Use the `Set` verb to modify an existing resource, optionally creating it if it doesn't exist, such as the `Set-Variable` cmdlet.

`Find` VS. `Search`

Use the `Find` verb to look for an object. Use the `Search` verb to create a reference to a resource in a container.

`Get` VS. `Read`

Use the `Get` verb to obtain information about a resource (such as a file) or to obtain an object with which you can access the resource in future. Use the `Read` verb to open a resource and extract information contained within.

`Invoke` VS. `Start`

Use the `Invoke` verb to perform synchronous operations, such as running a command and waiting for it to end. Use the `Start` verb to begin asynchronous operations, such as starting an autonomous process.

`Ping` VS. `Test`

Use the `Test` verb.

Common Verbs

PowerShell uses the [System.Management.Automation.VerbsCommon](#) enumeration class to define generic actions that can apply to almost any cmdlet. The following table lists most of the defined verbs.

 Expand table

Verb (alias)	Action	Synonyms to avoid
Add (a)	Adds a resource to a container, or attaches an item to another item. For example, the <code>Add-Content</code> cmdlet adds content to a file. This verb is paired with <code>Remove</code> .	Append, Attach, Concatenate, Insert
Clear (cl)	Removes all the resources from a container but doesn't delete the container. For example, the <code>Clear-Content</code> cmdlet removes the contents of a file but doesn't delete the file.	Flush, Erase, Release, Unmark, Unset, Nullify
Close (cs)	Changes the state of a resource to make it inaccessible, unavailable, or unusable. This verb is paired with <code>Open</code> .	
Copy (cp)	Copies a resource to another name or to another container. For example, the <code>Copy-Item</code> cmdlet copies an item (such as a file) from one location in the data store to another location.	Duplicate, Clone, Replicate, Sync
Enter (et)	Specifies an action that allows the user to move into a resource. For example, the <code>Enter-PSSession</code> cmdlet places the user in an interactive session. This verb is paired with <code>Exit</code> .	Push, Into
Exit (ex)	Sets the current environment or context to the most recently used context. For example, the <code>Exit-PSSession</code> cmdlet places the user in the session that was used to start the interactive session. This verb is paired with <code>Enter</code> .	Pop, Out
Find (fd)	Looks for an object in a container that's unknown, implied, optional, or specified.	Search
Format (f)	Arranges objects in a specified form or layout	
Get (g)	Specifies an action that retrieves a resource. This verb is paired with <code>Set</code> .	Read, Open, Cat, Type, Dir, Obtain, Dump, Acquire, Examine, Find, Search
Hide (h)	Makes a resource undetectable. For example, a cmdlet whose name includes the Hide verb might conceal a service from a user. This verb is paired with <code>Show</code> .	Block

Verb (alias)	Action	Synonyms to avoid
Join (j)	Combines resources into one resource. For example, the <code>Join-Path</code> cmdlet combines a path with one of its child paths to create a single path. This verb is paired with <code>Split</code> .	Combine, Unite, Connect, Associate
Lock (lk)	Secures a resource. This verb is paired with <code>Unlock</code> .	Restrict, Secure
Move (m)	Moves a resource from one location to another. For example, the <code>Move-Item</code> cmdlet moves an item from one location in the data store to another location.	Transfer, Name, Migrate
New (n)	Creates a resource. (The <code>Set</code> verb can also be used when creating a resource that includes data, such as the <code>Set-Variable</code> cmdlet.)	Create, Generate, Build, Make, Allocate
Open (op)	Changes the state of a resource to make it accessible, available, or usable. This verb is paired with <code>Close</code> .	
Optimize (om)	Increases the effectiveness of a resource.	
Pop (pop)	Removes an item from the top of a stack. For example, the <code>Pop-Location</code> cmdlet changes the current location to the location that was most recently pushed onto the stack.	
Push (pu)	Adds an item to the top of a stack. For example, the <code>Push-Location</code> cmdlet pushes the current location onto the stack.	
Redo (re)	Resets a resource to the state that was undone.	
Remove (r)	Deletes a resource from a container. For example, the <code>Remove-Variable</code> cmdlet deletes a variable and its value. This verb is paired with <code>Add</code> .	Clear, Cut, Dispose, Discard, Erase
Rename (rn)	Changes the name of a resource. For example, the <code>Rename-Item</code> cmdlet, which is used to access stored data, changes the name of an item in the data store.	Change
Reset (rs)	Sets a resource back to its original state.	
Resize(rz)	Changes the size of a resource.	
Search (sr)	Creates a reference to a resource in a container.	Find, Locate
Select (sc)	Locates a resource in a container. For example, the <code>Select-String</code> cmdlet finds text in strings and files.	Find, Locate

Verb (alias)	Action	Synonyms to avoid
Set (s)	Replaces data on an existing resource or creates a resource that contains some data. For example, the Set-Date cmdlet changes the system time on the local computer. (The New verb can also be used to create a resource.) This verb is paired with Get.	Write, Reset, Assign, Configure, Update
Show (sh)	Makes a resource visible to the user. This verb is paired with Hide.	Display, Produce
Skip (sk)	Bypasses one or more resources or points in a sequence.	Bypass, Jump
Split (s1)	Separates parts of a resource. For example, the Split-Path cmdlet returns different parts of a path. This verb is paired with Join.	Separate
Step (st)	Moves to the next point or resource in a sequence.	
Switch (sw)	Specifies an action that alternates between two resources, such as to change between two locations, responsibilities, or states.	
Undo (un)	Sets a resource to its previous state.	
Unlock (uk)	Releases a resource that was locked. This verb is paired with Lock.	Release, Unrestrict, Unsecure
Watch (wc)	Continually inspects or monitors a resource for changes.	

Communications Verbs

PowerShell uses the [System.Management.Automation.VerbsCommunications](#) class to define actions that apply to communications. The following table lists most of the defined verbs.

[\[+\] Expand table](#)

Verb (alias)	Action	Synonyms to avoid
Connect (cc)	Creates a link between a source and a destination. This verb is paired with Disconnect.	Join, Telnet, Login
Disconnect (dc)	Breaks the link between a source and a destination. This verb is paired with Connect.	Break, Logoff
Read (rd)	Acquires information from a source. This verb is paired with Write.	Acquire, Prompt, Get
Receive (rc)	Accepts information sent from a source. This verb is paired with Read.	Read, Accept, Peek

Verb (alias)	Action	Synonyms to avoid
	Send .	
Send (sd)	Delivers information to a destination. This verb is paired with Receive .	Put, Broadcast, Mail, Fax
Write (wr)	Adds information to a target. This verb is paired with Read .	Put, Print

Data Verbs

PowerShell uses the [System.Management.Automation.VerbsData](#) class to define actions that apply to data handling. The following table lists most of the defined verbs.

[\[+\] Expand table](#)

Verb Name (alias)	Action	Synonyms to avoid
Backup (ba)	Stores data by replicating it.	Save, Burn, Replicate, Sync
Checkpoint (ch)	Creates a snapshot of the current state of the data or of its configuration.	Diff
Compare (cr)	Evaluates the data from one resource against the data from another resource.	Diff
Compress (cm)	Compacts the data of a resource. Pairs with Expand .	Compact
Convert (cv)	Changes the data from one representation to another when the cmdlet supports bidirectional conversion or when the cmdlet supports conversion between multiple data types.	Change, Resize, Resample
ConvertFrom (cf)	Converts one primary type of input (the cmdlet noun indicates the input) to one or more supported output types.	Export, Output, Out
ConvertTo (ct)	Converts from one or more types of input to a primary output type (the cmdlet noun indicates the output type).	Import, Input, In
Dismount (dm)	Detaches a named entity from a location. This verb is paired with Mount .	Unmount, Unlink
Edit (ed)	Modifies existing data by adding or removing content.	Change, Update, Modify
Expand (en)	Restores the data of a resource that has been compressed to its original state. This verb is paired with Compress .	Explode, Uncompress

Verb Name (alias)	Action	Synonyms to avoid
Export (ep)	Encapsulates the primary input into a persistent data store, such as a file, or into an interchange format. This verb is paired with Import.	Extract, Backup
Group (gp)	Arranges or associates one or more resources	
Import (ip)	Creates a resource from data that's stored in a persistent data store (such as a file) or in an interchange format. For example, the Import-Csv cmdlet imports data from a comma-separated value (.csv) file to objects that can be used by other cmdlets. This verb is paired with Export.	BulkLoad, Load
Initialize (in)	Prepares a resource for use, and sets it to a default state.	Erase, Init, Renew, Rebuild, Reinitialize, Setup
Limit (l)	Applies constraints to a resource.	Quota
Merge (mg)	Creates a single resource from multiple resources.	Combine, Join
Mount (mt)	Attaches a named entity to a location. This verb is paired with Dismount.	Connect
Out (o)	Sends data out of the environment. For example, the Out-Printer cmdlet sends data to a printer.	
Publish (pb)	Makes a resource available to others. This verb is paired with Unpublish.	Deploy, Release, Install
Restore (rr)	Sets a resource to a predefined state, such as a state set by Checkpoint. For example, the Restore-Computer cmdlet starts a system restore on the local computer.	Repair, Return, Undo, Fix
Save (sv)	Preserves data to avoid loss.	
Sync (sy)	Assures that two or more resources are in the same state.	Replicate, Coerce, Match
Unpublish (ub)	Makes a resource unavailable to others. This verb is paired with Publish.	Uninstall, Revert, Hide
Update (ud)	Brings a resource up-to-date to maintain its state, accuracy, conformance, or compliance. For example, the Update-FormatData cmdlet updates and adds formatting files to the current PowerShell console.	Refresh, Renew, Recalculate, Re-index

Diagnostic Verbs

PowerShell uses the [System.Management.Automation.VerbsDiagnostic](#) class to define actions that apply to diagnostics. The following table lists most of the defined verbs.

[+] [Expand table](#)

Verb (alias)	Action	Synonyms to avoid
Debug (db)	Examines a resource to diagnose operational problems.	Diagnose
Measure (ms)	Identifies resources that are consumed by a specified operation, or retrieves statistics about a resource.	Calculate, Determine, Analyze
Ping (pi)	Deprecated - Use the Test verb instead.	
Repair (rp)	Restores a resource to a usable condition	Fix, Restore
Resolve (rv)	Maps a shorthand representation of a resource to a more complete representation.	Expand, Determine
Test (t)	Verifies the operation or consistency of a resource.	Diagnose, Analyze, Salvage, Verify
Trace (tr)	Tracks the activities of a resource.	Track, Follow, Inspect, Dig

Lifecycle Verbs

PowerShell uses the [System.Management.Automation.VerbsLifecycle](#) class to define actions that apply to the lifecycle of a resource. The following table lists most of the defined verbs.

[+] [Expand table](#)

Verb (alias)	Action	Synonyms to avoid
Approve (ap)	Confirms or agrees to the status of a resource or process.	
Assert (as)	Affirms the state of a resource.	Certify
Build (bd)	Creates an artifact (usually a binary or document) out of some set of input files (usually source code or declarative documents.) This verb was added in PowerShell 6.	

Verb (alias)	Action	Synonyms to avoid
Complete (cp)	Concludes an operation.	
Confirm (cn)	Acknowledges, verifies, or validates the state of a resource or process.	Acknowledge, Agree, Certify, Validate, Verify
Deny (dn)	Refuses, objects, blocks, or opposes the state of a resource or process.	Block, Object, Refuse, Reject
Deploy (dp)	Sends an application, website, or solution to a remote target[s] in such a way that a consumer of that solution can access it after deployment is complete. This verb was added in PowerShell 6.	
Disable (d)	Configures a resource to an unavailable or inactive state. For example, the <code>Disable-PSBreakpoint</code> cmdlet makes a breakpoint inactive. This verb is paired with <code>Enable</code> .	Halt, Hide
Enable (e)	Configures a resource to an available or active state. For example, the <code>Enable-PSBreakpoint</code> cmdlet makes a breakpoint active. This verb is paired with <code>Disable</code> .	Start, Begin
Install (is)	Places a resource in a location, and optionally initializes it. This verb is paired with <code>Uninstall</code> .	Setup
Invoke (i)	Performs an action, such as running a command or a method.	Run, Start
Register (rg)	Creates an entry for a resource in a repository such as a database. This verb is paired with <code>Unregister</code> .	
Request (rq)	Asks for a resource or asks for permissions.	
Restart (rt)	Stops an operation and then starts it again. For example, the <code>Restart-Service</code> cmdlet stops and then starts a service.	Recycle
Resume (ru)	Starts an operation that has been suspended. For example, the <code>Resume-Service</code> cmdlet starts a service that has been suspended. This verb is paired with <code>Suspend</code> .	
Start (sa)	Initiates an operation. For example, the <code>Start-Service</code> cmdlet starts a service. This verb is paired with <code>Stop</code> .	Launch, Initiate, Boot
Stop (sp)	Discontinues an activity. This verb is paired with <code>Start</code> .	End, Kill, Terminate, Cancel
Submit (sb)	Presents a resource for approval.	Post

Verb (alias)	Action	Synonyms to avoid
Suspend (ss)	Pauses an activity. For example, the <code>Suspend-Service</code> cmdlet pauses a service. This verb is paired with <code>Resume</code> .	Pause
Uninstall (us)	Removes a resource from an indicated location. This verb is paired with <code>Install</code> .	
Unregister (ur)	Removes the entry for a resource from a repository. This verb is paired with <code>Register</code> .	Remove
Wait (w)	Pauses an operation until a specified event occurs. For example, the <code>Wait-Job</code> cmdlet pauses operations until one or more of the background jobs are complete.	Sleep, Pause

Security Verbs

PowerShell uses the `System.Management.Automation.VerbsSecurity` class to define actions that apply to security. The following table lists most of the defined verbs.

[] Expand table

Verb (alias)	Action	Synonyms to avoid
Block (bl)	Restricts access to a resource. This verb is paired with <code>Unblock</code> .	Prevent, Limit, Deny
Grant (gr)	Allows access to a resource. This verb is paired with <code>Revoke</code> .	Allow, Enable
Protect (pt)	Safeguards a resource from attack or loss. This verb is paired with <code>Unprotect</code> .	Encrypt, Safeguard, Seal
Revoke (rk)	Specifies an action that doesn't allow access to a resource. This verb is paired with <code>Grant</code> .	Remove, Disable
Unblock (ul)	Removes restrictions to a resource. This verb is paired with <code>Block</code> .	Clear, Allow
Unprotect (up)	Removes safeguards from a resource that were added to prevent it from attack or loss. This verb is paired with <code>Protect</code> .	Decrypt, Unseal

Other Verbs

PowerShell uses the [System.Management.Automation.VerbsOther](#) class to define canonical verb names that don't fit into a specific verb name category such as the common, communications, data, lifecycle, or security verb names verbs.

 Expand table

Verb (alias)	Action	Synonyms to avoid
Use (u)	Uses or includes a resource to do something.

Cmdlet Input Processing Methods

Article • 09/17/2021

Cmdlets must override one or more of the input processing methods described in this topic to perform their work. These methods allow the cmdlet to perform operations of pre-processing, input processing, and post-processing. These methods also allow you to stop cmdlet processing. For a more detailed example of how to use these methods, see [SelectStr Tutorial](#).

Pre-Processing Operations

Cmdlets should override the [System.Management.Automation.Cmdlet.BeginProcessing](#) method to add any preprocessing operations that are valid for all the records that will be processed later by the cmdlet. When PowerShell processes a command pipeline, PowerShell calls this method once for each instance of the cmdlet in the pipeline. For more information about how PowerShell invokes the command pipeline, see [Cmdlet Processing Lifecycle](#).

The following code shows an implementation of the BeginProcessing method.

```
C#  
  
protected override void BeginProcessing()  
{  
    // Replace the WriteObject method with the logic required by your cmdlet.  
    WriteObject("This is a test of the BeginProcessing template.");  
}
```

Input Processing Operations

Cmdlets can override the [System.Management.Automation.Cmdlet.ProcessRecord](#) method to process the input that is sent to the cmdlet. When PowerShell processes a command pipeline, PowerShell calls this method for each input record that is processed by the cmdlet. For more information about how PowerShell invokes the command pipeline, see [Cmdlet Processing Lifecycle](#).

The following code shows an implementation of the ProcessRecord method.

```
C#  
  
protected override void ProcessRecord()  
{
```

```
// Replace the WriteObject method with the logic required by your cmdlet.  
WriteObject("This is a test of the ProcessRecord template.");  
}
```

Post-Processing Operations

Cmdlets should override the [System.Management.Automation.Cmdlet.EndProcessing](#) method to add any post-processing operations that are valid for all the records that were processed by the cmdlet. For example, your cmdlet might have to clean up object variables after it is finished processing.

When PowerShell processes a command pipeline, PowerShell calls this method once for each instance of the cmdlet in the pipeline. However, it is important to remember that the PowerShell runtime will not call the EndProcessing method if the cmdlet is canceled midway through its input processing or if a terminating error occurs in any part of the cmdlet. For this reason, a cmdlet that requires object cleanup should implement the complete [System.IDisposable](#) pattern, including a finalizer, so that the runtime can call both the EndProcessing and [System.IDisposable.Dispose](#) methods at the end of processing. For more information about how PowerShell invokes the command pipeline, see [Cmdlet Processing Lifecycle](#).

The following code shows an implementation of the EndProcessing method.

C#

```
protected override void EndProcessing()  
{  
    // Replace the WriteObject method with the logic required by your cmdlet.  
    WriteObject("This is a test of the EndProcessing template.");  
}
```

Cmdlet Parameters

Article • 09/17/2021

Cmdlet parameters provide the mechanism that allows a cmdlet to accept input. Parameters can accept input directly from the command line, or from objects passed to the cmdlet through the pipeline. The arguments (also known as *values*) of these parameters can specify the input that the cmdlet accepts, how the cmdlet should perform its actions, and the data that the cmdlet returns to the pipeline.

In This Section

[Declaring Properties as Parameters](#) Provides basic information you must understand before you declare the parameters of a cmdlet.

[Types of Cmdlet Parameters](#) Describes the different types of parameters that you can declare in cmdlets.

[Cmdlet Parameter Name and Functionality Guidelines](#) Discusses the names, recommended data type, and functionality of standard parameters.

[Parameter Aliases](#) Discusses the aliases that you can define for parameters.

[Common Parameter Names](#) This topic describes the parameters that Windows PowerShell adds to cmdlets.

[Cmdlet Parameter Sets](#) Discusses how parameter sets enable you to write a single cmdlet that can perform different actions for different scenarios.

[Cmdlet Dynamic Parameters](#) Discusses parameters that are available to the user under special conditions.

[Supporting Wildcard Characters in Cmdlet Parameters](#) Describes how to provide support for wildcard characters when you design a cmdlet that will be run against a group of resources.

Declaring Properties as Parameters

Article • 09/17/2021

This topic provides basic information you must understand before you declare the parameters of a cmdlet.

To declare the parameters of a cmdlet within your cmdlet class, define the public properties that represent each parameter, and then add one or more Parameter attributes to each property. The Windows PowerShell runtime uses the Parameter attributes to identify the property as a cmdlet parameter. The basic syntax for declaring the Parameter attribute is `[Parameter()]`.

Here is an example of a property defined as a required parameter.

C#

```
[Parameter(Position = 0, Mandatory = true)]
public string UserName
{
    get { return userName; }
    set { userName = value; }
}
private string userName;
```

Here are some things to remember about parameters.

- A parameter must be explicitly marked as public. Parameters that are not marked as public default to internal and will not be found by the Windows PowerShell runtime.
- Parameters should be defined as Microsoft .NET Framework types to provide better parameter validation. For example, parameters that are restricted to one value out of a set of values should be defined as an enumeration type. Parameters that take a Uniform Resource Identifier (URI) value should be of type `System.Uri`.
- Avoid basic string parameters for all but free-form text properties.
- You can add a parameter to any number of parameter sets. For more information about parameter sets, see [Cmdlet Parameter Sets](#).

Windows PowerShell also provides a set of common parameters that are automatically available to every cmdlet. For more information about these parameters and their aliases, see [Cmdlet Common Parameters](#).

Types of Cmdlet Parameters

Article • 02/25/2025

This topic describes the different types of parameters that you can declare in cmdlets. Cmdlet parameters can be positional, named, required, optional, or switch parameters.

Positional and Named Parameters

All cmdlet parameters are either named or positional parameters. A named parameter requires that you type the parameter name and argument when calling the cmdlet. A positional parameter requires only that you type the arguments in relative order. The system then maps the first unnamed argument to the first positional parameter. The system maps the second unnamed argument to the second unnamed parameter, and so on. By default, all cmdlet parameters are named parameters.

To define a named parameter, omit the `Position` keyword in the `Parameter` attribute declaration, as shown in the following parameter declaration.

```
C#  
  
[Parameter(ValueFromPipeline=true)]  
public string UserName  
{  
    get { return userName; }  
    set { userName = value; }  
}  
private string userName;
```

To define a positional parameter, add the `Position` keyword in the `Parameter` attribute declaration, and then specify a position. In the following sample, the `UserName` parameter is declared as a positional parameter with position 0. This means that the first argument of the call is automatically bound to this parameter.

```
C#  
  
[Parameter(Position = 0)]  
public string UserName  
{  
    get { return userName; }  
    set { userName = value; }  
}  
private string userName;
```

Note

Good cmdlet design recommends that the most-used parameters be declared as positional parameters so that the user doesn't have to enter the parameter name when the cmdlet is run.

Positional and named parameters accept single arguments or multiple arguments separated by commas. Multiple arguments are allowed only if the parameter accepts a collection such as an array of strings. You may mix positional and named parameters in the same cmdlet. In this case, the system retrieves the named arguments first, and then attempts to map the remaining unnamed arguments to the positional parameters.

The following commands show the different ways in which you can specify single and multiple arguments for the parameters of the `Get-Command` cmdlet. Notice that in the last two samples, `-Name` doesn't need to be specified because the `Name` parameter is defined as a positional parameter.

PowerShell

```
Get-Command -Name Get-Service
Get-Command -Name Get-Service,Set-Service
Get-Command Get-Service
Get-Command Get-Service,Set-Service
```

Mandatory and Optional Parameters

You can also define cmdlet parameters as mandatory or optional parameters. (A mandatory parameter must be specified before the PowerShell runtime invokes the cmdlet.) By default, parameters are defined as optional.

To define a mandatory parameter, add the `Mandatory` keyword in the Parameter attribute declaration, and set it to `true`, as shown in the following parameter declaration.

C#

```
[Parameter(Position = 0, Mandatory = true)]
public string UserName
{
    get { return userName; }
    set { userName = value; }
```

```
}
```

```
private string userName;
```

To define an optional parameter, omit the `Mandatory` keyword in the `Parameter` attribute declaration, as shown in the following parameter declaration.

C#

```
[Parameter(Position = 0)]
public string UserName
{
    get { return userName; }
    set { userName = value; }
}
private string userName;
```

Switch Parameters

PowerShell provides a `System.Management.Automation.SwitchParameter` type that allows you to define a parameter whose default value `false` unless the parameter is specified when the cmdlet is called. Whenever possible, use switch parameters instead of Boolean parameters.

Consider the following example. Many PowerShell cmdlets return output. However, these cmdlets have a `PassThru` switch parameter that overrides the default behavior. When you use the `PassThru` parameter, the cmdlet returns output objects to the pipeline.

To define a switch parameter, declare the property as the `[SwitchParameter]` type, as shown in the following sample.

C#

```
[Parameter()]
public SwitchParameter GoodBye
{
    get { return goodbye; }
    set { goodbye = value; }
}
private bool goodbye;
```

To make the cmdlet act on the parameter when it's specified, use the following structure within one of the input processing methods.

C#

```
protected override void ProcessRecord()
{
    WriteObject("Switch parameter test: " + userName + ".");
    if (goodbye)
    {
        WriteObject(" Goodbye!");
    }
} // End ProcessRecord
```

By default, switch parameters are excluded from positional parameters. You *can* override that in the **Parameter** attribute, but it can confuse users.

Design switch parameters so that using parameter changes the default behavior of the command to a less common or more complicated mode. The simplest behavior of a command should be the default behavior that doesn't require the use of switch parameters. Base the behavior controlled by the switch on the value of the switch, not the presence of the parameter.

There are several ways to test for the presence of a switch parameters:

- `Invocation.BoundParameters` contains the switch parameter name as a key
- `PSCmdlet.ParameterSetName` when the switch defines a unique parameter set

For example, it's possible to provide an explicit value for the switch using `-MySwitch:$false` or splatting. If you only test for the presence of the parameter, the command behaves as if the switch value is `$true` instead of `$false`.

Activity Parameters

Article • 06/23/2022

The following table lists the recommended names and functionality for activity parameters.

[Expand table](#)

Parameter	Functionality
Append Data type: SwitchParameter	Implement this parameter so that the user can add content to the end of a resource when the parameter is specified.
CaseSensitive Data type: SwitchParameter	Implement this parameter so the user can require case sensitivity when the parameter is specified.
Command Data type: String	Implement this parameter so the user can specify a command string to run.
CompatibleVersion Data type: System.Version object	Implement this parameter so the user can specify the semantics that the cmdlet must be compatible with for compatibility with previous versions.
Compress Data type: SwitchParameter	Implement this parameter so that data compression is used when the parameter is specified.
Compress Data type: Keyword	Implement this parameter so that the user can specify the algorithm to use for data compression.
Continuous Data type: SwitchParameter	Implement this parameter so that data is processed until the user terminates the cmdlet when the parameter is specified. If the parameter is not specified, the cmdlet processes a predefined amount of data and then terminates the operation.
Create Data type: SwitchParameter	Implement this parameter to indicate that a resource is created if one does not already exist when the parameter is specified.
Delete Data type: SwitchParameter	Implement this parameter so that resources are deleted when the cmdlet has completed its operation when the parameter is specified.
Drain Data type: SwitchParameter	Implement this parameter to indicate that outstanding work items are processed before the cmdlet processes new data when the parameter is

Parameter	Functionality
	specified. If the parameter is not specified, the work items are processed immediately.
Erase Data type: Int32	Implement this parameter so that the user can specify the number of times a resource is erased before it is deleted.
ErrorLevel Data type: Int32	Implement this parameter so that the user can specify the level of errors to report.
Exclude Data type: String[]	Implement this parameter so that the user can exclude something from an activity. For more information about how to use input filters, see Input Filter Parameters .
Filter Data type: Keyword	Implement this parameter so that the user can specify a filter that selects the resources upon which to perform the cmdlet action. For more information about how to use input filters, see Input Filter Parameters .
Follow Data type: SwitchParameter	Implement this parameter so that progress is tracked when the parameter is specified.
Force Data type: SwitchParameter	Implement this parameter to indicate that the user can perform an action even if restrictions are encountered when the parameter is specified. The parameter does not allow security to be compromised. For example, this parameter lets a user overwrite a read-only file.
Include Data type: String[]	Implement this parameter so that the user can include something in an activity. For more information about how to use input filters, see Input Filter Parameters .
Incremental Data type: SwitchParameter	Implement this parameter to indicate that processing is performed incrementally when the parameter is specified. For example, this parameter lets a user perform incremental backups that back up files only since the last backup.
InputObject Data type: Object	Implement this parameter when the cmdlet takes input from other cmdlets. When you define an InputObject parameter, always specify the ValueFromPipeline keyword when you declare the Parameter attribute. For more information about using input filters, see Input Filter Parameters .
Insert Data type: SwitchParameter	Implement this parameter so that the cmdlet inserts an item when the parameter is specified.
Interactive Data type: SwitchParameter	Implement this parameter so that the cmdlet works interactively with the user when the parameter is specified.

Parameter	Functionality
Interval Data type: HashTable	Implement this parameter so that the user can specify a hash table of keywords that contains the values. The following example shows sample values for the Interval parameter: <code>-interval @{ResumeScan=15; Retry=3}</code> .
Log Data type: SwitchParameter	Implement this parameter audit the actions of the cmdlet when the parameter is specified.
NoClobber Data type: SwitchParameter	Implement this parameter so that the resource will not be overwritten when the parameter is specified. This parameter generally applies to cmdlets that create new objects so that they can be prevented from overwriting existing objects with the same name.
Notify Data type: SwitchParameter	Implement this parameter so that the user will be notified that the activity is complete when the parameter is specified.
NotifyAddress Data type: Email address	Implement this parameter so that the user can specify the e-mail address to use to send a notification when the Notify parameter is specified.
Overwrite Data type: SwitchParameter	Implement this parameter so that the cmdlet overwrites any existing data when the parameter is specified.
Prompt Data type: String	Implement this parameter so that the user can specify a prompt for the cmdlet.
Quiet Data type: SwitchParameter	Implement this parameter so that the cmdlet suppresses user feedback during its actions when the parameter is specified.
Recurse Data type: SwitchParameter	Implement this parameter so that the cmdlet recursively performs its actions on resources when the parameter is specified.
Repair Data type: SwitchParameter	Implement this parameter so that the cmdlet will attempt to correct something from a broken state when the parameter is specified.
RepairString Data type: String	Implement this parameter so that the user can specify a string to use when the Repair parameter is specified.
Retry Data type: Int32	Implement this parameter so the user can specify the number of times the cmdlet will attempt an action.
Select Data type: Keyword array	Implement this parameter so that the user can specify an array of the types of items.

Parameter	Functionality
Stream Data type: SwitchParameter	Implement this parameter so the user can stream multiple output objects through the pipeline when the parameter is specified.
Strict Data type: SwitchParameter	Implement this parameter so that all errors are handled as terminating errors when the parameter is specified.
TempLocation Data type: String	Implement this parameter so the user can specify the location of temporary data that is used during the operation of the cmdlet.
Timeout Data type: Int32	Implement this parameter so that the user can specify the timeout interval (in milliseconds).
Truncate Data type: SwitchParameter	Implement this parameter so that the cmdlet will truncate its actions when the parameter is specified. If the parameter is not specified, the cmdlet performs another action.
Verify Data type: SwitchParameter	Implement this parameter so that the cmdlet will test to determine whether an action has occurred when the parameter is specified.
Wait Data type: SwitchParameter	Implement this parameter so that the cmdlet will wait for user input before continuing when the parameter is specified.
WaitTime Data type: Int32	Implement this parameter so that the user can specify the duration (in seconds) that the cmdlet will wait for user input when the Wait parameter is specified.

Date and Time Parameters

Article • 09/17/2021

The following table lists recommended names and functionality for parameters that handle date and time information. Date and time parameters are typically used to record when something is created or accessed.

[+] Expand table

Parameter	Functionality
Accessed Data type: SwitchParameter	Implement this parameter so that when it is specified the cmdlet will operate on the resources that have been accessed based on the date and time specified by the Before and After parameters. If this parameter is specified, the Created and Modified parameters must not be specified.
After Data type: DateTime	Implement this parameter to specify the date and time after which the cmdlet was used. For the After parameter to work, the cmdlet must also have an Accessed , Created , or Modified parameter. And, that parameter must be set to true when the cmdlet is called.
Before Data type: DateTime	Implement this parameter to specify the date and time before which the cmdlet was used. For the Before parameter to work, the cmdlet must also have an Accessed , Created , or Modified parameter. And, that parameter must be set to true when the cmdlet is called.
Created Data type: SwitchParameter	Implement this parameter so that when it is specified the cmdlet will operate on the resources that have been created based on the date and time specified by the Before and After parameters. If this parameter is specified, the Accessed and Modified parameters must not be specified.
Exact Data type: SwitchParameter	Implement this parameter so that when it is specified the resource term must match the resource name exactly. When the parameter is not specified the resource term and name do not need to match exactly.
Modified Data type: DateTime	Implement this parameter so that when it is specified the cmdlet will operate on resources that have been changed based on the date and time specified by the Before and After parameters. If this parameter is specified, the Accessed and Created parameters must not be specified.

Format Parameters

Article • 09/17/2021

The following table lists recommended names and functionality for parameters that are used to format or to generate data.

 Expand table

Parameter	Functionality
As Data type: Keyword	Implement this parameter to specify the cmdlet output format. For example, possible values could be Text or Script.
Binary Data type: SwitchParameter	Implement this parameter to indicate that the cmdlet handles binary values.
Encoding Data type: Keyword	Implement this parameter to specify the type of encoding that is supported. For example, possible values could be ASCII, UTF8, Unicode, UTF7, BigEndianUnicode, Byte, and String.
NewLine Data type: SwitchParameter	Implement this parameter so that the newline characters are supported when the parameter is specified.
ShortName Data type: SwitchParameter	Implement this parameter so that short names are supported when the parameter is specified.
Width Data type: Int32	Implement this parameter so that the user can specify the width of the output device.
Wrap Data type: SwitchParameter	Implement this parameter so that text wrapping is supported when the parameter is specified.

Property Parameters

Article • 09/17/2021

The following table lists the recommended names and functionality for property parameters.

[Expand table](#)

Parameter	Functionality
Count Data type: Int32	Implement this parameter so that the user can specify the number of objects to be processed.
Description Data type: String	Implement this parameter so that the user can specify a description for a resource.
From Data type: String	Implement this parameter so that the user can specify the reference object to get information from.
Id Data type: Resource dependent	Implement this parameter so that the user can specify the identifier of a resource.
Input Data type: String	Implement this parameter so that the user can specify the input file specification.
Location Data type: String	Implement this parameter so that the user can specify the location of the resource.
LogName Data type: String	Implement this parameter so that the user can specify the name of the log file to process or use.
Name Data type: String	Implement this parameter so that the user can specify the name of the resource.
Output Data type: String	Implement this parameter so that the user can specify the output file.
Owner Data type: String	Implement this parameter so that the user can specify the name of the owner of the resource.
Property Data type: String	Implement this parameter so that the user can specify the name or the names of the properties to use.
Reason Data type: String	Implement this parameter so that the user can specify why this cmdlet is being invoked.
Regex Data type:	Implement this parameter so that regular expressions are used when the parameter is specified. When this parameter is specified, wildcard

Parameter	Functionality
SwitchParameter	characters are not resolved.
Speed Data type: Int32	Implement this parameter so that the user can specify the baud rate. The user sets this parameter to the speed of the resource.
State Data type: Keyword array	Implement this parameter so that the user can specify the names of states, such as KEYDOWN.
Value Data type: Object	Implement this parameter so that the user can specify a value to provide to the cmdlet.
Version Data type: String	Implement this parameter so that the user can specify the version of the property.

Resource Parameters

Article • 09/17/2021

The following table lists the recommended names and functionality for resource parameters. For these parameters, the resources could be the assembly that contains the cmdlet class or the host application that is running the cmdlet.

[\[+\] Expand table](#)

Parameter	Functionality
Application Data type: String	Implement this parameter so that the user can specify an application.
Assembly Data type: String	Implement this parameter so that the user can specify an assembly.
Attribute Data type: String	Implement this parameter so that the user can specify an attribute.
Class Data type: String	Implement this parameter so that the user can specify a Microsoft .NET Framework class.
Cluster Data type: String	Implement this parameter so that the user can specify a cluster.
Culture Data type: String	Implement this parameter so that the user can specify the culture in which to run the cmdlet.
Domain Data type: String	Implement this parameter so that the user can specify the domain name.
Drive Data type: String	Implement this parameter so that the user can specify a drive name.
Event Data type: String	Implement this parameter so that the user can specify an event name.

Parameter	Functionality
Interface Data type: String	Implement this parameter so that the user can specify a network interface name.
IpAddress Data type: String	Implement this parameter so that the user can specify an IP address.
Job Data type: String	Implement this parameter so that the user can specify a job.
LiteralPath Data type: String	Implement this parameter so that the user can specify the path to a resource when wildcard characters are not supported. (Use the Path parameter when wildcard characters are supported.)
Mac Data type: String	Implement this parameter so that the user can specify a media access controller (MAC) address.
ParentId Data type: String	Implement this parameter so that the user can specify the parent identifier.
Path Data type: String, String[]	Implement this parameter so that the user can indicate the paths to a resource when wildcard characters are supported. (Use the LiteralPath parameter when wildcard characters are not supported.) We recommend that you develop this parameter so that it supports the full <code>provider:path</code> syntax used by providers. We also recommend that you develop it so that it works with as many providers as possible.
Port Data type: Integer, String	Implement this parameter so that the user can specify an integer value for networking or a string value such as "biztalk" for other types of port.
Printer Data type: Integer, String	Implement this parameter so that the user can specify the printer for the cmdlet to use.
Size Data type: Int32	Implement this parameter so that the user can specify a size.
TID Data type: String	Implement this parameter so that the user can specify a transaction identifier (TID) for the cmdlet.

Parameter	Functionality
Type Data type: String	Implement this parameter so that the user can specify the type of resource on which to operate.
URL Data type: String	Implement this parameter so that the user can specify a Uniform Resource Locator (URL).
User Data type: String	Implement this parameter so that the user can specify their name or the name of another user.

Security Parameters

Article • 10/13/2023

The following table lists the recommended names and functionality for parameters used to provide security information for an operation, such as parameters that specify certificate key and privilege information.

[\[\] Expand table](#)

Parameter	Functionality
ACL Data type: String	Implement this parameter to specify the access control level of protection for a catalog or for a Uniform Resource Identifier (URI).
CertFile Data type: String	Implement this parameter so that the user can specify the name of a file that contains one of the following: <ul style="list-style-type: none">- A Base64 or Distinguished Encoding Rules (DER) encoded x.509 certificate- A Public Key Cryptography Standards (PKCS) #12 file that contains at least one certificate and key
CertIssuerName Data type: String	Implement this parameter so that the user can specify the name of the issuer of a certificate or so that the user can specify a substring.
CertRequestFile Data type: String	Implement this parameter to specify the name of a file that contains a Base64 or DER-encoded PKCS #10 certificate request.
CertSerialNumber Data type: String	Implement this parameter to specify the serial number that was issued by the certification authority.
CertStoreLocation Data type: String	Implement this parameter so that the user can specify the location of the certificate store. The location is typically a file path.
CertSubjectName Data type: String	Implement this parameter so that the user can specify the issuer of a certificate or so that the user can specify a substring.
CertUsage Data type: String	Implement this parameter to specify the key usage or the enhanced key usage. The key can be represented as a bit mask, a bit, an object identifier (OID), or a string.

Parameter	Functionality
Credential Data type: <code>System.Management.Automation.PSCredential</code>	Implement this parameter so that the cmdlet will automatically prompt the user for a user name or password. A prompt for both is displayed if a full credential is not supplied directly.
CSPName Data type: String	Implement this parameter so that the user can specify the name of the certificate service provider (CSP).
CSPType Data type: Integer	Implement this parameter so that the user can specify the type of CSP.
Group Data type: String	Implement this parameter so that the user can specify a collection of principals for access. For more information, see the description of the Principal parameter.
KeyAlgorithm Data type: String	Implement this parameter so that the user can specify the key generation algorithm to use for security.
KeyContainerName Data type: String	Implement this parameter so that the user can specify the name of the key container.
KeyLength Data type: Integer	Implement this parameter so that the user can specify the length of the key in bits.
Operation Data type: String	Implement this parameter so that the user can specify an action that can be performed on a protected object.
Principal Data type: String	Implement this parameter so that the user can specify a unique identifiable entity for access.
Privilege Data type: String, String[]	Implement this parameter so that the user can specify the rights a cmdlet needs to perform an operation for a particular entity.
Role Data type: String	Implement this parameter so that the user can specify a set of operations that can be performed by an entity.
SaveCred Data type: SwitchParameter	Implement this parameter so that credentials that were previously saved by the user will be used when the parameter is specified.
Scope Data type: String	Implement this parameter so that the user can specify the group of protected objects for the

Parameter	Functionality
	cmdlet.
SID Data type: String	Implement this parameter so that the user can specify a unique identifier that represents a principal.
Trusted Data type: SwitchParameter	Implement this parameter so that trust levels are supported when the parameter is specified.
TrustLevel Data type: Keyword	Implement this parameter so that the user can specify the trust level that is supported. For example, possible values include internet, intranet, and fulltrust.

Parameter Aliases

Article • 09/17/2021

Cmdlet parameters can also have aliases. You can use the aliases instead of the parameter names when you type or specify the parameter in a command.

Benefits of Using Aliases

Adding aliases to parameters provides the following benefits.

- You can provide a shortcut so that the user does not have to use the complete parameter name when the cmdlet is called. For example, you could use the "CN" alias instead of the parameter name "ComputerName".
- You can define multiple aliases if you want to provide different names for the same parameter. You might want to define multiple aliases if you have to work with multiple user groups that refer to the same data in different ways.
- You can provide backwards compatibility for existing scripts if the name of a parameter changes.
- By using the Alias attribute along with the ValueFromPipelineByName attribute, you can define a parameter that allows your cmdlet to bind to different object types. For example, say you had two objects of different types and the first object had a writer property and the second object had an editor property. If your cmdlet had a parameter that had writer and editor aliases and the cmdlet accepted pipeline input based in property names, your cmdlet could bind to both objects using the two parameter aliases.

For more information about aliases that can be used with specific parameters, see [Common Parameter Names](#).

Defining Parameter Aliases

To define an alias for a parameter, declare the Alias attribute, as shown in the following parameter declaration. In this example, multiple aliases are defined for the same parameter. (For more information, see [How to Declare Cmdlet Parameters](#).)

C#

```
[Alias("UN","Writer","Editor")]
[Parameter()]
```

```
public string UserName
{
    get { return userName; }
    set { userName = value; }
}
private string userName;
```

Common Parameter Names

Article • 10/04/2023

The parameters described in this topic are referred to as **common parameters**. They're added to cmdlets by the PowerShell runtime and can't be declared by the cmdlet.

ⓘ Note

These parameters are also added to provider cmdlets and to functions that are decorated with the `CmdletBinding` attribute.

General Common Parameters

The following parameters are added to all cmdlets and can be accessed whenever the cmdlet is run. These parameters are defined by the [CommonParameters](#) class.

Debug (alias: db)

Data type: [SwitchParameter](#)

This parameter specifies whether programmer-level debugging messages that can be displayed at the command line. These messages are intended for troubleshooting the operation of the cmdlet, and are generated by calls to the [WriteDebug](#) method. Debug messages don't need to be localized.

ErrorAction (alias: ea)

Data type: [Enumeration](#)

This parameter specifies what action should take place when an error occurs. The possible values for this parameter are defined by the [ActionPreference](#) enumeration.

ErrorVariable (alias: ev)

Data type: [String](#)

This parameter specifies the variable in which to place objects when an error occurs. To append to this variable, use `+varname` rather than clearing and setting the variable.

InformationAction (alias: inf)

Data type: Enumeration

This parameter specifies what action should take place when output is sent to the **Information** stream. The possible values for this parameter are defined by the [ActionPreference](#) enumeration.

InformationVariable (alias: iv)

Data type: String

This parameter specifies the variable in which to save output objects written to the **Information** stream. To append to this variable, use `+varname` rather than clearing and setting the variable.

OutBuffer (alias: ob)

Data type: Int32

This parameter defines the number of objects to store in the output buffer before any objects are passed down the pipeline. By default, objects are passed immediately down the pipeline.

OutVariable (alias: ov)

Data type: String

This parameter specifies the variable in which to place all output objects generated by the cmdlet. To append to this variable, use `+varname` rather than clearing and setting the variable.

PipelineVariable (alias: pv)

Data type: String

This parameter stores the value of the current pipeline element as a variable for any named command as it flows through the pipeline.

ProgressAction (alias: proga)

Data type: Enumeration

Determines how PowerShell responds to progress updates generated by a script, cmdlet, or provider, such as the progress bars generated by the `Write-Progress` cmdlet.

This parameter was added in PowerShell 7.4.

Verbose (alias: vb)

Data type: `SwitchParameter`

This parameter specifies whether the cmdlet writes explanatory messages that can be displayed at the command line. These messages are intended to provide additional help to the user, and are generated by calls to the [WriteVerbose](#) method.

WarningAction (alias: wa)

Data type: `Enumeration`

This parameter specifies what action should take place when the cmdlet writes a warning message. The possible values for this parameter are defined by the [ActionPreference](#) enumeration.

WarningVariable (alias: wv)

Data type: `String`

This parameter specifies the variable in which warning messages can be saved. To append to this variable, use `+varname` rather than clearing and setting the variable.

Risk-Mitigation Parameters

The following parameters are added to cmdlets that requests confirmation before they perform their action. For more information about confirmation requests, see [Requesting Confirmation](#). These parameters are defined by the [ShouldProcessParameters](#) class.

Confirm (alias: cf)

Data type: `SwitchParameter`

This parameter specifies whether the cmdlet displays a prompt that asks if the user is sure that they want to continue.

WhatIf (alias: wi)

Data type: **SwitchParameter**

This parameter specifies whether the cmdlet writes a message that describes the effects of running the cmdlet without actually performing any action.

Transaction Parameters

The following parameter is added to cmdlets that support transactions. These parameters are defined by the [TransactionParameters](#) class.

Transaction support was introduced in PowerShell 3.0 and discontinued in PowerShell 6.0.

UseTransaction (alias: usetx)

Data type: **SwitchParameter**

This parameter specifies whether the cmdlet uses the current transaction to perform its action.

Cmdlet parameter sets

Article • 09/17/2021

PowerShell uses parameter sets to enable you to write a single cmdlet that can do different actions for different scenarios. Parameter sets enable you to expose different parameters to the user. And, to return different information based on the parameters specified by the user.

Examples of parameter sets

For example, the PowerShell `Get-EventLog` cmdlet returns different information depending on whether the user specifies the `List` or `LogName` parameter. If the `List` parameter is specified, the cmdlet returns information about the log files themselves but not the event information they contain. If the `LogName` parameter is specified, the cmdlet returns information about the events in a specific event log. The `List` and `LogName` parameters identify two separate parameter sets.

Unique parameter

Each parameter set must have a unique parameter that the PowerShell runtime uses to expose the appropriate parameter set. If possible, the unique parameter should be a mandatory parameter. When a parameter is mandatory, the user must specify the parameter, and the PowerShell runtime uses that parameter to identify the parameter set. The unique parameter can't be mandatory if your cmdlet is designed to run without specifying any parameters.

Multiple parameter sets

In the following illustration, the left column shows three valid parameter sets. **Parameter A** is unique to the first parameter set, **parameter B** is unique to the second parameter set, and **parameter C** is unique to the third parameter set. In the right column, the parameter sets don't have a unique parameter.

Valid Parameter Sets	Invalid Parameter Sets
A D	A B
B D E	B C
C D	A C

Parameter set requirements

The following requirements apply to all parameter sets.

- Each parameter set must have at least one unique parameter. If possible, make this parameter a mandatory parameter.
- A parameter set that contains multiple positional parameters must define unique positions for each parameter. No two positional parameters can specify the same position.
- Only one parameter in a set can declare the `valueFromPipeline` keyword with a value of `true`. Multiple parameters can define the `ValueFromPipelineByPropertyName` keyword with a value of `true`.
- If no parameter set is specified for a parameter, the parameter belongs to all parameter sets.

ⓘ Note

For a cmdlet or function, there is a limit of 32 parameter sets.

Default parameter sets

When multiple parameter sets are defined, you can use the `DefaultParameterSetName` keyword of the **Cmdlet** attribute to specify the default parameter set. PowerShell uses the default parameter set if it can't determine the parameter set to use based on the information provided by the command. For more information about the **Cmdlet** attribute, see [Cmdlet Attribute Declaration](#).

Declaring parameter sets

To create a parameter set, you must specify the `ParameterSetName` keyword when you declare the **Parameter** attribute for every parameter in the parameter set. For parameters that belong to multiple parameter sets, add a **Parameter** attribute for each parameter set. This attribute enables you to define the parameter differently for each parameter set. For example, you can define a parameter as mandatory in one set and optional in another. However, each parameter set must contain one unique parameter. For more information, see [Parameter Attribute Declaration](#).

In the following example, the **UserName** parameter is the unique parameter of the **Test01** parameter set, and the **ComputerName** parameter is the unique parameter of the **Test02** parameter set. The **SharedParam** parameter belongs to both sets and is mandatory for the **Test01** parameter set but optional for the **Test02** parameter set.

C#

```
[Parameter(Position = 0, Mandatory = true, ParameterSetName = "Test01")]
public string UserName
{
    get { return userName; }
    set { userName = value; }
}
private string userName;

[Parameter(Position = 0, Mandatory = true, ParameterSetName = "Test02")]
public string ComputerName
{
    get { return computerName; }
    set { computerName = value; }
}
private string computerName;

[Parameter(Mandatory= true, ParameterSetName = "Test01")]
[Parameter(ParameterSetName = "Test02")]
public string SharedParam
{
    get { return sharedParam; }
    set { sharedParam = value; }
}
private string sharedParam;
```

Cmdlet dynamic parameters

Article • 01/31/2024

Cmdlets can define parameters that are available to the user under special conditions, such as when the argument of another parameter is a specific value. These parameters are added at runtime and are referred to as dynamic parameters because they're only added when needed. For example, you can design a cmdlet that adds several parameters only when a specific switch parameter is specified.

ⓘ Note

Providers and PowerShell functions can also define dynamic parameters.

Dynamic parameters in PowerShell cmdlets

PowerShell uses dynamic parameters in several of its provider cmdlets. For example, the `Get-Item` and `Get-ChildItem` cmdlets add a `CodeSigningCert` parameter at runtime when the `Path` parameter specifies the `Certificate` provider path. If the `Path` parameter specifies a path for a different provider, the `CodeSigningCert` parameter isn't available.

The following examples show how the `CodeSigningCert` parameter is added at runtime when `Get-Item` is run.

In this example, the PowerShell runtime has added the parameter and the cmdlet is successful.

PowerShell

```
Get-Item -Path Cert:\CurrentUser -CodeSigningCert
```

Output

```
Location    : CurrentUser
StoreNames  : {SmartCardRoot, UserDS, AuthRoot, CA...}
```

In this example, a `FileSystem` drive is specified and an error is returned. The error message indicates that the `CodeSigningCert` parameter can't be found.

PowerShell

```
Get-Item -Path C:\ -CodeSigningCert
```

Output

```
Get-Item : A parameter cannot be found that matches parameter name
'CodeSigningCert'.
At line:1 char:37
+ Get-Item -Path C:\ -CodeSigningCert <<<
-----
CategoryInfo          : InvalidArgument: (:) [Get-Item],
ParameterBindingException
FullyQualifiedErrorId :
NamedParameterNotFound,Microsoft.PowerShell.Commands.GetItemCommand
```

Support for dynamic parameters

To support dynamic parameters, the following elements must be included in the cmdlet code.

Interface

[System.Management.Automation.IDynamicParameters](#). This interface provides the method that retrieves the dynamic parameters.

For example:

```
public class SendGreetingCommand : Cmdlet, IDynamicParameters
```

Method

[System.Management.Automation.IDynamicParameters.GetDynamicParameters](#). This method retrieves the object that contains the dynamic parameter definitions.

For example:

C#

```
public object GetDynamicParameters()
{
    if (employee)
    {
        context= new SendGreetingCommandDynamicParameters();
        return context;
    }
    return null;
```

```
}
```

```
private SendGreetingCommandDynamicParameters context;
```

Class

A class that defines the dynamic parameters to be added. This class must include a **Parameter** attribute for each parameter and any optional **Alias** and **Validation** attributes that are needed by the cmdlet.

For example:

C#

```
public class SendGreetingCommandDynamicParameters
{
    [Parameter]
    [ValidateSet ("Marketing", "Sales", "Development")]
    public string Department
    {
        get { return department; }
        set { department = value; }
    }
    private string department;
}
```

For a complete example of a cmdlet that supports dynamic parameters, see [How to Declare Dynamic Parameters](#).

Supporting Wildcard Characters in Cmdlet Parameters

Article • 12/18/2023

Often, you will have to design a cmdlet to run against a group of resources rather than against a single resource. For example, a cmdlet might need to locate all the files in a data store that have the same name or extension. You must provide support for wildcard characters when you design a cmdlet that will be run against a group of resources.

ⓘ Note

Using wildcard characters is sometimes referred to as *globbing*.

Windows PowerShell Cmdlets That Use Wildcards

Many Windows PowerShell cmdlets support wildcard characters for their parameter values. For example, almost every cmdlet that has a `Name` or `Path` parameter supports wildcard characters for these parameters. (Although most cmdlets that have a `Path` parameter also have a `LiteralPath` parameter that does not support wildcard characters.) The following command shows how a wildcard character is used to return all the cmdlets in the current session whose name contains the Get verb.

```
Get-Command get-*
```

Supported Wildcard Characters

Windows PowerShell supports the following wildcard characters.

[] Expand table

Wildcard	Description	Example	Matches	Does not match
*	Matches zero or more characters, starting at the specified position	a*	A, ag, Apple	
?	Matches any character at the specified position	?n	An, in, on ran	

Wildcard	Description	Example	Matches	Does not match
[]	Matches a range of characters	[a-] []ook	book, cook, look	nook, took
[]	Matches the specified characters	[bn]ook	book, nook	cook, look

When you design cmdlets that support wildcard characters, allow for combinations of wildcard characters. For example, the following command uses the `Get-ChildItem` cmdlet to retrieve all the .txt files that are in the C:\Techdocs folder and that begin with the letters "a" through "l."

```
Get-ChildItem C:\techdocs\[a-l]*.txt
```

The previous command uses the range wildcard `[a-1]` to specify that the file name should begin with the characters "a" through "l" and uses the `*` wildcard character as a placeholder for any characters between the first letter of the filename and the `.txt` extension.

The following example uses a range wildcard pattern that excludes the letter "d" but includes all the other letters from "a" through "f."

```
Get-ChildItem C:\techdocs\[a-cef]*.txt
```

Handling Literal Characters in Wildcard Patterns

If the wildcard pattern you specify contains literal characters that should not be interpreted as wildcard characters, use the backtick character (`\``) as an escape character. When you specify literal characters int the PowerShell API, use a single backtick. When you specify literal characters at the PowerShell command prompt, use two backticks.

For example, the following pattern contains two brackets that must be taken literally.

When used in the PowerShell API use:

- "John Smith `[*]`"

When used from the PowerShell command prompt:

- "John Smith ``[*]``"

This pattern matches "John Smith [Marketing]" or "John Smith [Development]". For example:

```
PS> "John Smith [Marketing]" -like "John Smith ``[*``]"
True

PS> "John Smith [Development]" -like "John Smith ``[*``]"
True
```

Cmdlet Output and Wildcard Characters

When cmdlet parameters support wildcard characters, the operation usually generates an array output. Occasionally, it makes no sense to support an array output because the user might use only a single item. For example, the `Set-Location` cmdlet does not support array output because the user sets only a single location. In this instance, the cmdlet still supports wildcard characters, but it forces resolution to a single location.

Validating Parameter Input

Article • 09/17/2021

PowerShell can validate the arguments passed to cmdlet parameters in several ways. PowerShell can validate the length, the range, and the pattern of the characters of the argument. It can validate the number of arguments available (the count). These validation rules are defined by validation attributes that are declared with the `Parameter` attribute on public properties of the cmdlet class.

To validate a parameter argument, the PowerShell runtime uses the information provided by the validation attributes to confirm the value of the parameter before the cmdlet is run. If the parameter input is not valid, the user receives an error message. Each validation parameter defines a validation rule that is enforced by PowerShell.

PowerShell enforces the validation rules based on the following attributes.

ValidateCount

Specifies the minimum and maximum number of arguments that a parameter can accept. For more information, see [ValidateCount Attribute Declaration](#).

ValidateLength

Specifies the minimum and maximum number of characters in the parameter argument. For more information, see [ValidateLength Attribute Declaration](#).

ValidatePattern

Specifies a regular expression that validates the parameter argument. For more information, see [ValidatePattern Attribute Declaration](#).

ValidateRange

Specifies the minimum and maximum values of the parameter argument. For more information, see [ValidateRange Attribute Declaration](#).

ValidateScript

Specifies the valid values for the parameter argument. For more information, see [ValidateScript Attribute Declaration](#).

ValidateSet

Specifies the valid values for the parameter argument. For more information, see [ValidateSet Attribute Declaration](#).

Input Filter Parameters

Article • 09/17/2021

A cmdlet can define `Filter`, `Include`, and `Exclude` parameters that filter the set of input objects that the cmdlet affects.

Typically, the set of input objects is specified by an `InputObject`, `Path`, or `Name` parameter. For example, a cmdlet can have a `Path` parameter that accepts multiple paths by using wildcard characters, and each path points to an input object. Used together, the `Filter`, `Include`, and `Exclude` parameters further qualify the paths the cmdlet works on each time it is invoked.

Include and Exclude Parameters

The `Include` and `Exclude` parameters identify the objects that are included or excluded from the set of input objects passed to the cmdlet. Use these parameters when the filter can be expressed in the standard wildcard language. (For more information about wildcard characters, see [Supporting Wildcards in Cmdlet Parameters](#).) The `Include` parameter includes all the objects whose names match the inclusion filter. The `Exclude` parameter excludes all the objects whose names match the filter.

Filter Parameter

The `Filter` parameter specifies a filter that is not expressed in the standard wildcard language. For example, Active Directory Service Interfaces (ADSI) or SQL filters might be passed to the cmdlet through its `Filter` parameter. In the cmdlets provided by Windows PowerShell, these filters are specified by the Windows PowerShell providers that use the cmdlet to access a data store. Each provider typically defines its own filter.

Filtering If No Set of Input Objects Is Specified

If no set of input objects is specified, this typically means to filter against all objects. For more information, see [Get-Process](#).

Cmdlet Attributes

Article • 09/17/2021

Windows PowerShell defines several attributes that you can use to add common functionality to your cmdlets without implementing that functionality within your own code. This includes the Cmdlet attribute that identifies a Microsoft .NET Framework class as a cmdlet class, the OutputType attribute that specifies the .NET Framework types returned by the cmdlet, the Parameter attribute that identifies public properties as cmdlet parameters, and more.

In This Section

[Attributes in Cmdlet Code](#) Describes the benefit of using attributes in cmdlet code.

[Attribute Types](#) Describes the different attributes that can decorate a cmdlet class.

[Alias Attribute Declaration](#) Describes how to define aliases for a cmdlet parameter name.

[Cmdlet Attribute Declaration](#) Describes how to define a .NET Framework class as a cmdlet.

[Credential Attribute Declaration](#) Describes how to add support for converting string input into a `System.Management.Automation.PSCredential` object.

[OutputType attribute Declaration](#) Describes how to specify the .NET Framework types returned by the cmdlet.

[Parameter Attribute Declaration](#) Describes how to define the parameters of a cmdlet.

[ValidateCount Attribute Declaration](#) Describes how to define how many arguments are allowed for a parameter.

[ValidateLength Attribute Declaration](#) Describes how to define the length (in characters) of a parameter argument.

[ValidatePattern Attribute Declaration](#) Describes how to define the valid patterns for a parameter argument.

[ValidateRange Attribute Declaration](#) Describes how to define the valid range for a parameter argument.

[ValidateScript Attribute Declaration](#) Describes how to define the possible values for a parameter argument.

[ValidateSet Attribute Declaration](#) Describes how to define the possible values for a parameter argument.

Attributes in Cmdlet Code

Article • 09/17/2021

To use the common functionality provided by Windows PowerShell, the classes and public properties defined in the cmdlet code are decorated with attributes. For example, the following class definition uses the `Cmdlet` attribute to identify the Microsoft .NET Framework class in which the `Get-Proc` cmdlet is implemented. (This cmdlet is used as an example in this document, and is similar to the `Get-Process` cmdlet provided by Windows PowerShell.)

C#

```
[Cmdlet(VerbsCommon.Get, "Proc")]
public class GetProcCommand : Cmdlet
```

These attributes are considered metadata because their implementation is separate from the implementation of the cmdlet code. When the Windows PowerShell runtime runs the cmdlet, it recognizes the attributes and then performs the appropriate action for each attribute.

Although you might want to implement your own version of the functionality provided by these attributes, a good cmdlet design uses these common functionalities.

For more information about the different attributes that can be declared in your cmdlets, see [Attribute Types](#).

Attribute Types

Article • 09/17/2021

Cmdlet attributes can be grouped by functionality. The following sections describe the available attributes and describe what the runtime does when the attribute is invoked.

Cmdlet Attributes

Cmdlet

Identifies a .NET Framework class as a cmdlet. This is the required base attribute. For more information, see [Cmdlet Attribute Declaration](#).

Parameter Attributes

Parameter

Identifies a public property in the cmdlet class as a cmdlet parameter. For more information, see [Parameter Attribute Declaration](#).

Alias

Specifies one or more aliases for a parameter. For more information, see [Alias Attribute Declaration](#).

Argument Validation Attributes

ValidateCount

Specifies the minimum and maximum number of arguments that are allowed for a cmdlet parameter. For more information, see [ValidateCount Attribute Declaration](#).

ValidateLength

Specifies a minimum and maximum number of characters for a cmdlet parameter argument. For more information, see [ValidateLength Attribute Declaration](#).

ValidatePattern

Specifies a regular expression pattern that the cmdlet parameter argument must match. For more information, see [ValidatePattern Attribute Declaration](#).

ValidateRange

Specifies the minimum and maximum values for a cmdlet parameter argument. For more information, see [ValidateRange Attribute Declaration](#).

ValidateSet

Specifies a set of valid values for the cmdlet parameter argument. For more information, see [ValidateSet Attribute Declaration](#).

Alias Attribute Declaration

Article • 03/24/2025

The **Alias** attribute allows the user to specify different names for a cmdlet or a cmdlet parameter. Aliases can be used to provide shortcuts for a parameter name, or they can provide different names that are appropriate for different scenarios.

Syntax

C#

```
[Alias(aliasNames)]
```

Parameters

`aliasNames` (String[]) Required. Specifies a set of comma-separated alias names for the cmdlet parameter.

Remarks

The **Alias** attribute is defined by the [System.Management.Automation.AliasAttribute](#) class.

Cmdlet aliases

- The **Alias** attribute is used with the cmdlet declaration. For more information about how to declare these attributes, see [Cmdlet Aliases](#).
- Each parameter alias name must be unique. Windows PowerShell does not check for duplicate alias names.

Parameter aliases

- The **Alias** attribute is used with the **Parameter** attribute when you specify a cmdlet parameter. For more information about how to declare these attributes, see [How to Declare Cmdlet Parameters](#).
- Each parameter alias name must be unique within a cmdlet. Windows PowerShell does not check for duplicate alias names.
- The **Alias** attribute is used once for each parameter in a cmdlet.

Cmdlet Attribute Declaration

Article • 09/17/2021

The `Cmdlet` attribute identifies a Microsoft .NET Framework class as a cmdlet and specifies the verb and noun used to invoke the cmdlet.

Syntax

C#

```
[Cmdlet("verbName", "nounName")]
[Cmdlet("verbName", "nounName", Named Parameters...)]
```

Parameters

`VerbName` ([System.String](#)) Required. Specifies the cmdlet verb. This verb specifies the action taken by the cmdlet. For more information about approved cmdlet verbs, see [Cmdlet Verb Names](#) and [Required Development Guidelines](#).

`NounName` ([System.String](#)) Required. Specifies the cmdlet noun. This noun specifies the resource that the cmdlet acts upon. For more information about cmdlet nouns, see [Cmdlet Declaration](#) and [Strongly Encouraged Development Guidelines](#).

`SupportsShouldProcess` ([System.Boolean](#)) Optional named parameter. `True` indicates that the cmdlet supports calls to the [System.Management.Automation.Cmdlet.ShouldProcess](#) method, which provides the cmdlet with a way to prompt the user before an action that changes the system is performed. `False`, the default value, indicates that the cmdlet does not support calls to the [System.Management.Automation.Cmdlet.ShouldProcess](#) method. For more information about confirmation requests, see [Requesting Confirmation](#).

`ConfirmImpact` ([System.Management.Automation.ConfirmImpact](#)) Optional named parameter. Specifies when the action of the cmdlet should be confirmed by a call to the [System.Management.Automation.Cmdlet.ShouldProcess](#) method. [System.Management.Automation.Cmdlet.ShouldProcess](#) will only be called when the `ConfirmImpact` value of the cmdlet (by default, Medium) is equal to or greater than the value of the `$ConfirmPreference` variable. This parameter should be specified only when the `SupportsShouldProcess` parameter is specified.

`DefaultParameterSetName` ([System.String](#)) Optional named parameter. Specifies the default parameter set that the Windows PowerShell runtime attempts to use when it cannot determine which parameter set to use. Notice that this situation can be eliminated by making the unique parameter of each parameter set a mandatory parameter.

There is one case where Windows PowerShell cannot use the default parameter set even if a default parameter set name is specified. The Windows PowerShell runtime cannot distinguish between parameter sets based solely on object type. For example, if you have one parameter set that takes a string as the file path, and another set that takes a [FileInfo](#) object directly, Windows PowerShell cannot determine which parameter set to use based on the values passed to the cmdlet, nor does it use the default parameter set. In this case, even if you specify a default parameter set name, Windows PowerShell throws an ambiguous parameter set error message.

`SupportsTransactions` ([System.Boolean](#)) Optional named parameter. `True` indicates that the cmdlet can be used within a transaction. When `True` is specified, the Windows PowerShell runtime adds the `UseTransaction` parameter to the parameter list of the cmdlet. `False`, the default value, indicates that the cmdlet cannot be used within a transaction.

Remarks

- Together, the verb and noun are used to identify your registered cmdlet and to invoke your cmdlet within a script.
- When the cmdlet is invoked from the Windows PowerShell console, the command resembles the following command:

VerbName-NounName

- All cmdlets that change resources outside of Windows PowerShell should include the `SupportsShouldProcess` keyword when the `Cmdlet` attribute is declared, which allows the cmdlet to call the [System.Management.Automation.Cmdlet.ShouldProcess](#) method before the cmdlet performs its action. If the [System.Management.Automation.Cmdlet.ShouldProcess](#) call returns `false`, the action should not be taken. For more information about the confirmation requests generated by the [System.Management.Automation.Cmdlet.ShouldProcess](#) call, see [Requesting Confirmation](#).

The `Confirm` and `WhatIf` cmdlet parameters are available only for cmdlets that support `System.Management.Automation.Cmdlet.ShouldProcess` calls.

Example

The following class definition uses the `Cmdlet` attribute to identify the .NET Framework class for a **Get-Proc** cmdlet that retrieves information about the processes running on the local computer.

```
C#  
  
[Cmdlet(VerbsCommon.Get, "Proc")]
public class GetProcCommand : Cmdlet
```

For more information about the **Get-Proc** cmdlet, see [GetProc Tutorial](#).

[Writing a Windows PowerShell Cmdlet](#)

Credential Attribute Declaration

Article • 09/17/2021

The Credential attribute is an optional attribute that can be used with credential parameters of type [System.Management.Automation.PSCredential](#) so that a string can also be passed as an argument to the parameter. When this attribute is added to a parameter declaration, Windows PowerShell converts the string input into a [System.Management.Automation.PSCredential](#) object. For example, the [Get-Credential](#) cmdlet uses this attribute to have Windows PowerShell generate the [System.Management.Automation.PSCredential](#) object that is returned by the cmdlet.

Syntax

C#

```
[Credential]
```

Remarks

- Typically this attribute is used by parameters of type [System.Management.Automation.PSCredential](#) so that a string can also be passed as an argument to the parameter. When a [System.Management.Automation.PSCredential](#) object is passed to the parameter, Windows PowerShell does nothing.
- When creating the [System.Management.Automation.PSCredential](#) object, Windows PowerShell uses the current Host to display the appropriate prompts to the user. For example, the default Host displays a prompt for a user name and password when this attribute is used. However, if a custom host is being used that defines a different prompt then that prompt would be displayed.
- This attribute is used with the Parameter attribute. For more information about that attribute, see [Parameter Attribute Declaration](#).
- The credential attribute is defined by the [System.Management.Automation.CredentialAttribute](#) class.

OutputType Attribute Declaration

Article • 09/17/2021

The `OutputType` attribute identifies the .NET Framework types returned by a cmdlet, function, or script.

Syntax

C#

```
[OutputType(params string[] type)]
[OutputType(params Type[] type)]
[OutputType(params string[] type, Named Parameters...)]
[OutputType(params Type[] type, Named Parameters...)]
```

Parameters

Type (`string[]` or `Type[]`) Required. Specifies the types returned by the cmdlet function, or script.

ParameterSetName (`string[]`) Optional. Specifies the parameter sets that return the types specified in the `type` parameter.

providerCmdlet Optional. Specifies the provider cmdlet that returns the types specified in the `type` parameter.

Parameter Attribute Declaration

Article • 01/06/2025

The Parameter attribute identifies a public property of the cmdlet class as a cmdlet parameter.

Syntax

C#

```
[Parameter()]
[Parameter(Named Parameters...)]
```

Parameters

`Mandatory` (`System.Boolean`) Optional named parameter. `True` indicates the cmdlet parameter is required. If a required parameter is not provided when the cmdlet is invoked, Windows PowerShell prompts the user for a parameter value. The default is `false`.

`ParameterSetName` (`System.String`) Optional named parameter. Specifies the parameter set that this cmdlet parameter belongs to. If no parameter set is specified, the parameter belongs to all parameter sets.

`Position` (`System.Int32`) Optional named parameter. Specifies the position of the parameter within a Windows PowerShell command.

`ValueFromPipeline` (`System.Boolean`) Optional named parameter. `True` indicates that the cmdlet parameter takes its value from a pipeline object. Specify this keyword if the cmdlet accesses the complete object, not just a property of the object. The default is `false`.

`ValueFromPipelineByPropertyName` (`System.Boolean`) Optional named parameter. `True` indicates that the cmdlet parameter takes its value from a property of a pipeline object that has either the same name or the same alias as this parameter. For example, if the cmdlet has a `Name` parameter and the pipeline object also has a `Name` property, the value of the `Name` property is assigned to the `Name` parameter of the cmdlet. The default is `false`.

`ValueFromRemainingArguments` ([System.Boolean](#)) Optional named parameter. `True` indicates that the cmdlet parameter accepts all remaining arguments that are passed to the cmdlet. The default is `false`.

`HelpMessage` ([System.String](#)) Optional named parameter. Specifies a short description of the parameter. Windows PowerShell displays this message when a cmdlet is run and a mandatory parameter is not specified.

`HelpMessageBaseName` ([System.String](#)) Optional named parameter. Specifies the location where resource identifiers reside. For example, this parameter could specify a resource assembly that contains Help messages that you want to localize.

`HelpMessageResourceId` ([System.String](#)) Optional named parameter. Specifies the resource identifier for a Help message.

`DontShow` ([System.Boolean](#)) Optional named parameter. `True` indicates that the parameter is hidden from the user for tab expansion and IntelliSense. The default is `false`.

Remarks

- For more information about how to declare this attribute, see [How to Declare Cmdlet Parameters](#).
- A cmdlet can have any number of parameters. However, for a better user experience, limit the number of parameters.
- Parameters must be declared on public non-static fields or properties. Parameters should be declared on properties. The property must have a public set accessor, and if the `ValueFromPipeline` or `ValueFromPipelineByPropertyName` keyword is specified, the property must have a public get accessor.
- When you specify positional parameters, limit the number of positional parameters in a parameter set to less than five. And, positional parameters do not have to be contiguous. Positions 5, 100, and 250 work the same as positions 0, 1, and 2.
- When the `Position` keyword is not specified, the cmdlet parameter must be referenced by its name.
- When you use parameter sets, note the following:
 - Each parameter set must have at least one unique parameter. Good cmdlet design indicates this unique parameter should also be mandatory if possible. If

your cmdlet is designed to be run without parameters, the unique parameter cannot be mandatory.

- No parameter set should contain more than one positional parameter with the same position.
- Only one parameter in a parameter set should declare `ValueFromPipeline = true`.
- Multiple parameters can define `ValueFromPipelineByPropertyName = true`.
- For more information about the guidelines for parameter names, see [Cmdlet Parameter Names](#).
- The parameter attribute is defined by the [System.Management.Automation.ParameterAttribute](#) class.
- The `DontShow` parameter has the following side effects:
 - Affects all parameter sets for the associated parameter, even if there's a parameter set in which `DontShow` is unused.
 - Hides common parameters from tab completion and IntelliSense. `DontShow` doesn't hide the optional common parameters: `WhatIf`, `Confirm`, or `UseTransaction`.

ValidateCount Attribute Declaration

Article • 09/17/2021

The ValidateCount attribute specifies the minimum and maximum number of arguments allowed for a cmdlet parameter.

Syntax

C#

```
[ValidateCount(int minLength, int maxLength)]
```

Parameters

`MinLength` ([System.Int32](#)) Required. Specifies the minimum number of arguments.

`MaxLength` ([System.Int32](#)) Required. Specifies the maximum number of arguments.

Remarks

- For more information about how to declare this attribute, see [How to Validate an Argument Count](#).
- When this attribute is not invoked, the corresponding cmdlet parameter can have any number of arguments.
- The Windows PowerShell runtime throws an error under the following conditions:
 - The `MinLength` and `MaxLength` attribute parameters are not of type [System.Int32](#).
 - The value of the `MaxLength` attribute parameter is less than the value of the `MinLength` attribute parameter.
- The ValidateCount attribute is defined by the [System.Management.Automation.ValidateCountAttribute](#) class.

ValidateLength Attribute Declaration

Article • 09/17/2021

The ValidateLength attribute specifies the minimum and maximum number of characters for a cmdlet parameter argument. This attribute can also be used by Windows PowerShell functions.

Syntax

C#

```
[ValidateLength(int minLength, int maxLength)]
```

Parameters

`MinLength` ([System.Int32](#)) Required. Specifies the minimum number of characters allowed.

`MaxLength` ([System.Int32](#)) Required. Specifies the maximum number of characters allowed.

Remarks

- For more information about how to declare this attribute, see [How to Declare Input Validation Rules](#).
- When this attribute is not used, the corresponding parameter argument can be of any length.
- The Windows PowerShell runtime throws an error under the following conditions:
 - When the value of the `MaxLength` attribute parameter is less than the value of the `MinLength` attribute parameter.
 - When the `MaxLength` attribute parameter is set to 0.
 - When the argument is not a string.
- The ValidateLength attribute is defined by the [System.Management.Automation.ValidateLengthAttribute](#) class.

See Also

[System.Management.Automation.ValidateLengthAttribute](#)

[Writing a Windows PowerShell Cmdlet](#)

ValidatePattern Attribute Declaration

Article • 03/24/2025

The `ValidatePattern` attribute specifies a regular expression pattern that validates the argument of a cmdlet parameter. This attribute can also be used by Windows PowerShell functions.

When `ValidatePattern` is invoked within a cmdlet, the Windows PowerShell runtime converts the argument of the cmdlet parameter to a string and then compares that string to the pattern supplied by the `ValidatePattern` attribute. The cmdlet is run only if the converted string representation of the argument and the supplied pattern match. If they do not match, an error is thrown by the Windows PowerShell runtime.

Syntax

C#

```
[ValidatePattern(string regexString)]
[ValidatePattern(string regexString, Named Parameters)]
```

Parameters

`RegexString` ([System.String](#)) Required. Specifies a regular expression that validates the parameter argument.

`Options` ([System.Text.RegularExpressions.RegexOptions](#)) Optional named parameter. Specifies a bitwise combination of [System.Text.RegularExpressions.RegexOptions](#) flags that specify regular expression options.

Remarks

- This attribute can be used only once per parameter.
- You can use the `Option` parameter of the attribute to further define the pattern. For example, you can make the pattern case sensitive.
- If this attribute is applied to a collection, each element in the collection must match the pattern.

- The ValidatePattern attribute is defined by the [System.Management.Automation.ValidatePatternAttribute](#) class.

ValidateRange Attribute Declaration

Article • 09/17/2021

The ValidateRange attribute specifies the minimum and maximum values (the range) for the cmdlet parameter argument. This attribute can also be used by Windows PowerShell functions.

Syntax

C#

```
[ValidateRange(object minRange, object maxRange)]
```

Parameters

`MinRange` ([System.Object](#)) Required. Specifies the minimum value allowed.

`MaxRange` ([System.Object](#)) Required. Specifies the maximum value allowed.

Remarks

- The Windows PowerShell runtime throws a construction error when the value of the `MinRange` parameter is greater than the value of the `MaxRange` parameter.
- The Windows PowerShell runtime throws a validation error under the following conditions:
 - When the value of the argument is less than the `MinRange` limit or greater than the `MaxRange` limit.
 - When the argument is not of the same type as the `MinRange` and the `MaxRange` parameters.
- The ValidateRange attribute is defined by the [System.Management.Automation.ValidateRangeAttribute](#) class.

ValidateScript Attribute Declaration

Article • 10/03/2022

The `ValidateScript` attribute specifies a script that's used to validate a parameter or variable value. PowerShell pipes the value to the script, and generates an error if the script returns `$false` or if the script throws an exception.

When you use the `ValidateScript` attribute, the value that's being validated is mapped to the `$_` variable. You can use the `$_` variable to refer to the value in the script.

Syntax

C#

```
[ValidateScriptAttribute( ScriptBlock scriptBlock )]  
[ValidateScriptAttribute( ScriptBlock scriptBlock, Named Parameters )]
```

Parameters

- `scriptBlock` - ([System.Management.Automation.ScriptBlock](#)) Required. The script block used to validate the input.
- `ErrorMessage` - Optional named parameter - The item being validated and the validating scriptblock are passed as the first and second formatting arguments.

ⓘ Note

The `ErrorMessage` argument was added in PowerShell 6.

Remarks

- This attribute can be used only once per parameter.
- If this attribute is applied to a collection, each element in the collection must match the pattern.
- The `ValidateScript` attribute is defined by the [System.Management.Automation.ValidateScriptAttribute](#) class.

 [Provide product feedback](#)

ValidateSet Attribute Declaration

Article • 03/24/2025

The `ValidateSetAttribute` attribute specifies a set of possible values for a cmdlet parameter argument. This attribute can also be used by Windows PowerShell functions.

When this attribute is specified, the Windows PowerShell runtime determines whether the supplied argument for the cmdlet parameter matches an element in the supplied element set. The cmdlet is run only if the parameter argument matches an element in the set. If no match is found, an error is thrown by the Windows PowerShell runtime.

Syntax

C#

```
[ValidateSetAttribute(params string[] validValues)]
[ValidateSetAttribute(params string[] validValues, Named Parameters)]
```

Parameters

`ValidValues` ([System.String](#)) Required. Specifies the valid parameter element values. The following sample shows how to specify one element or multiple elements.

C#

```
[ValidateSetAttribute("Steve")]
[ValidateSetAttribute("Steve", "Mary")]
```

`IgnoreCase` ([System.Boolean](#)) Optional named parameter. The default value of `true` indicates that case is ignored. A value of `false` makes the cmdlet case-sensitive.

Remarks

- This attribute can be used only once per parameter.
- If the parameter value is an array, every element of the array must match an element of the attribute set.
- The `ValidateSetAttribute` attribute is defined by the [System.Management.Automation.ValidateSetAttribute](#) class.

Cmdlet Aliases

Article • 09/17/2021

You can use cmdlet aliases to improve the cmdlet user experience. You can add aliases to frequently used cmdlets to reduce typing and to make it easier to complete tasks quickly. You can include built-in aliases in your cmdlets, or users can define their own custom aliases.

For example, the [Get-Command](#) cmdlet has a built-in `gcm` alias. You can also use aliases to add command names from other languages so that users do not have to learn new commands.

Alias Guidelines

Follow these guidelines when you create built-in aliases for your cmdlets:

- Before you assign aliases, start Windows PowerShell, and then run the [Get-Alias](#) cmdlet to see the aliases that are already used.
- Include an alias prefix that references the verb of the cmdlet name and an alias suffix that references the noun of the cmdlet name. For example, the alias for the `Import-Module` cmdlet is `ipmo`. For a list of all the verbs and their aliases, see [Cmdlet Verbs](#).
- For cmdlets that have the same verb, include the same alias prefix. For example, the aliases for all the Windows PowerShell cmdlets that have the "Get" verb in their name use the "g" prefix.
- For cmdlets that have the same noun, include the same alias suffix. For example, the aliases for all the Windows PowerShell cmdlets that have the "Session" noun in their name use the "sn" suffix.
- For cmdlets that are equivalent to commands in other languages, use the name of the command.
- In general, make aliases as short as possible. Make sure the alias has at least one distinct character for the verb and one distinct character for the noun. Add more characters as needed to make the alias unique.
- For cmdlet written in C# (or any other compiled .NET language), the alias can be defined using the [Alias attribute](#). For example:

C#

```
[Cmdlet("Get", "SomeObject")]
[Alias("gso")]
public class GetSomeObjectCommand : Cmdlet
```

Cmdlet Output

Article • 09/17/2021

This section discusses the types of cmdlet output and the methods that cmdlets can call to generate output such as error messages and objects. This section also describes how to define the .NET Framework types that are returned by your cmdlets and how those objects are displayed.

In This Section

[Types of Cmdlet Output](#) Describes the types and output that cmdlets can generate and the methods that cmdlets call to generate the output.

[Cmdlet Error Reporting](#) Discusses cmdlet error reporting, a subset of cmdlet output.

[Extending Output Objects](#) Discusses how to use the types files (`.ps1xml`) to extend the .NET Framework objects that are returned by cmdlets, functions, and scripts.

[PowerShell Formatting Files](#) Describes the formatting files (`.format.ps1xml`) files that define the default display for a specific set of .NET Framework objects in Windows PowerShell.

[Custom Formatting Files](#) Describes how to create your own custom formatting files to overwrite the default display formats or to define the display of objects returned by your own commands.

See Also

[Writing a Windows PowerShell Cmdlet](#)

Types of cmdlet output

Article • 09/17/2021

PowerShell provides several methods that can be called by cmdlets to generate output. These methods use a specific operation to write their output to a specific data stream, such as the success data stream or the error data stream. This article describes the types of output and the methods used to generate them.

Types of output

Success output

Cmdlets can report success by returning an object that can be processed by the next command in the pipeline. After the cmdlet has successfully performed its action, the cmdlet calls the [System.Management.Automation.Cmdlet.WriteObject](#) method. We recommend that you call this method instead of the [System.Console.WriteLine](#) or [System.Management.Automation.Host.PSHostUserInterface.WriteLine](#) methods.

You can provide a **PassThru** switch parameter for cmdlets that do not typically return objects. When the **PassThru** switch parameter is specified at the command line, the cmdlet is asked to return an object. For an example of a cmdlet that has a **PassThru** parameter, see [Add-History](#).

Error output

Cmdlets can report errors. When a terminating error occurs, the cmdlet throws an exception. When a non-terminating error occurs, the cmdlet calls the [System.Management.Automation.Provider.CmdletProvider.WriteError](#) method to send an error record to the error data stream. For more information about error reporting, see [Error Reporting Concepts](#).

Verbose output

Cmdlets can provide useful information to you while the cmdlet is correctly processing records by calling the [System.Management.Automation.Cmdlet.WriteVerbose](#) method. The method generates verbose messages that indicate how the action is proceeding.

By default, verbose messages are not displayed. You can specify the **Verbose** parameter when the cmdlet is run to display these messages. **Verbose** is a common parameter that

is available to all cmdlets.

Progress output

Cmdlets can provide progress information to you when the cmdlet is performing tasks that take a long time to complete, such as copying a directory recursively. To display progress information the cmdlet calls the [System.Management.Automation.Cmdlet.WriteProgress](#) method.

Debug output

Cmdlets can provide debug messages that are helpful when troubleshooting the cmdlet code. To display debug information the cmdlet calls the [System.Management.Automation.Cmdlet.WriteDebug](#) method.

By default, debug messages are not displayed. You can specify the **Debug** parameter when the cmdlet is run to display these messages. **Debug** is a common parameter that is available to all cmdlets.

Warning output

Cmdlets can display warning messages by calling the [System.Management.Automation.Cmdlet.WriteWarning](#) method.

By default, warning messages are displayed. However, you can configure warning messages by using the `$WarningPreference` variable or by using the **Verbose** and **Debug** parameters when the cmdlet is called.

Displaying output

For all write-method calls, the content display is determined by specific runtime variables. The exception is the [System.Management.Automation.Cmdlet.WriteObject](#) method. By using these variables, you can make the appropriate write call at the correct place in your code and not worry about when or if the output should be displayed.

Accessing the output functionality of a host application

You can also design a cmdlet to directly access the output functionality of a host application through the PowerShell runtime. Using the host APIs provided by PowerShell

instead of `System.Console` or `System.Windows.Forms` ensures that your cmdlet will work with a variety of hosts. For example: the `powershell.exe` console host, the `powershell_ise.exe` graphical host, the PowerShell remoting host, and third-party hosts.

[Error Reporting Concepts](#)

[Cmdlet Overview](#)

[Writing a Windows PowerShell Cmdlet](#)

Cmdlet error reporting

Article • 09/15/2023

Cmdlets should report errors differently depending on whether the errors are terminating errors or non-terminating errors. Terminating errors are errors that cause the pipeline to be terminated immediately, or errors that occur when there's no reason to continue processing. Non-terminating errors are those errors that report a current error condition, but the cmdlet can continue to process input objects. With non-terminating errors, the user is typically notified of the problem, but the cmdlet continues to process the next input object.

Unless specified otherwise, all classes and methods mentioned in this document come from the [System.Management.Automation](#) namespace.

Terminating and non-terminating errors

The following guidelines can be used to determine if an error condition is a terminating error or a non-terminating error.

- Does the error condition prevent your cmdlet from successfully processing any further input objects? If so, this is a terminating error.
- Is the error condition related to a specific input object or a subset of input objects? If so, this is a non-terminating error.
- Does the cmdlet accept multiple input objects, such that processing may succeed on another input object? If so, this is a non-terminating error.
- Cmdlets that can accept multiple input objects should decide between what are terminating and non-terminating errors, even when a particular situation applies to only a single input object.
- Cmdlets can receive any number of input objects and send any number of success or error objects before throwing a terminating exception. There's no relationship between the number of input objects received and the number of success and error objects sent.
- Cmdlets that can accept only 0-1 input objects and generate only 0-1 output objects should treat errors as terminating errors and generate terminating exceptions.

Reporting non-terminating errors

The reporting of a non-terminating error should always be done within the cmdlet's implementation of the following methods:

- [Cmdlet.BeginProcessing](#)
- [Cmdlet.ProcessRecord](#)
- [Cmdlet.EndProcessing](#)

These types of errors are reported by calling the [Cmdlet.WriteError](#) method that in turn sends an error record to the error stream.

Reporting terminating errors

Terminating errors are reported by throwing exceptions or by calling the [Cmdlet.ThrowTerminatingError](#) method. Be aware that cmdlets can also catch and rethrow exceptions such as [OutOfMemory](#), however, they aren't required to rethrow exceptions as the PowerShell runtime will catch them as well.

You can also define your own exceptions for issues specific to your situation, or add additional information to an existing exception using its error record.

Error records

PowerShell describes a non-terminating error condition with [ErrorRecord](#) objects. Each object provides error category information, an optional target object, and details about the error condition.

Error identifiers

The error identifier is a simple string that identifies the error condition within the cmdlet. PowerShell combines this identifier with a cmdlet identifier to create a fully qualified error identifier that can be used later when filtering error streams or logging errors, when responding to specific errors, or with other user-specific activities.

The following guidelines should be followed when specifying error identifiers:

- Assign different, highly specific, error identifiers to different code paths. Each code path that calls [Cmdlet.WriteError](#) or [Cmdlet.ThrowTerminatingError](#) should have its own error identifier.

- Error identifiers should be unique to Common Language Runtime (CLR) exception types for both terminating and non-terminating errors.
- Don't change the semantics of an error identifier between versions of your cmdlet or PowerShell provider. After the semantics of an error identifier is established, it should remain constant throughout the lifecycle of your cmdlet.
- For terminating errors, use a unique error identifier for a particular CLR exception type. If the exception type changes, use a new error identifier.
- For non-terminating errors, use a specific error identifier for a specific input object.
- Choose text for the identifier that tersely corresponds to the error being reported. Don't use white space or punctuation.
- Don't generate error identifiers that aren't reproducible. For example, don't generate identifiers that include a process identifier. Error identifiers are useful only when they correspond to identifiers that are seen by other users who are experiencing the same problem.

Error categories

Error categories are used to group errors for the user. PowerShell defines these categories and cmdlets and PowerShell providers must choose between them when generating the error record.

For a description of the error categories that are available, see the [ErrorCategory](#) enumeration. In general, you should avoid using **NoError**, **UndefinedError**, and **GenericError** whenever possible.

Users can view errors based on category when they set `$ErrorView` to **CategoryView**.

Extending Output Objects

Article • 02/24/2025

You can extend the .NET Framework objects that are returned by cmdlets, functions, and scripts by using types files (`.ps1xml`). Types files are XML-based files that let you add properties and methods to existing objects. For example, Windows PowerShell provides the `Types.ps1xml` file, which adds elements to several existing .NET Framework objects. The `Types.ps1xml` file is located in the Windows PowerShell installation directory (`$PSHOME`). You can create your own types file to further extend those objects or to extend other objects. When you extend an object by using a types file, any instance of the object is extended with the new elements.

Extending the `System.Array` Object

The following example shows how Windows PowerShell extends the `System.Array` object in the `Types.ps1xml` file. By default, `System.Array` objects have a `Length` property that lists the number of objects in the array. However, because the name "length" does not clearly describe the property, Windows PowerShell adds the `Count` alias property, which displays the same value as the `Length` property. The following XML adds the `Count` property to the `System.Array` type.

```
XML

<Type>
  <Name>System.Array</Name>
  <Members>
    <AliasProperty>
      <Name>Count</Name>
      <ReferencedMemberName>Length</ReferencedMemberName>
    </AliasProperty>
  </Members>
</Type>
```

To see this new alias property, use a `Get-Member` command on any array, as shown in the following example.

```
PowerShell

Get-Member -InputObject (1,2,3,4)
```

The command returns the following results.

Output

Name	MemberType	Definition
Count	AliasProperty	Count = Length
Address	Method	System.Object& Address(Int32)
Clone	Method	System.Object Clone()
CopyTo	Method	System.Void CopyTo(Array array, Int32 index):
Equals	Method	System.Boolean Equals(Object obj)
Get	Method	System.Object Get(Int32)
...		
Length	Property	System.Int32 Length {get;}

You can use either the `Count` property or the `Length` property to determine how many objects are in an array. For example:

PowerShell

```
PS> (1, 2, 3, 4).Count
```

Output

```
4
```

PowerShell

```
PS> (1, 2, 3, 4).Length
```

Output

```
4
```

Custom Types Files

To create a custom types file, start by copying an existing types file. The new file can have any name, but it must have a `.ps1xml` file name extension. When you copy the file, you can place the new file in any directory that is accessible to Windows PowerShell, but it is useful to place the files in the Windows PowerShell installation directory (`$PSHOME`) or in a subdirectory of the installation directory.

To add your own extended types to the file, add a `types` element for each object that you want to extend. The following topics provide examples.

- For more information about adding properties and property sets, see [Extended Properties](#)
- For more information about adding methods, see [Extended Methods](#).
- For more information about adding member sets, see [Extended Member Sets](#).

After you define your own extended types, use one of the following methods to make your extended objects available:

- To make your extended types file available to the current session, use the [Update-TypeData](#) cmdlet to add the new file. If you want your types to take precedence over the types that are defined in other types files (including the Types.ps1xml file), use the `PrependData` parameter of the [Update-TypeData](#) cmdlet.
- To make your extended types file available to all future sessions, add the types file to a module, export the current session, or add the [Update-TypeData](#) command to your Windows PowerShell profile.

Signing Types Files

Types files should be digitally signed to prevent tampering because the XML can include script blocks. For more information about adding digital signatures, see [about_Signing](#)

[Writing a Windows PowerShell Cmdlet](#)

Extending Properties for Objects

Article • 09/17/2021

When you extend .NET Framework objects, you can add alias properties, code properties, note properties, script properties, and property sets to the objects. The XML that defines these properties is described in the following sections.

ⓘ Note

The examples in the following sections are from the default `Types.ps1xml` types file in the PowerShell installation directory (`$PSHOME`). For more information, see [About Types.ps1xml](#).

Alias properties

An alias property defines a new name for an existing property.

In the following example, the `Count` property is added to the `System.Array` type. The `AliasProperty` element defines the extended property as an alias property. The `Name` element specifies the new name. And, the `ReferencedMemberName` element specifies the existing property that is referenced by the alias. You can also add the `AliasProperty` element to the members of the `MemberSets` element.

XML

```
<Type>
  <Name>System.Array</Name>
  <Members>
    <AliasProperty>
      <Name>Count</Name>
      <ReferencedMemberName>Length</ReferencedMemberName>
    </AliasProperty>
  </Members>
</Type>
```

Code properties

A code property references a static property of a .NET Framework object.

In the following example, the `Mode` property is added to the `System.IO.DirectoryInfo` type. The `CodeProperty` element defines the extended property as a code property. The

Name element specifies the name of the extended property. And, the **GetCodeReference** element defines the static method that is referenced by the extended property. You can also add the **CodeProperty** element to the members of the **MemberSets** element.

XML

```
<Type>
  <Name>System.IO.DirectoryInfo</Name>
  <Members>
    <CodeProperty>
      <Name>Mode</Name>
      <GetCodeReference>

    <Type>
      <Name>Microsoft.PowerShell.Commands.FileSystemProvider</Name>
      <Method>
        <Name>Mode</Name>
        <GetCodeReference>
      </Method>
    </Type>
  </Members>
</Type>
```

Note properties

A note property defines a property that has a static value.

In the following example, the **Status** property, whose value is always **Success**, is added to the **System.IO.DirectoryInfo** type. The **NoteProperty** element defines the extended property as a note property. The **Name** element specifies the name of the extended property. The **Value** element specifies the static value of the extended property. The **NoteProperty** element can also be added to the members of the **MemberSets** element.

XML

```
<Type>
  <Name>System.IO.DirectoryInfo</Name>
  <Members>
    <NoteProperty>
      <Name>Status</Name>
      <Value>Success</Value>
    </NoteProperty>
  </Members>
</Type>
```

Script properties

A script property defines a property whose value is the output of a script.

In the following example, the **VersionInfo** property is added to the **System.IO.FileInfo** type. The **ScriptProperty** element defines the extended property as a script property. The **Name** element specifies the name of the extended property. And, the **GetScriptBlock** element specifies the script that generates the property value. You can also add the **ScriptProperty** element to the members of the **MemberSets** element.

XML

```
<Type>
  <Name>System.IO.FileInfo</Name>
  <Members>
    <ScriptProperty>
      <Name>VersionInfo</Name>
      <GetScriptBlock>
        [System.Diagnostics.FileVersionInfo]::GetVersionInfo($this.FullName)
      </GetScriptBlock>
    </ScriptProperty>
  </Members>
</Type>
```

Property sets

A property set defines a group of extended properties that can be referenced by the name of the set. For example, the **Format-Table** **Property** parameter can specify a specific property set to be displayed. When a property set is specified, only those properties that belong to the set are displayed.

There's no restriction on the number of property sets that can be defined for an object. However, the property sets used to define the default display properties of an object must be specified within the **PSStandardMembers** member set. In the **Types.ps1xml** types file, the default property set names include **DefaultDisplayProperty**, **DefaultDisplayPropertySet**, and **DefaultKeyPropertySet**. Any additional property sets that you add to the **PSStandardMembers** member set are ignored.

In the following example, the **DefaultDisplayPropertySet** property set is added to the **PSStandardMembers** member set of the **System.ServiceProcess.ServiceController** type. The **PropertySet** element defines the group of properties. The **Name** element specifies the name of the property set. And, the **ReferencedProperties** element specifies the properties of the set. You can also add the **PropertySet** element to the members of the **Type** element.

XML

```
<Type>
  <Name>System.ServiceProcess.ServiceController</Name>
  <Members>
    <MemberSet>
      <Name>PSStandardMembers</Name>
      <Members>
        <PropertySet>
          <Name>DefaultDisplayPropertySet</Name>
          <ReferencedProperties>
            <Name>Status</Name>
            <Name>Name</Name>
            <Name>DisplayName</Name>
          </ReferencedProperties>
        </PropertySet>
      </Members>
    </MemberSet>
  </Members>
</Type>
```

[Writing a Windows PowerShell Cmdlet](#)

Defining Default Methods for Objects

Article • 09/17/2021

When you extend .NET Framework objects, you can add code methods and script methods to the objects. The XML that is used to define these methods is described in the following sections.

ⓘ Note

The examples in the following sections are from the `Types.ps1xml` types file in the Windows PowerShell installation directory (`$PSHOME`). For more information, see [About Types.ps1xml](#).

Code methods

A code method references a static method of a .NET Framework object.

In the following example, the `ToString` method is added to the `System.Xml.XmlNode` type. The `PSCodeMethod` element defines the extended method as a code method. The `Name` element specifies the name of the extended method. And, the `CodeReference` element specifies the static method. You can also add the `PSCodeMethod` element to the members of the `PSMemberSets` element.

XML

```
<Type>
  <Name>System.Xml.XmlNode</Name>
  <Members>
    <CodeMethod>
      <Name>ToString</Name>
      <CodeReference>
        <TypeName>Microsoft.PowerShell.ToStringCodeMethods</TypeName>
        <MethodName>XmlNode</MethodName>
      </CodeReference>
    </CodeMethod>
  </Members>
</Type>
```

Script methods

A script method defines a method whose value is the output of a script. In the following example, the `Convert.ToDateTime` method is added to the `System.Management.ManagementObject` type. The `PSScriptMethod` element defines the extended method as a script method. The `Name` element specifies the name of the extended method. And, the `Script` element specifies the script that generates the method value. You can also add the `PSScriptMethod` element to the members of the `PSMemberSets` element.

XML

```
<Type>
  <Name>System.Management.ManagementObject</Name>
  <Members>
    <ScriptMethod>
      <Name>Convert.ToDateTime</Name>
      <Script>

[System.Management.ManagementDateTimeConverter]::ToDateTIme($args[0])
      </Script>
    </ScriptMethod>
  </Members>
</Type>
```

Defining Default Member Sets for Objects

Article • 09/17/2021

The PSStandardMembers member set is used by Windows PowerShell to define the default property sets for an object. The default property sets can be used by commands such as the formatting cmdlets to display only those properties that are defined by the property set. The default property sets include DefaultDisplayProperty, DefaultDisplayPropertySet, and DefaultKeyPropertySet. Windows PowerShell ignores all other member sets and any other property sets added to the PSStandardMembers member set.

Member Set for System.Diagnostics.Process

In the following example, the PSStandardMembers member set defines the DefaultDisplayPropertySet property set for [System.Diagnostics.Process](#) objects. This property set is used by the [Format-List](#) cmdlet.

XML

```
<Type>
  <Name>System.Diagnostics.Process</Name>
  <Members>
    <MemberSet>
      <Name>PSStandardMembers</Name>
      <Members>
        <PropertySet>
          <Name>DefaultDisplayPropertySet</Name>
          <ReferencedProperties>
            <Name>Id</Name>
            <Name>Handles</Name>
            <Name>CPU</Name>
            <Name>Name</Name>
          </ReferencedProperties>
        </PropertySet>
      </Members>
    </MemberSet>
```

The following output shows the default properties returned by the [Format-List](#) cmdlet. Only the `Id`, `Handles`, `CPU`, and `Name` properties are returned for each process object.

PowerShell

```
Get-Process | Format-List
```

Output

```
Id      : 2036
Handles : 27
CPU     :
Name    : AEADISRV
```

```
Id      : 272
Handles : 38
CPU     :
Name    : agrsmsvc
...
```

Custom Formatting Files

Article • 09/17/2021

The display format for the objects returned by cmdlets, functions, and scripts are defined using formatting files (`format.ps1xml` files). Several of these files are provided by Windows PowerShell to define the default display format for those objects returned by Windows PowerShell cmdlets. However, you can also create your own custom formatting files to overwrite the default display formats or to define the display of objects returned by your own commands.

Windows PowerShell uses the data in these formatting files to determine what is displayed and how the data is formatted. The displayed data can include the properties of an object or the value of a script block. Script blocks are used if you want to display some value that is not available directly from the properties of an object. For example, you may want to add the value of two properties of an object and display the sum as a separate piece of data. When you write your own formatting file, you will need to define *views* for the objects that you want to display. You can define a single view for each object, you can define a single view for multiple objects, or you can define multiple views for the same object. There is no limit to the number of views that you can define.

Important

Formatting files do not determine the elements of an object that are returned to the pipeline. When an object is returned to the pipeline, all members of that object are available.

Format Views

Formatting views can display objects in a table format, a list format, a wide format, and a custom format. For the most part, each formatting definition is described by a set of XML tags that describe a view. Each view contains the name of the view, the objects that use the view, and the elements of the view, such as the column and row information for a table view.

The following views are available.

Table view Lists the properties of an object or a script block value in one or more columns. Each column represents a property of the object or a script block value. You can define a table view that displays all the properties of an object, a subset of the properties of an object, or a combination of properties and script block values. Each row

of the table represents a returned object. For more information about this view, see [Table View](#).

List view Lists the properties of an object or a script block value in a single column. Each row of the list displays an optional label or the property name followed by the value of the property or script block. For more information about this view, see [List View](#).

Wide view Lists a single property of an object or a script block value in one or more columns. There is no label or header for this view. For more information about this view, see [Wide View](#).

Custom view Displays a customizable view of object properties or script block values that does not adhere to the rigid structure of table views, list views, or wide views. You can define a standalone custom view, or you can define a custom view that is used by another view, such as a table view or list view. For more information about this view, see [Custom View](#).

View XML Elements

The following example shows the XML tags used to define a table view that contains two columns. The [ViewDefinitions](#) element is the container element for all the views defined in the formatting file. The [View](#) element defines the specific table, list, wide, or custom view. Within each view, the [Name](#) element specifies the name of the view, the [ViewSelectedBy](#) element defines the objects that use the view, and the different control elements (such as the [TableControl](#) element) define the format of the view.

XML

```
ViewDefinitions
  <View>
    <Name>Name of View</Name>
    <ViewSelectedBy>
      <TypeName>Object to display using this view</TypeName>
      <TypeName>Object to display using this view</TypeName>
    </ViewSelectedBy>
    <TableControl>
      <TableHeaders>
        < TableColumnHeader>
          <Width></Width>
        </ TableColumnHeader>
        < TableColumnHeader>
          <Width></Width>
        </ TableColumnHeader>
      </TableHeaders>
      < TableRowEntries>
        < TableRowEntry>
          < TableColumnItems>
```

```
< TableColumnItem>
    <PropertyName>Header for column 1</PropertyName>
</TableColumnItem>
< TableColumnItem>
    <PropertyName>Header for column 2</PropertyName>
</TableColumnItem>
</TableColumnItems>
</TableRowEntry>
</TableRowEntries>
</TableControl>
</View>
</ViewDefinitions>
```

Requesting Confirmation from Cmdlets

Article • 09/17/2021

Cmdlets should request confirmation when they are about to make a change to the system that is outside of the Windows PowerShell environment. For example, if a cmdlet is about to add a user account or stop a process, the cmdlet should require confirmation from the user before it proceeds. In contrast, if a cmdlet is about to change a Windows PowerShell variable, the cmdlet does not need to require confirmation.

In order to make a confirmation request, the cmdlet must indicate that it supports confirmation requests, and it must call the [System.Management.Automation.Cmdlet.ShouldProcess](#) and [System.Management.Automation.Cmdlet.ShouldContinue](#) (optional) methods to display a confirmation request message.

Supporting Confirmation Requests

To support confirmation requests, the cmdlet must set the `SupportsShouldProcess` parameter of the `Cmdlet` attribute to `true`. This enables the `Confirm` and `WhatIf` cmdlet parameters that are provided by Windows PowerShell. The `Confirm` parameter allows the user to control whether the confirmation request is displayed. The `WhatIf` parameter allows the user to determine whether the cmdlet should display a message or perform its action. Do not manually add the `Confirm` and `WhatIf` parameters to a cmdlet.

The following example shows a `Cmdlet` attribute declaration that supports confirmation requests.

C#

```
[Cmdlet(VerbsDiagnostic.Test, "RequestConfirmationTemplate1",
    SupportsShouldProcess = true)]
```

Calling the Confirmation request methods

In the cmdlet code, call the [System.Management.Automation.Cmdlet.ShouldProcess](#) method before the operation that changes the system is performed. Design the cmdlet so that if the call returns a value of `false`, the operation is not performed, and the cmdlet processes the next operation.

Calling the ShouldContinue Method

Most cmdlets request confirmation using only the [System.Management.Automation.Cmdlet.ShouldProcess](#) method. However, some cases might require additional confirmation. For these cases, supplement the [System.Management.Automation.Cmdlet.ShouldProcess](#) call with a call to the [System.Management.Automation.Cmdlet.ShouldContinue](#) method. This allows the cmdlet or provider to more finely control the scope of the **Yes to all** response to the confirmation prompt.

If a cmdlet calls the [System.Management.Automation.Cmdlet.ShouldContinue](#) method, the cmdlet must also provide a [Force](#) switch parameter. If the user specifies [Force](#) when the user invokes the cmdlet, the cmdlet should still call [System.Management.Automation.Cmdlet.ShouldProcess](#), but it should bypass the call to [System.Management.Automation.Cmdlet.ShouldContinue](#).

[System.Management.Automation.Cmdlet.ShouldContinue](#) will throw an exception when it is called from a non-interactive environment where the user cannot be prompted. Adding a [Force](#) parameter ensures that the command can still be performed when it is invoked in a non-interactive environment.

The following example shows how to call [System.Management.Automation.Cmdlet.ShouldProcess](#) and [System.Management.Automation.Cmdlet.ShouldContinue](#).

```
C#  
  
if (ShouldProcess (...))  
{  
    if (Force || ShouldContinue(...))  
    {  
        // Add code that performs the operation.  
    }  
}
```

The behavior of a [System.Management.Automation.Cmdlet.ShouldProcess](#) call can vary depending on the environment in which the cmdlet is invoked. Using the previous guidelines will help ensure that the cmdlet behaves consistently with other cmdlets, regardless of the host environment.

For an example of calling the [System.Management.Automation.Cmdlet.ShouldProcess](#) method, see [How to Request Confirmations](#).

Specify the Impact Level

When you create the cmdlet, specify the impact level (the severity) of the change. To do this, set the value of the `ConfirmImpact` parameter of the `Cmdlet` attribute to High, Medium, or Low. You can specify a value for `ConfirmImpact` only when you also specify the `SupportsShouldProcess` parameter for the cmdlet.

For most cmdlets, you do not have to explicitly specify `ConfirmImpact`. Instead, use the default setting of the parameter, which is Medium. If you set `ConfirmImpact` to High, the operation will be confirmed by default. Reserve this setting for highly disruptive actions, such as reformatting a hard-disk volume.

Calling Non-Confirmation Methods

If the cmdlet or provider must send a message but not request confirmation, it can call the following three methods. Avoid using the `System.Management.Automation.Cmdlet.WriteObject` method to send messages of these types because `System.Management.Automation.Cmdlet.WriteObject` output is intermingled with the normal output of your cmdlet or provider, which makes script writing difficult.

- To caution the user and continue with the operation, the cmdlet or provider can call the `System.Management.Automation.Cmdlet.WriteWarning` method.
- To provide additional information that the user can retrieve using the `Verbose` parameter, the cmdlet or provider can call the `System.Management.Automation.Cmdlet.WriteVerbose` method.
- To provide debugging-level detail for other developers or for product support, the cmdlet or provider can call the `System.Management.Automation.Cmdlet.WriteDebug` method. The user can retrieve this information using the `Debug` parameter.

Cmdlets and providers first call the following methods to request confirmation before they attempt to perform an operation that changes a system outside of Windows PowerShell:

- `System.Management.Automation.Cmdlet.ShouldProcess`
- `System.Management.Automation.Provider.CmdletProvider.ShouldProcess`

They do so by calling the `System.Management.Automation.Cmdlet.ShouldProcess` method, which prompts the user to confirm the operation based on how the user invoked the command.

Writing a Windows PowerShell Cmdlet

Users Requesting Confirmation

Article • 09/24/2024

When you specify a value of `true` for the `SupportsShouldProcess` parameter of the Cmdlet attribute declaration, the **Confirm** parameter is added to the parameters of the cmdlet.

In the default environment, users can specify the **Confirm** parameter so that confirmation is requested when the `ShouldProcess()` method is called. This forces confirmation regardless of the impact level setting.

If **Confirm** parameter is not used, the `ShouldProcess()` call requests confirmation if the `ConfirmImpact` setting is equal to or greater than the `$ConfirmPreference` preference variable. The default setting of `$ConfirmPreference` is **High**. Therefore, in the default environment, only cmdlets and providers that specify a high-impact action request confirmation.

If **Confirm** is explicitly set to false (`-Confirm:$false`), the cmdlet runs without prompting for confirmation and the `$ConfirmPreference` shell variable is ignored.

Remarks

- For cmdlets and providers that specify `SupportsShouldProcess`, but not `ConfirmImpact`, those actions are handled as `Medium` impact actions, and they will not prompt by default. Their impact level is less than the default setting of the `$ConfirmPreference` preference variable.
- If the user specifies the `Verbose` parameter, they will be notified of the operation even if they are not prompted for confirmation.

Confirmation Messages

Article • 03/24/2025

Here are different confirmation messages that can be displayed depending on the variants of the [System.Management.Automation.Cmdlet.ShouldProcess](#) and [System.Management.Automation.Cmdlet.ShouldContinue](#) methods that are called.

ⓘ Important

For sample code that shows how to request confirmations, see [How to Request Confirmations](#).

Specifying the Resource

You can specify the resource that is about to be changed by calling the [System.Management.Automation.Cmdlet.ShouldProcess](#) method. In this case, you supply the resource by using the `target` parameter of the method, and the operation is added by Windows PowerShell. In the following message, the text "MyResource" is the resource acted on and the operation is the name of the command that makes the call.

Output

```
Confirm
Are you sure you want to perform this action?
Performing operation "Test-RequestConfirmationTemplate1" on Target
"MyResource".
[Y] Yes [A] Yes to All [N] No [L] No to All [S] Suspend [?] Help
(default is "Y"):
```

If the user selects **Yes** or **Yes to All** to the confirmation request (as shown in the following example), a call to the [System.Management.Automation.Cmdlet.ShouldContinue](#) method is made, which causes a second confirmation message to be displayed.

Output

```
Confirm
Are you sure you want to perform this action?
Performing operation "Test-RequestConfirmationTemplate1" on Target
"MyResource".
[Y] Yes [A] Yes to All [N] No [L] No to All [S] Suspend [?] Help
(default is "Y"): y
```

```
Confirm  
Continue with this operation?  
[Y] Yes [N] No [S] Suspend [?] Help (default is "Y"):
```

Specifying the Operation and Resource

You can specify the resource that is about to be changed and the operation that the command is about to perform by calling the [System.Management.Automation.Cmdlet.ShouldProcess](#) method. In this case, you supply the resource by using the `target` parameter and the operation by using the `target` parameter. In the following message, the text "MyResource" is the resource acted on and "MyAction" is the operation to be performed.

Output

```
Confirm  
Are you sure you want to perform this action?  
Performing operation "MyAction" on Target "MyResource".  
[Y] Yes [A] Yes to All [N] No [L] No to All [S] Suspend [?] Help  
(default is "Y"):
```

If the user selects **Yes** or **Yes to All** to the previous message, a call to the [System.Management.Automation.Cmdlet.ShouldContinue](#) method is made, which causes a second confirmation message to be displayed.

Output

```
Confirm  
Are you sure you want to perform this action?  
Performing operation "MyAction" on Target "MyResource".  
[Y] Yes [A] Yes to All [N] No [L] No to All [S] Suspend [?] Help  
(default is "Y"): y  
  
Confirm  
Continue with this operation?  
[Y] Yes [N] No [S] Suspend [?] Help (default is "Y"):
```

Error Reporting Concepts

Article • 03/24/2025

Windows PowerShell provides two mechanisms for reporting errors: one mechanism for *terminating errors* and another mechanism for *non-terminating errors*. It is important for your cmdlet to report errors correctly so that the host application that is running your cmdlets can react in an appropriate manner.

Your cmdlet should call the

[System.Management.Automation.Cmdlet.ThrowTerminatingError*](#) method when an error occurs that does not or should not allow the cmdlet to continue to process its input objects. Your cmdlet should call the [System.Management.Automation.Cmdlet.WriteError](#) method to report non-terminating errors when the cmdlet can continue processing the input objects. Both methods provide an error record that the host application can use to investigate the cause of the error.

Use the following guidelines to determine whether an error is a terminating or non-terminating error.

- An error is a terminating error if it prevents your cmdlet from continuing to process the current object or from successfully processing any further input objects, regardless of their content.
- An error is a terminating error if you do not want your cmdlet to continue processing the current object or any further input objects, regardless of their content.
- An error is a terminating error if it occurs in a cmdlet that does not accept or return an object or if it occurs in a cmdlet that accepts or returns only one object.
- An error is a non-terminating error if you want your cmdlet to continue processing the current object and any further input objects.
- An error is a non-terminating error if it is related to a specific input object or subset of input objects.

Writing a Windows PowerShell Cmdlet

Terminating Errors

Article • 03/24/2025

This topic discusses the method used to report terminating errors. It also discusses how to call the method from within the cmdlet, and it discusses the exceptions that can be returned by the Windows PowerShell runtime when the method is called.

When a terminating error occurs, the cmdlet should report the error by calling the [System.Management.Automation.Cmdlet.ThrowTerminatingError*](#) method. This method allows the cmdlet to send an error record that describes the condition that caused the terminating error. For more information about error records, see [Windows PowerShell Error Records](#).

When the [System.Management.Automation.Cmdlet.ThrowTerminatingError*](#) method is called, the Windows PowerShell runtime permanently stops the execution of the pipeline and throws a [System.Management.Automation.PipelineStoppedException](#) exception. Any subsequent attempts to call [System.Management.Automation.Cmdlet.WriteObject](#), [System.Management.Automation.Cmdlet.WriteError](#), or several other APIs causes those calls to throw a [System.Management.Automation.PipelineStoppedException](#) exception.

The [System.Management.Automation.PipelineStoppedException](#) exception can also occur if another cmdlet in the pipeline reports a terminating error, if the user has asked to stop the pipeline, or if the pipeline has been halted before completion for any reason. The cmdlet does not need to catch the [System.Management.Automation.PipelineStoppedException](#) exception unless it must clean up open resources or its internal state.

Cmdlets can write any number of output objects or non-terminating errors before reporting a terminating error. However, the terminating error permanently stops the pipeline, and no further output, terminating errors, or non-terminating errors can be reported.

Cmdlets can call [System.Management.Automation.Cmdlet.ThrowTerminatingError*](#) only from the thread that called the [System.Management.Automation.Cmdlet.BeginProcessing](#), [System.Management.Automation.Cmdlet.ProcessRecord](#), or [System.Management.Automation.Cmdlet.EndProcessing](#) input processing method. Do not attempt to call [System.Management.Automation.Cmdlet.ThrowTerminatingError*](#) or [System.Management.Automation.Cmdlet.WriteError](#) from another thread. Instead, errors must be communicated back to the main thread.

It is possible for a cmdlet to throw an exception in its implementation of the [System.Management.Automation.Cmdlet.BeginProcessing](#), [System.Management.Automation.Cmdlet.ProcessRecord](#), or [System.Management.Automation.Cmdlet.EndProcessing](#) method. Any exception thrown from these methods (except for a few severe error conditions that stop the Windows PowerShell host) is interpreted as a terminating error which stops the pipeline, but not Windows PowerShell as a whole. (This applies only to the main cmdlet thread. Uncaught exceptions in threads spawned by the cmdlet, in general, halt the Windows PowerShell host.) We recommend that you use

[System.Management.Automation.Cmdlet.ThrowTerminatingError*](#) rather than throwing an exception because the error record provides additional information about the error condition, which is useful to the end-user. Cmdlets should honor the managed code guideline against catching and handling all exceptions (`catch (Exception e)`). Convert only exceptions of known and expected types into error records.

Non-Terminating Errors

Article • 09/17/2021

This topic discusses the method used to report non-terminating errors. It also discusses how to call the method from within the cmdlet.

When a non-terminating error occurs, the cmdlet should report this error by calling the [System.Management.Automation.Cmdlet.WriteError](#) method. When the cmdlet reports a non-terminating error, the cmdlet can continue to operate on this input object and on further incoming pipeline objects. If the cmdlet calls the [System.Management.Automation.Cmdlet.WriteError](#) method, the cmdlet can write an error record that describes the condition that caused the non-terminating error. For more information about error records, see [Windows PowerShell Error Records](#).

Cmdlets can call [System.Management.Automation.Cmdlet.WriteError](#) as necessary from within their input processing methods. However, cmdlets can call [System.Management.Automation.Cmdlet.WriteError](#) only from the thread that called the [System.Management.Automation.Cmdlet.BeginProcessing](#), [System.Management.Automation.Cmdlet.ProcessRecord](#), or [System.Management.Automation.Cmdlet.EndProcessing](#) input processing method. Do not call [System.Management.Automation.Cmdlet.WriteError](#) from another thread. Instead, communicate errors back to the main thread.

Displaying Error Information

Article • 09/17/2021

This topic discusses the ways in which users can display error information.

When your cmdlet encounters an error, the presentation of the error information will, by default, resemble the following error output.

PowerShell

```
$ Stop-Service lanmanworkstation  
You do not have sufficient permissions to stop the service Workstation.
```

However, users can view errors by category by setting the `$ErrorView` variable to `"CategoryView"`. Category view displays specific information from the error record rather than a free-text description of the error. This view can be useful if you have a long list of errors to scan. In category view, the previous error message is displayed as follows.

PowerShell

```
$ $ErrorView = "CategoryView"  
$ Stop-Service lanmanworkstation  
CloseError: (System.ServiceProcess.ServiceController:ServiceController)  
[Stop-Service], ServiceCommandException
```

For more information about error categories, see [Windows PowerShell Error Records](#).

Windows PowerShell Error Records

Article • 09/17/2021

Cmdlets must pass an [System.Management.Automation.ErrorRecord](#) object that identifies the error condition for terminating and non-terminating errors.

The [System.Management.Automation.ErrorRecord](#) object contains the following information:

- The exception that describes the error. Often, this is an exception that the cmdlet caught and converted into an error record. Every error record must contain an exception.

If the cmdlet did not catch an exception, it must create a new exception and choose the exception class that best describes the error condition. However, you do not need to throw the exception because it can be accessed through the [System.Management.Automation.ErrorRecord.Exception](#) property of the [System.Management.Automation.ErrorRecord](#) object.

- An error identifier that provides a targeted designator that can be used for diagnostic purposes and by Windows PowerShell scripts to handle specific error conditions with specific error handlers. Every error record must contain an error identifier (see Error Identifier).
- An error category that provides a general designator that can be used for diagnostic purposes. Every error record must specify an error category (see Error Category).
- An optional replacement error message and a recommended action (see Replacement Error Message).
- Optional invocation information about the cmdlet that threw the error. This information is specified by Windows PowerShell (see Invocation Message).
- The target object that was being processed when the error occurred. This might be the input object, or it might be another object that your cmdlet was processing. For example, for the command `Remove-Item -Recurse C:\somedirectory`, the error might be an instance of a FileInfo object for "C:\somedirectory\lockedfile". The target object information is optional.

Error Identifier

When you create an error record, specify an identifier that designates the error condition within your cmdlet. Windows PowerShell combines the targeted identifier with the name of your cmdlet to create a fully qualified error identifier. The fully qualified error identifier can be accessed through the

[System.Management.Automation.ErrorRecord.FullyQualifiedErrorId](#) property of the [System.Management.Automation.ErrorRecord](#) object. The error identifier is not available by itself. It is available only as part of the fully qualified error identifier.

Use the following guidelines to generate error identifiers when you create error records:

- Make error identifiers specific to an error condition. Target the error identifiers for diagnostic purposes and for scripts that handle specific error conditions with specific error handlers. A user should be able to use the error identifier to identify the error and its source. Error identifiers also enable reporting for specific error conditions from existing exceptions so that new exception subclasses are not required.
- In general, assign different error identifiers to different code paths. The end-user benefits from specific identifiers. Often, each code path that calls [System.Management.Automation.Cmdlet.WriteError](#) or [System.Management.Automation.Cmdlet.ThrowTerminatingError*](#) has its own identifier. As a rule, define a new identifier when you define a new template string for the error message, and vice-versa. Do not use the error message as an identifier.
- When you publish code using a particular error identifier, you establish the semantics of errors with that identifier for your complete product support lifecycle. Do not reuse it in a context that is semantically different from the original context. If the semantics of this error change, create and then use a new identifier.
- You should generally use a particular error identifier only for exceptions of a particular CLR type. If the type of the exception or the type of the target object changes, create and then use a new identifier.
- Choose text for your error identifier that concisely corresponds to the error that you are reporting. Use standard .NET Framework naming and capitalization conventions. Do not use white space or punctuation. Do not localize error identifiers.
- Do not dynamically generate error identifiers in a non-reproducible way. For example, do not incorporate error information such as a process ID. Error identifiers are useful only if they correspond to the error identifiers seen by other users who are experiencing the same error condition.

Error Category

When you create an error record, specify the category of the error using one of the constants defined by the [System.Management.Automation.ErrorCategory](#) enumeration. Windows PowerShell uses the error category to display error information when users set the `$ErrorView` variable to `"CategoryView"`.

Avoid using the [System.Management.Automation.ErrorCategory](#) **NotSpecified** constant. If you have any information about the error or about the operation that caused the error, choose the category that best describes the error or the operation, even if the category is not a perfect match.

The information displayed by Windows PowerShell is referred to as the category-view string and is built from the properties of the [System.Management.Automation.ErrorCategoryInfo](#) class. (This class is accessed through the error [System.Management.Automation.ErrorRecord.CategoryInfo](#) property.)

```
{Category}: ({TargetName}:{TargetType}):[{Activity}], {Reason}
```

The following list describes the information displayed:

- Category: A Windows PowerShell-defined [System.Management.Automation.ErrorCategory](#) constant.
- TargetName: By default, the name of the object the cmdlet was processing when the error occurred. Or, another cmdlet-defined string.
- TargetType: By default, the type of the target object. Or, another cmdlet-defined string.
- Activity: By default, the name of the cmdlet that created the error record. Or, some other cmdlet-defined string.
- Reason: By default, the exception type. Or, another cmdlet-defined string.

Replacement Error Message

When you develop an error record for a cmdlet, the default error message for the error comes from the default message text in the [System.Exception.Message](#) property. This is a read-only property whose message text is intended only for debugging purposes (according to the .NET Framework guidelines). We recommend that you create an error

message that replaces or augments the default message text. Make the message more user-friendly and more specific to the cmdlet.

The replacement message is provided by an [System.Management.Automation.ErrorDetails](#) object. Use one of the following constructors of this object because they provide additional localization information that can be used by Windows PowerShell.

- [ErrorDetails\(Cmdlet, String, String, Object\[\]\)](#): Use this constructor if your template string is a resource string in the same assembly in which the cmdlet is implemented or if you want to load the template string through an override of the [System.Management.Automation.Cmdlet.GetResourceString](#) method.
- [ErrorDetails\(Assembly, String, String, Object\[\]\)](#): Use this constructor if the template string is in another assembly and you do not load it through an override of [System.Management.Automation.Cmdlet.GetResourceString](#).

The replacement message should conform to the .NET Framework design guidelines for writing exception messages with a small difference. The guidelines state that exception messages should be written for developers. These replacement messages should be written for the cmdlet user.

The replacement error message must be added before the [System.Management.Automation.Cmdlet.WriteError](#) or [System.Management.Automation.Cmdlet.ThrowTerminatingError*](#) methods are called. To add a replacement message, set the [System.Management.Automation.ErrorRecord.ErrorDetails](#) property of the error record. When this property is set, Windows PowerShell displays the [System.Management.Automation.ErrorDetails.Message*](#) property instead of the default message text.

Recommended Action Information

The [System.Management.Automation.ErrorDetails](#) object can also provide information about what actions are recommended when the error occurs.

Invocation information

When a cmdlet uses [System.Management.Automation.Cmdlet.WriteError](#) or [System.Management.Automation.Cmdlet.ThrowTerminatingError*](#) to report an error record, Windows PowerShell automatically adds information that describes the command that was invoked when the error occurred. This information is provided by a

[System.Management.Automation.InvocationInfo](#) object that contains the name of the cmdlet that was invoked by the command, the command itself, and information about the pipeline or script. This property is read-only.

Interpreting ErrorRecord Objects

Article • 09/15/2023

In most cases, an [System.Management.Automation.ErrorRecord](#) object represents a non-terminating error generated by a command or script. Terminating errors can also specify the additional information in an ErrorRecord via the [System.Management.Automation.IContainsErrorRecord](#) interface.

If you want to write an error handler in your script or a host to handle specific errors that occur during command or script execution, you must interpret the [System.Management.Automation.ErrorRecord](#) object to determine whether it represents the class of error that you want to handle.

When a cmdlet encounters a terminating or non-terminating error, it should create an error record that describes the error condition. The host application must investigate these error records and perform whatever action will mitigate the error. The host application must also investigate error records for non-terminating errors that failed to process a record but were able to continue, and it must investigate error records for terminating errors that caused the pipeline to stop.

ⓘ Note

For terminating errors, the cmdlet calls the [System.Management.Automation.Cmdlet.ThrowTerminatingError](#) method. For non-terminating errors, the cmdlet calls the [System.Management.Automation.Cmdlet.WriteError](#) method.

Error Record Design

Error records are designed to provide additional error information that is not available in exceptions while ensuring that the combined information in each error record is unique. This uniqueness allows the host application to inspect the different parts of the error record so that it can identify the error condition and the action the host must take.

Interpreting Error Records

You can review several parts of the error record to identify the error. These parts include the following:

- The error category
- The error exception
- The fully qualified error identifier (FQID)
- Other information

The Error Category

The error category of the error record is one of the predefined constants provided by the [System.Management.Automation.ErrorCategory](#) enumeration. This information is available through the [System.Management.Automation.ErrorRecord.CategoryInfo](#) property of the [System.Management.Automation.ErrorRecord](#) object.

The cmdlet can specify the CloseError, OpenError, InvalidType, ReadError, and WriteError categories, and other error categories. The host application can use the error category to capture groups of errors.

The Exception

The exception included in the error record is provided by the cmdlet and can be accessed through the [System.Management.Automation.ErrorRecord.Exception](#) property of the [System.Management.Automation.ErrorRecord](#) object.

Host applications can use the `is` keyword to identify that the exception is of a specific class or of a derived class. It is better to branch on the exception type, as shown in the following example.

PowerShell

```
`if (MyNonTerminatingError.Exception is AccessDeniedException)`  
{  
    ...  
}
```

This way, you catch the derived classes. However, there are problems if the exception is serialized.

The FQID

The FQID is the most specific information you can use to identify the error. It is a string that includes a cmdlet-defined identifier, the name of the cmdlet class, and the source

that reported the error. In general, an error record is analogous to an event record of a Windows Event log. The FQID is analogous to the following tuple, which identifies the class of the event record: (*log name*, *source*, *event ID*).

The FQID is designed to be inspected as a single string. However, cases exist in which the error identifier is designed to be parsed by the host application. The following example is a well-formed fully qualified error identifier.

```
CommandNotFoundException,Microsoft.PowerShell.Commands.GetCommandCommand.
```

In the previous example, the first token is the error identifier, which is followed by the name of the cmdlet class. The error identifier can be a single token, or it can be a dot-separated identifier that allows for branching on inspection of the identifier. Do not use white space or punctuation in the error identifier. It is especially important not to use a comma; a comma is used by Windows PowerShell to separate the identifier and the cmdlet class name.

Other Information

The [System.Management.Automation.ErrorRecord](#) object might also provide information that describes the environment in which the error occurred. This information includes items such as error details, invocation information, and the target object that was being processed when the error occurred. Although this information might be useful to the host application, it is not typically used to identify the error. This information is available through the following properties:

- [System.Management.Automation.ErrorRecord.ErrorDetails](#)
- [System.Management.Automation.ErrorRecord.InvocationInfo](#)
- [System.Management.Automation.ErrorRecord.TargetObject](#)

Background Jobs

Article • 09/17/2021

Cmdlets can perform their action internally or as a Windows PowerShell *background job*. When a cmdlet runs as a background job, the work is done asynchronously in its own thread separate from the pipeline thread that the cmdlet is using. From the user perspective, when a cmdlet runs as a background job, the command prompt returns immediately even if the job takes an extended amount of time to complete, and the user can continue without interruption while the job runs.

Background Jobs, Child Jobs, and the Job Repository

The job object that is returned by the cmdlets that support background jobs defines the job. (The [Start-Job](#) cmdlet also returns a job object.) The name of the job, an identifier that is used to specify the job, the state information, and the child jobs are included in this definition. The job does not perform any of the work. Each background job has at least one child job because the child job performs the actual work. When you run a cmdlet so that the work is performed as a background job, the cmdlet must add the job and the child jobs to a common repository, referred to as the *job repository*.

For more information about how background jobs are handled at the command line, see the following:

- [about_Jobs](#)
- [about_Job_Details](#)
- [about_Remote_Jobs](#)

Writing a Cmdlet That Runs as a Background Job

To write a cmdlet that can be run as a background job, you must complete the following tasks:

- Define an `asJob` switch parameter so that the user can decide whether to run the cmdlet as a background job.

- Create an object that derives from the [System.Management.Automation.Job](#) class. This object can be a custom job object or a job object provided by Windows PowerShell, such as a [System.Management.Automation.PSEventJob](#) object.
- In a record processing method, add an `if` statement that detects whether the cmdlet should run as a background job.
- For custom job objects, implement the job class.
- Return the appropriate objects, depending on whether the cmdlet is run as a background job.

For a code example, see [How to Support Jobs](#).

Background Job-Related APIs

The following APIs are provided by Windows PowerShell to manage background jobs.

[System.Management.Automation.Job](#) Derives custom job objects. This is an abstract class.

[System.Management.Automation.JobRepository](#) Manages and provides information about the current active background jobs.

[System.Management.Automation.JobState](#) Defines the state of the background job. States include Started, Running, and Stopped.

[System.Management.Automation.JobStateInfo](#) Provides information about the state of a background job and, if the last state change was caused by an error, the reason the job entered its current state.

[System.Management.Automation.JobStateEventArgs](#) Provides the arguments for an event that is raised when a background job changes state.

Windows PowerShell Job Cmdlets

The following cmdlets are provided by Windows PowerShell to manage background jobs.

[Get-Job](#)

Gets Windows PowerShell background jobs that are running in the current session.

[Receive-Job](#)

Gets the results of the Windows PowerShell background jobs in the current session.

[Remove-Job](#)

Deletes a Windows PowerShell background job.

[Start-Job](#)

Starts a Windows PowerShell background job.

[Stop-Job](#)

Stops a Windows PowerShell background job.

[Wait-Job](#)

Suppresses the command prompt until one or all of the Windows PowerShell background jobs running in the session are complete.

Invoking Cmdlets and Scripts Within a Cmdlet

Article • 12/18/2023

A cmdlet can invoke other cmdlets and scripts from within the input processing method of the cmdlet. This allows you to add the functionality of existing cmdlets and scripts to your cmdlet without having to rewrite the code.

The Invoke Method

All cmdlets can invoke an existing cmdlet by calling the [System.Management.Automation.Cmdlet.Invoke](#) method from within an input processing method, such as [System.Management.Automation.Cmdlet.BeginProcessing](#), that is overridden by the cmdlet. However, you can invoke only those cmdlets that derive directly from the [System.Management.Automation.Cmdlet](#) class. You cannot invoke a cmdlet that derives from the [System.Management.Automation.PSCmdlet](#) class.

The [System.Management.Automation.Cmdlet.Invoke*](#) method has the following variants.

[System.Management.Automation.Cmdlet.Invoke](#) This variant invokes the cmdlet object and returns a collection of "T" type objects.

[System.Management.Automation.Cmdlet.Invoke](#) This variant invokes the cmdlet object and returns a strongly typed enumerator. This variant allows the user to use the objects in the collection to perform custom operations.

Examples

[] [Expand table](#)

Example	Description
Invoking Cmdlets Within a Cmdlet	This example shows how to invoke a cmdlet from within another cmdlet.
Invoking Scripts Within a Cmdlet	This example shows how to invoke a script that is supplied to the cmdlet from within another cmdlet.

Cmdlet Sets

Article • 03/24/2025

When you design your cmdlets, you might encounter cases in which you need to perform several actions on the same piece of data. For example, you might need to get and set data or start and stop a process. Although you will need to create separate cmdlets to perform each action, your cmdlet design should include a base class from which the classes for the individual cmdlets are derived.

Keep the following things in mind when implementing a base class.

- Declare any common parameters used by all the derived cmdlets in the base class.
- Add cmdlet-specific parameters to the appropriate cmdlet class.
- Override the appropriate input processing method in the base class.
- Declare the [System.Management.Automation.CmdletAttribute](#) attribute on all cmdlet classes, but do not declare it on the base class.
- Implement a [System.Management.Automation.PSSnapIn](#) or [System.Management.Automation.CustomPSSnapIn](#) class whose name and description reflects the set of cmdlets.

Example

The following example shows the implementation of a base class that is used by Get-Proc and Stop-Proc cmdlet that derive from the same base class.

C#

```
using System;
using System.Diagnostics;
using System.Management.Automation;           //Windows PowerShell
namespace.

namespace Microsoft.Samples.PowerShell.Commands
{

    #region ProcessCommands

    /// <summary>
    /// This class implements a Stop-Proc cmdlet. The parameters
    /// for this cmdlet are defined by the BaseProcCommand class.
    /// </summary>
    [Cmdlet(VerbsLifecycle.Stop, "Proc", SupportsShouldProcess = true)]
```

```

public class StopProcCommand : BaseProcCommand
{
    public override void ProcessObject(Process process)
    {
        if (ShouldProcess(process.ProcessName, "Stop-Proc"))
        {
            process.Kill();
        }
    }
}

/// <summary>
/// This class implements a Get-Proc cmdlet. The parameters
/// for this cmdlet are defined by the BaseProcCommand class.
/// </summary>

[Cmdlet(VerbsCommon.Get, "Proc")]
public class GetProcCommand : BaseProcCommand
{
    public override void ProcessObject(Process process)
    {
        WriteObject(process);
    }
}

/// <summary>
/// This class is the base class that defines the common
/// functionality used by the Get-Proc and Stop-Proc
/// cmdlets.
/// </summary>
public class BaseProcCommand : Cmdlet
{
    #region Parameters

    // Defines the Name parameter that is used to
    // specify a process by its name.
    [Parameter()
        Position = 0,
        Mandatory = true,
        ValueFromPipeline = true,
        ValueFromPipelineByPropertyName = true
    ]
    public string[] Name
    {
        get { return processNames; }
        set { processNames = value; }
    }
    private string[] processNames;

    // Defines the Exclude parameter that is used to
    // specify which processes should be excluded when
    // the cmdlet performs its action.
    [Parameter()]
    public string[] Exclude
    {

```

```

        get { return excludeNames; }
        set { excludeNames = value; }
    }
    private string[] excludeNames = new string[0];
#endregion Parameters

    public virtual void ProcessObject(Process process)
    {
        throw new NotImplementedException("This method should be
overridden.");
    }

#region Cmdlet Overrides
// <summary>
// For each of the requested process names, retrieve and write
// the associated processes.
// </summary>
protected override void ProcessRecord()
{
    // Set up the wildcard characters used in resolving
    // the process names.
    WildcardOptions options = WildcardOptions.IgnoreCase |
                                WildcardOptions.Compiled;

    WildcardPattern[] include = new WildcardPattern[Name.Length];
    for (int i = 0; i < Name.Length; i++)
    {
        include[i] = new WildcardPattern(Name[i], options);
    }

    WildcardPattern[] exclude = new WildcardPattern[Exclude.Length];
    for (int i = 0; i < Exclude.Length; i++)
    {
        exclude[i] = new WildcardPattern(Exclude[i], options);
    }

    foreach (Process p in Process.GetProcesses())
    {
        foreach (WildcardPattern wIn in include)
        {
            if (wIn.IsMatch(p.ProcessName))
            {
                bool processThisOne = true;
                foreach (WildcardPattern wOut in exclude)
                {
                    if (wOut.IsMatch(p.ProcessName))
                    {
                        processThisOne = false;
                        break;
                    }
                }
                if (processThisOne)
                {
                    ProcessObject(p);
                }
            }
        }
    }
}

```

```
        break;
    }
}
}
#endregion Cmdlet Overrides
}
#endregion ProcessCommands
}
```

[Writing a Windows PowerShell Cmdlet](#)

Windows PowerShell Session State

Article • 09/17/2021

Session state refers to the current configuration of a Windows PowerShell session or module. A Windows PowerShell session is the operational environment that is used interactively by the command-line user or programmatically by a host application. The session state for a session is referred to as the global session state.

From a developer perspective, a Windows PowerShell session refers to the time between when a host application opens a Windows PowerShell runspace and when it closes the runspace. Looked at another way, the session is the lifetime of an instance of the Windows PowerShell engine that is invoked while the runspace exists.

Module Session State

Module session states are created whenever the module or one of its nested modules is imported into the session. When a module exports an element such as a cmdlet, function, or script, a reference to that element is added to the global session state of the session. However, when the element is run, it is executed within the session state of the module.

Session-State Data

Session state data can be public or private. Public data is available to calls from outside the session state while private data is available only to calls from within the session state. For example, a module can have a private function that can be called only by the module or only internally by a public element that has been exported. This is similar to the private and public members of a .NET Framework type.

Session-state data is stored by the current instance of the execution engine within the context of the current Windows PowerShell session. Session-state data consists of the following items:

- Path information
- Drive information
- Windows PowerShell provider information
- Information about the imported modules and references to the module elements (such as cmdlets, functions, and scripts) that are exported by the module. This

information and these references are for the global session state only.

- Session-state variable information

Accessing Session-State Data Within Cmdlets

Cmdlets can access session-state data either indirectly through the [System.Management.Automation.PSCmdlet.SessionState*](#) property of the cmdlet class or directly through the [System.Management.Automation.SessionState](#) class. The [System.Management.Automation.SessionState](#) class provides properties that can be used to investigate different types of session-state data.

Examples of Cmdlet Code

Article • 09/17/2021

This section contains examples of cmdlet code that you can use to start writing your own cmdlets.

ⓘ Important

If you want step-by-step instructions for writing cmdlets, see [Tutorials for Writing Cmdlets](#).

In This Section

[How to Write a Simple Cmdlet](#) This example shows the basic structure of cmdlet code.

[How to Declare Cmdlet Parameters](#) This example shows how to declare the different types of parameters.

[How to Declare Parameter Sets](#) This example shows how to declare sets of parameters that can change the action a cmdlet performs.

[How to Validate Parameter Input](#) These examples show how to validate parameter input.

[How to Declare Dynamic Parameters](#) This example shows how to declare a parameter that is added at runtime.

[How to Invoke Scripts Within a Cmdlet](#) This example shows how to invoke a script that is supplied to a cmdlet.

[How To Override Input Processing Methods](#) These examples show the basic structure used to override the BeginProcessing, ProcessRecord, and EndProcessing methods.

[How to Support ShouldProcess Calls](#) This example shows how the `System.Management.Automation.Cmdlet.ShouldProcess` and `System.Management.Automation.Cmdlet.ShouldContinue` methods should be called from within a cmdlet.

[How to Support Transactions](#) This example shows how to indicate that the cmdlet supports transactions and how to implement the action that is taken when the cmdlet is used within a transaction.

[How to Support Jobs](#) This example shows how to support jobs when you write cmdlets.

[How to Invoke a Cmdlet From Within a Cmdlet](#) This example shows how to invoke a cmdlet from within another cmdlet, which allows you to add the functionality of the invoked cmdlet to the cmdlet you are developing.

How to write a cmdlet

Article • 09/17/2021

This article shows how to write a cmdlet. The `Send-Greeting` cmdlet takes a single user name as input and then writes a greeting to that user. Although the cmdlet does not do much work, this example demonstrates the major sections of a cmdlet.

Steps to write a cmdlet

1. To declare the class as a cmdlet, use the **Cmdlet** attribute. The **Cmdlet** attribute specifies the verb and the noun for the cmdlet name.

For more information about the **Cmdlet** attribute, see [CmdletAttribute Declaration](#).

2. Specify the name of the class.

3. Specify that the cmdlet derives from either of the following classes:

- [System.Management.Automation.Cmdlet](#)
- [System.Management.Automation.PSCmdlet](#)

4. To define the parameters for the cmdlet, use the **Parameter** attribute. In this case, only one required parameter is specified.

For more information about the **Parameter** attribute, see [ParameterAttribute Declaration](#).

5. Override the input processing method that processes the input. In this case, the [System.Management.Automation.Cmdlet.ProcessRecord](#) method is overridden.

6. To write the greeting, use the method

[System.Management.Automation.Cmdlet.WriteObject](#). The greeting is displayed in the following format:

Output

Hello <UserName>!

Example

C#

```
using System.Management.Automation; // Windows PowerShell assembly.

namespace SendGreeting
{
    // Declare the class as a cmdlet and specify the
    // appropriate verb and noun for the cmdlet name.
    [Cmdlet(VerbsCommunications.Send, "Greeting")]
    public class SendGreetingCommand : Cmdlet
    {
        // Declare the parameters for the cmdlet.
        [Parameter(Mandatory=true)]
        public string Name
        {
            get { return name; }
            set { name = value; }
        }
        private string name;

        // Override the ProcessRecord method to process
        // the supplied user name and write out a
        // greeting to the user by calling the WriteObject
        // method.
        protected override void ProcessRecord()
        {
            WriteObject("Hello " + name + "!");
        }
    }
}
```

How to Declare Cmdlet Parameters

Article • 09/17/2021

These examples show how to declare named, positional, required, optional, and switch parameters. These examples also show how to define a parameter alias.

How to Declare a Named Parameter

- Define a public property as shown in the following code. When you add the `Parameter` attribute, omit the `Position` keyword from the attribute.

```
C#  
  
[Parameter()]
public string UserName
{
    get { return userName; }
    set { userName = value; }
}
private string userName;
```

For more information about the `Parameter` attribute, see [Parameter Attribute Declaration](#).

How to Declare a Positional Parameter

- Define a public property as shown in the following code. When you add the `Parameter` attribute, set the `Position` keyword to the argument position. A value of 0 indicates the first position.

```
C#  
  
[Parameter(Position = 0)]
public string UserName
{
    get { return userName; }
    set { userName = value; }
}
private string userName;
```

For more information about the `Parameter` attribute, see [Parameter Attribute Declaration](#).

How to Declare a Mandatory Parameter

- Define a public property as shown in the following code. When you add the Parameter attribute, set the `Mandatory` keyword to `true`.

C#

```
[Parameter(Position = 0, Mandatory = true)]
public string UserName
{
    get { return userName; }
    set { userName = value; }
}
private string userName;
```

For more information about the Parameter attribute, see [Parameter Attribute Declaration](#).

How to Declare an Optional Parameter

- Define a public property as shown in the following code. When you add the Parameter attribute, omit the `Mandatory` keyword.

C#

```
[Parameter(Position = 0)]
public string UserName
{
    get { return userName; }
    set { userName = value; }
}
private string userName;
```

How to Declare a Switch Parameter

- Define a public property as type `System.Management.Automation.SwitchParameter`, and then declare the Parameter attribute.

C#

```
[Parameter(Position = 1)]
public SwitchParameter GoodBye
{
    get { return goodbye; }
```

```
    set { goodbye = value; }
}
private bool goodbye;
```

For more information about the Parameter attribute, see [Parameter Attribute Declaration](#).

How to Declare a Parameter with Aliases

- Define a public property as shown in the following code. Add an Alias attribute that lists the aliases for the parameter. In this example, three aliases are defined for the same parameter. The first alias provides a shortcut. The second and third aliases provide names you can use for different scenarios.

```
C#  
  
[Alias("UN","Writer","Editor")]
[Parameter()]
public string UserName
{
    get { return userName; }
    set { userName = value; }
}
private string userName;
```

For more information about the Alias attribute, see [Alias Attribute Declaration](#).

How to Declare Parameter Sets

Article • 09/17/2021

This example shows how to define two parameter sets when you declare the parameters for a cmdlet. Each parameter set has both a unique parameter and a shared parameter that is used by both parameter sets. For more information about parameters sets, including how to specify the default parameter set, see [Cmdlet Parameter Sets](#).

ⓘ Important

Whenever possible, define the unique parameter of a parameter set as a required parameter. However, if you want your cmdlet to run without specifying any parameters, the unique parameter can be an optional parameter. For example, the unique parameter of the `Get-Command` cmdlet is optional.

How to Define Two Parameter Sets

1. Add the `ParameterSet` keyword to the `Parameter` attribute for the unique parameter of the first parameter set.

C#

```
[Parameter(Position = 0, Mandatory = true,
          ParameterSetName = "Test01")]
public string UserName
{
    get { return userName; }
    set { userName = value; }
}
private string userName;
```

2. Add the `ParameterSet` keyword to the `Parameter` attribute for the unique parameter of the second parameter set.

C#

```
[Parameter(Position = 0, Mandatory = true,
          ParameterSetName = "Test02")]
public string ComputerName
{
    get { return computerName; }
    set { computerName = value; }
```

```
}
```

```
private string computerName;
```

3. For the parameter that belongs to both parameter sets, add a Parameter attribute for each parameter set and then add the `ParameterSet` keyword to each set. In each Parameter attribute, you can specify how that parameter is defined. A parameter can be optional in one set and mandatory in another.

C#

```
[Parameter(Mandatory= true, ParameterSetName = "Test01")]
[Parameter(ParameterSetName = "Test02")]
public string SharedParam
{
    get { return sharedParam; }
    set { sharedParam = value; }
}
private string sharedParam;
```

How to Validate Parameter Input

Article • 09/17/2021

This section contains examples that show how to validate parameter input by using various attributes to implement validation rules.

In This Section

[How to Validate an Argument with a Script](#) Describes how to validate an argument set by using the `ArgumentSet` attribute.

[How to Validate an Argument Set](#) Describes how to validate an argument set by using the `ArgumentSet` attribute.

[How to Validate an Argument Range](#) Describes how to validate an argument range by using the `ArgumentRange` attribute.

[How to Validate an Argument Pattern](#) Describes how to validate an argument pattern by using the `ArgumentPattern` attribute.

[How to Validate the Argument Length](#) Describes how to validate the length of an argument by using the `ArgumentLength` attribute.

[How to Validate an Argument Count](#) Describes how to validate an argument count by using the `ArgumentCount` attribute.

The way a parameter is declared can affect validation. For more information, see [How to Declare Cmdlet Parameters](#).

How to validate an argument using a script

Article • 06/11/2024

This example shows how to specify a validation rule that uses a script to check the parameter argument before the cmdlet is run. The value of the parameter is piped to the script. The script must return `$true` for every value piped to it.

ⓘ Note

For more information about the class that defines this attribute, see [System.Management.Automation.ValidateScriptAttribute](#).

To validate an argument using a script

- Add the `ValidateScript` attribute as shown in the following code. This example specifies a script to validate that the input value is an odd number.

C#

```
[ValidateScript("$_ % 2", ErrorMessage = "The item '{0}' did not pass validation of script '{1}'")]
[Parameter(Position = 0, Mandatory = true)]
public int32 OddNumber
{
    get { return oddNumber; }
    set { oddNumber = value; }
}

private int32 oddNumber;
```

For more information about how to declare this attribute, see [ValidateScript Attribute Declaration](#).

How to Validate an Argument Set

Article • 03/24/2025

This example shows how to specify a validation rule that the Windows PowerShell runtime can use to check the parameter argument before the cmdlet is run. This validation rule provides a set of the valid values for the parameter argument.

ⓘ Note

For more information about the class that defines this attribute, see

[System.Management.Automation.ValidateSetAttribute](#).

To validate an argument set

- Add the ValidateSet attribute as shown in the following code. This example specifies a set of three possible values for the `UserName` parameter.

C#

```
[ValidateSet("Steve", "Mary", "Carl", IgnoreCase = true)]
[Parameter(Position = 0, Mandatory = true)]
public string UserName
{
    get { return userName; }
    set { userName = value; }
}

private string userName;
```

For more information about how to declare this attribute, see [ValidateSet Attribute Declaration](#).

See Also

How to Validate an Argument Range

Article • 03/24/2025

This example shows how to specify a validation rule that the Windows PowerShell runtime can use to check the minimum and maximum values of the parameter argument before the cmdlet is run. You set this validation rule by declaring the `ValidateRange` attribute.

 **Note**

For more information about the class that defines this attribute, see [System.Management.Automation.ValidateRangeAttribute](#).

To validate an argument range

- Add the `ValidateRange` attribute as shown in the following code. This example specifies a range of 0 to 5 for the `InputData` parameter.

C#

```
[ValidateRange(0, 5)]
[Parameter(Position = 0, Mandatory = true)]
public int InputData
{
    get { return inputData; }
    set { inputData = value; }
}
private int inputData;
```

For more information about how to declare this attribute, see [ValidateRange Attribute Declaration](#).

See Also

How to Validate an Argument Pattern

Article • 09/17/2021

This example shows how to specify a validation rule that the Windows PowerShell runtime can use to check the character pattern of the parameter argument before the cmdlet is run. You set this validation rule by declaring the `ValidatePattern` attribute.

ⓘ Note

For more information about the class that defines this attribute, see

[System.Management.Automation.ValidatePatternAttribute](#).

To validate an argument pattern

- Add the `Validate` attribute as shown in the following code. This example specifies a pattern of four digits, where each digit has a value of 0 through 9.

C#

```
[ValidatePattern("[0-9][0-9][0-9][0-9]")]
[Parameter(Position = 0, Mandatory = true)]
public int InputData
{
    get { return inputData; }
    set { inputData = value; }
}

private int inputData;
```

For more information about how to declare this attribute, see [ValidatePattern Attribute Declaration](#).

See Also

How to Validate the Argument Length

Article • 09/17/2021

This example shows how to specify a validation rule that the Windows PowerShell runtime can use to check the number of characters (the length) of the parameter argument before the cmdlet is run. You set this validation rule by declaring the `ValidateLength` attribute.

ⓘ Note

For more information about the class that defines this attribute, see [System.Management.Automation.ValidateLengthAttribute](#).

To validate the argument length

- Add the `Validate` attribute as shown in the following code. This example specifies that the length of the argument should have a length of 0 to 10 characters.

C#

```
[ValidateLength(0, 10)]
[Parameter(Position = 0, Mandatory = true)]
public string UserName
{
    get { return userName; }
    set { userName = value; }
}
private string userName;
```

For more information about how to declare this attribute, see [ValidateLength Attribute Declaration](#).

See Also

[ValidateLength Attribute Declaration](#)

[Writing a Windows PowerShell Cmdlet](#)

How to Validate an Argument Count

Article • 09/17/2021

This example shows how to specify a validation rule that the Windows PowerShell runtime can use to check the number of arguments (the count) that a parameter accepts before the cmdlet is run. You set this validation rule by declaring the `ValidateCount` attribute.

 **Note**

For more information about the class that defines this attribute, see [System.Management.Automation.ValidateCountAttribute](#).

To validate an argument count

- Add the `Validate` attribute as shown in the following code. This example specifies that the parameter will accept one argument or as many as three arguments.

C#

```
[ValidateCount(1, 3)]
[Parameter(Position = 0, Mandatory = true)]
public string[] UserNames
{
    get { return userNames; }
    set { userNames = value; }
}

private string[] userNames;
```

For more information about how to declare this attribute, see [ValidateCount Attribute Declaration](#).

[ValidateCount Attribute Declaration](#)

[Writing a Windows PowerShell Cmdlet](#)

How to Declare Dynamic Parameters

Article • 03/24/2025

This example shows how to define dynamic parameters that are added to the cmdlet at runtime. In this example, the `Department` parameter is added to the cmdlet whenever the user specifies the `Employee` switch parameter. For more information about dynamic parameters, see [Cmdlet Dynamic Parameters](#).

To define dynamic parameters

1. In the cmdlet class declaration, add the `System.Management.Automation.IDynamicParameters` interface as shown.

```
C#  
  
public class SendGreetingCommand : Cmdlet, IDynamicParameters
```

2. Call the

`System.Management.Automation.IDynamicParameters.GetDynamicParameters*` method, which returns the object in which the dynamic parameters are defined. In this example, the method is called when the `Employee` parameter is specified.

```
C#  
  
public object GetDynamicParameters()  
{  
    if (employee)  
    {  
        context= new SendGreetingCommandDynamicParameters();  
        return context;  
    }  
    return null;  
}  
private SendGreetingCommandDynamicParameters context;
```

3. Declare a class that defines the dynamic parameters to be added. You can use the attributes that you used to declare the static cmdlet parameters to declare the dynamic parameters.

```
C#  
  
public class SendGreetingCommandDynamicParameters  
{
```

```

[Parameter]
[ValidateSet ("Marketing", "Sales", "Development")]
public string Department
{
    get { return department; }
    set { department = value; }
}
private string department;
}

```

Example

In this example, the `Department` parameter is added whenever the user specifies the `Employee` parameter. The `Department` parameter is an optional parameter, and the `ValidateSet` attribute is used to specify the allowed arguments.

C#

```

using System;
using System.Collections.Generic;
using System.Linq;
using System.Text;
using System.Management.Automation;      // PowerShell assembly.

namespace SendGreeting
{
    // Declare the cmdlet class that supports the
    // IDynamicParameters interface.
    [Cmdlet(VerbsCommunications.Send, "Greeting")]
    public class SendGreetingCommand : Cmdlet, IDynamicParameters
    {
        // Declare the parameters for the cmdlet.
        [Parameter(Mandatory = true)]
        public string Name
        {
            get { return name; }
            set { name = value; }
        }
        private string name;

        [Parameter]
        [Alias ("FTE")]
        public SwitchParameter Employee
        {
            get { return employee; }
            set { employee = value; }
        }
        private Boolean employee;

        // Implement GetDynamicParameters to
        // retrieve the dynamic parameter.
    }
}

```

```

public object GetDynamicParameters()
{
    if (employee)
    {
        context= new SendGreetingCommandDynamicParameters();
        return context;
    }
    return null;
}
private SendGreetingCommandDynamicParameters context;

// Override the ProcessRecord method to process the
// supplied user name and write out a greeting to
// the user by calling the WriteObject method.
protected override void ProcessRecord()
{
    WriteObject("Hello " + name + "! ");
    if (employee)
    {
        WriteObject("Department: " + context.Department);
    }
}
}

// Define the dynamic parameters to be added
public class SendGreetingCommandDynamicParameters
{
    [Parameter]
    [ValidateSet ("Marketing", "Sales", "Development")]
    public string Department
    {
        get { return department; }
        set { department = value; }
    }
    private string department;
}
}

```

How to Invoke Scripts Within a Cmdlet

Article • 12/05/2023

This example shows how to invoke a script that is supplied to a cmdlet. The script is executed by the cmdlet, and its results are returned to the cmdlet as a collection of [System.Management.Automation.PSObject](#) objects.

To invoke a script block

1. The command verifies that a script block was supplied to the cmdlet. If a script block was supplied, the command invokes the script block with its required parameters.

```
C#  
  
if (script != null)  
{  
    WriteDebug("Executing script block.");  
  
    // Invoke the script block with the required arguments.  
    Collection<PSObject> PSObjects = script.Invoke(  
        line,  
        simpleMatch,  
        caseSensitive  
    );  
    // more code as needed...  
}
```

2. Then, the script iterates through the returned collection of [System.Management.Automation.PSObject](#) objects and perform the necessary operations.

```
C#  
  
foreach (PSObject object in PSObjects)  
{  
    if (LanguagePrimitives.IsTrue(object))  
    {  
        result = new MatchInfo();  
        result.Line = line;  
        result.IgnoreCase = !caseSensitive;  
        break;  
    }  
}
```

How to Override Input Processing Methods

Article • 09/17/2021

These examples show how to overwrite the input processing methods within a cmdlet. These methods are used to perform the following operations:

- The [System.Management.Automation.Cmdlet.BeginProcessing](#) method is used to perform one-time startup operations that are valid for all the objects processed by the cmdlet. The Windows PowerShell runtime calls this method only once.
- The [System.Management.Automation.Cmdlet.ProcessRecord](#) method is used to process the objects passed to the cmdlet. The Windows PowerShell runtime calls this method for each object passed to the cmdlet.
- The [System.Management.Automation.Cmdlet.EndProcessing](#) method is used to perform one-time post processing operations. The Windows PowerShell runtime calls this method only once.

To override the BeginProcessing method

- Declare a protected override of the [System.Management.Automation.Cmdlet.BeginProcessing](#) method.

The following class prints a sample message. To use this class, change the verb and noun in the Cmdlet attribute, change the name of the class to reflect the new verb and noun, and then add the functionality you require to the override of the [System.Management.Automation.Cmdlet.BeginProcessing](#) method.

C#

```
[Cmdlet(VerbsDiagnostic.Test, "BeginProcessingClass")]
public class TestBeginProcessingClassTemplate : Cmdlet
{
    // Override the BeginProcessing method to add preprocessing
    //operations to the cmdlet.
    protected override void BeginProcessing()
    {
        // Replace the WriteObject method with the logic required
        // by your cmdlet. It is used here to generate the following
        // output:
        // "This is a test of the BeginProcessing template."
        WriteObject("This is a test of the BeginProcessing template.");
    }
}
```

```
}
```

To override the ProcessRecord method

- Declare a protected override of the [System.Management.Automation.Cmdlet.ProcessRecord](#) method.

The following class prints a sample message. To use this class, change the verb and noun in the Cmdlet attribute, change the name of the class to reflect the new verb and noun, and then add the functionality you require to the override of the [System.Management.Automation.Cmdlet.ProcessRecord](#) method.

C#

```
[Cmdlet(VerbsDiagnostic.Test, "ProcessRecordClass")]
public class TestProcessRecordClassTemplate : Cmdlet
{
    // Override the ProcessRecord method to add processing
    //operations to the cmdlet.
    protected override void ProcessRecord()
    {
        // Replace the WriteObject method with the logic required
        // by your cmdlet. It is used here to generate the following
        // output:
        // "This is a test of the ProcessRecord template."
        WriteObject("This is a test of the ProcessRecord template.");
    }
}
```

To override the EndProcessing method

- Declare a protected override of the [System.Management.Automation.Cmdlet.EndProcessing](#) method.

The following class prints a sample. To use this class, change the verb and noun in the Cmdlet attribute, change the name of the class to reflect the new verb and noun, and then add the functionality you require to the override of the [System.Management.Automation.Cmdlet.EndProcessing](#) method.

C#

```
[Cmdlet(VerbsDiagnostic.Test, "EndProcessingClass")]
public class TestEndProcessingClassTemplate : Cmdlet
```

```
{  
    // Override the EndProcessing method to add postprocessing  
    //operations to the cmdlet.  
    protected override void EndProcessing()  
    {  
        // Replace the WriteObject method with the logic required  
        // by your cmdlet. It is used here to generate the following  
        // output:  
        // "This is a test of the BeginProcessing template."  
        WriteObject("This is a test of the EndProcessing template.");  
    }  
}
```

Requesting Confirmation from Cmdlets

Article • 09/17/2021

Cmdlets should request confirmation when they are about to make a change to the system that is outside of the Windows PowerShell environment. For example, if a cmdlet is about to add a user account or stop a process, the cmdlet should require confirmation from the user before it proceeds. In contrast, if a cmdlet is about to change a Windows PowerShell variable, the cmdlet does not need to require confirmation.

In order to make a confirmation request, the cmdlet must indicate that it supports confirmation requests, and it must call the [System.Management.Automation.Cmdlet.ShouldProcess](#) and [System.Management.Automation.Cmdlet.ShouldContinue](#) (optional) methods to display a confirmation request message.

Supporting Confirmation Requests

To support confirmation requests, the cmdlet must set the `SupportsShouldProcess` parameter of the `Cmdlet` attribute to `true`. This enables the `Confirm` and `WhatIf` cmdlet parameters that are provided by Windows PowerShell. The `Confirm` parameter allows the user to control whether the confirmation request is displayed. The `WhatIf` parameter allows the user to determine whether the cmdlet should display a message or perform its action. Do not manually add the `Confirm` and `WhatIf` parameters to a cmdlet.

The following example shows a `Cmdlet` attribute declaration that supports confirmation requests.

C#

```
[Cmdlet(VerbsDiagnostic.Test, "RequestConfirmationTemplate1",
    SupportsShouldProcess = true)]
```

Calling the Confirmation request methods

In the cmdlet code, call the [System.Management.Automation.Cmdlet.ShouldProcess](#) method before the operation that changes the system is performed. Design the cmdlet so that if the call returns a value of `false`, the operation is not performed, and the cmdlet processes the next operation.

Calling the ShouldContinue Method

Most cmdlets request confirmation using only the [System.Management.Automation.Cmdlet.ShouldProcess](#) method. However, some cases might require additional confirmation. For these cases, supplement the [System.Management.Automation.Cmdlet.ShouldProcess](#) call with a call to the [System.Management.Automation.Cmdlet.ShouldContinue](#) method. This allows the cmdlet or provider to more finely control the scope of the **Yes to all** response to the confirmation prompt.

If a cmdlet calls the [System.Management.Automation.Cmdlet.ShouldContinue](#) method, the cmdlet must also provide a [Force](#) switch parameter. If the user specifies [Force](#) when the user invokes the cmdlet, the cmdlet should still call [System.Management.Automation.Cmdlet.ShouldProcess](#), but it should bypass the call to [System.Management.Automation.Cmdlet.ShouldContinue](#).

[System.Management.Automation.Cmdlet.ShouldContinue](#) will throw an exception when it is called from a non-interactive environment where the user cannot be prompted. Adding a [Force](#) parameter ensures that the command can still be performed when it is invoked in a non-interactive environment.

The following example shows how to call [System.Management.Automation.Cmdlet.ShouldProcess](#) and [System.Management.Automation.Cmdlet.ShouldContinue](#).

```
C#  
  
if (ShouldProcess (...))  
{  
    if (Force || ShouldContinue(...))  
    {  
        // Add code that performs the operation.  
    }  
}
```

The behavior of a [System.Management.Automation.Cmdlet.ShouldProcess](#) call can vary depending on the environment in which the cmdlet is invoked. Using the previous guidelines will help ensure that the cmdlet behaves consistently with other cmdlets, regardless of the host environment.

For an example of calling the [System.Management.Automation.Cmdlet.ShouldProcess](#) method, see [How to Request Confirmations](#).

Specify the Impact Level

When you create the cmdlet, specify the impact level (the severity) of the change. To do this, set the value of the `ConfirmImpact` parameter of the `Cmdlet` attribute to High, Medium, or Low. You can specify a value for `ConfirmImpact` only when you also specify the `SupportsShouldProcess` parameter for the cmdlet.

For most cmdlets, you do not have to explicitly specify `ConfirmImpact`. Instead, use the default setting of the parameter, which is Medium. If you set `ConfirmImpact` to High, the operation will be confirmed by default. Reserve this setting for highly disruptive actions, such as reformatting a hard-disk volume.

Calling Non-Confirmation Methods

If the cmdlet or provider must send a message but not request confirmation, it can call the following three methods. Avoid using the `System.Management.Automation.Cmdlet.WriteObject` method to send messages of these types because `System.Management.Automation.Cmdlet.WriteObject` output is intermingled with the normal output of your cmdlet or provider, which makes script writing difficult.

- To caution the user and continue with the operation, the cmdlet or provider can call the `System.Management.Automation.Cmdlet.WriteWarning` method.
- To provide additional information that the user can retrieve using the `Verbose` parameter, the cmdlet or provider can call the `System.Management.Automation.Cmdlet.WriteVerbose` method.
- To provide debugging-level detail for other developers or for product support, the cmdlet or provider can call the `System.Management.Automation.Cmdlet.WriteDebug` method. The user can retrieve this information using the `Debug` parameter.

Cmdlets and providers first call the following methods to request confirmation before they attempt to perform an operation that changes a system outside of Windows PowerShell:

- `System.Management.Automation.Cmdlet.ShouldProcess`
- `System.Management.Automation.Provider.CmdletProvider.ShouldProcess`

They do so by calling the `System.Management.Automation.Cmdlet.ShouldProcess` method, which prompts the user to confirm the operation based on how the user invoked the command.

How to Support Transactions

Article • 09/17/2021

This example shows the basic code elements that add support for transactions to a cmdlet.

ⓘ Important

For more information about how Windows PowerShell handles transactions, see [About Transactions](#).

To support transactions

- When you declare the Cmdlet attribute, specify that the cmdlet supports transactions. When the cmdlet supports transactions, Windows PowerShell adds the `UseTransaction` parameter to the cmdlet when it is run.

C#

```
[Cmdlet(VerbsCommunications.Send, "GreetingTx",
    SupportsTransactions=true )]
```

- Within one of the input processing methods, add an `if` block to determine if a transaction is available. If the `if` statement resolves to `true`, the actions within this statement can be performed within the context of the current transaction.

C#

```
if (TransactionAvailable())
{
    using (CurrentPSTransaction)
    {
        WriteObject("Hello " + name + " from within a transaction.");
    }
}
```

How to Support Jobs

Article • 09/23/2021

This example shows how to support jobs when you write cmdlets. If you want users to run your cmdlet as a background job, you must include the code described in the following procedure. For more information about background jobs, see [Background Jobs](#).

To support jobs

1. Define an `AsJob` switch parameter so that the user can decide whether to run the cmdlet as a job.

The following example shows an `AsJob` parameter declaration.

```
C#  
  
[Parameter()]
public SwitchParameter AsJob
{
    get { return asjob; }
    set { asjob = value; }
}
private bool asjob;
```

2. Create an object that derives from the `System.Management.Automation.Job` class. This object can be a custom job object or one of the job objects provided by Windows PowerShell, such a `System.Management.Automation.PSEventJob` object.

The following example shows a custom job object.

```
C#  
  
private SampleJob job = new SampleJob("Get-ProcAsJob");
```

3. In a record processing method, add an `if` statement to detect whether the cmdlet should run as a job. The following code uses the `System.Management.Automation.Cmdlet.ProcessRecord` method.

```
C#  
  
protected override void ProcessRecord()
{
```

```

if (asjob)
{
    // Add the job definition to the job repository,
    // return the job object, and then create the thread
    // used to run the job.
    JobRepository.Add(job);
    WriteObject(job);
    ThreadPool.QueueUserWorkItem(WorkItem);
}
else
{
    job.ProcessJob();
    foreach (PSObject p in job.Output)
    {
        WriteObject(p);
    }
}
}

```

4. For custom job objects, implement the job class.

```

C#

private class SampleJob : Job
{
    internal SampleJob(string command)
        : base(command)
    {
        SetJobState(JobState.NotStarted);
    }
    public override string StatusMessage
    {
        get { throw new NotImplementedException(); }
    }

    public override bool HasMoreData
    {
        get
        {
            return hasMoreData;
        }
    }
    private bool hasMoreData = true;

    public override string Location
    {
        get { throw new NotImplementedException(); }
    }

    public override void StopJob()
    {
        throw new NotImplementedException();
    }
}

```

```

internal void ProcessJob()
{
    SetJobState(JobState.Running);
    DoProcessLogic();
    SetJobState(JobState.Completed);
}

// Retrieve the processes of the local computer.
void DoProcessLogic()
{
    Process[] p = Process.GetProcesses();

    foreach (Process pl in p)
    {
        Output.Add(PSObject.AsPSObject(pl));
    }
    Output.Complete();
} // End DoProcessLogic.
} // End SampleJob class.

```

5. If the cmdlet performs the work, call the

`System.Management.Automation.Cmdlet.WriteObject` method to return a process object to the pipeline. If the work is performed as a job, add child job to the job.

C#

```

void DoProcessLogic(bool asJob)
{
    Process[] p = Process.GetProcesses();

    foreach (Process pl in p)
    {
        if (!asJob)
        {
            WriteObject(pl);
        }
        else
        {
            job.ChildJobs[0].Output.Add(PSObject.AsPSObject(pl));
        }
    }
} // End DoProcessLogic.

```

Example

The following sample code shows the code for a `Get-Proc` cmdlet that can retrieve processes internally or by using a background job.

C#

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Text;
using System.Management.Automation; // Windows PowerShell namespace.
using System.Threading;           // Thread pool namespace for posting
                                // work.
using System.Diagnostics;        // Diagnostics namespace for retrieving
                                // process objects.

// This sample shows a cmdlet whose work can be done by the cmdlet or by
using
// a background job. Background jobs are executed in their own thread,
// independent of the pipeline thread in which the cmdlet is executed.
//
// To load this cmdlet, create a module folder and copy the
GetProcessSample06.dll
// assembly into the module folder. Make sure that the path to the module
folder
// is added to the $PSModulePath environment variable.
// Module folder path:
//      user/documents/WindowsPowerShell/modules/GetProcessSample06
//
// To import the module, run the following command: Import-Module
GetProcessSample06.
// To test the cmdlet, run the following command: Get-Proc -Name <process
name>
//

//
namespace Microsoft.Samples.PowerShell.Commands
{
    /// <summary>
    /// This cmdlet retrieves process internally or returns
    /// a job that retrieves the processes.
    /// </summary>
    [Cmdlet(VerbsCommon.Get, "Proc")]
    public sealed class GetProcCommand : PSCmdlet
    {

        #region Parameters
        /// <summary>
        /// Specify the Name parameter. This parameter accepts
        /// process names from the command line.
        /// </summary>
        [Parameter(
            Position = 0,
            ValueFromPipeline = true,
            ValueFromPipelineByPropertyName = true)]
        [ValidateNotNullOrEmpty]
        public string[] Name
        {
```

```

        get { return processNames; }
        set { processNames = value; }
    }
    private string[] processNames;

    /// <summary>
    /// Specify the AsJob parameter. This parameter indicates
    /// whether the cmdlet should retrieve the processes internally
    /// or return a Job object that retrieves the processes.
    /// </summary>
    [Parameter()]
    public SwitchParameter AsJob
    {
        get { return asjob; }
        set { asjob = value; }
    }
    private bool asjob;

#endregion Parameters

#region Cmdlet Overrides

// Create a custom job object.
private SampleJob job = new SampleJob("Get-ProcAsJob");

{
    job.ProcessJob();
}

// Display the results of the work. If not a job,

```

```
// process objects are returned. If a job, the
// output is added to the job as a child job.
void DoProcessLogic(bool asJob)
{
    Process[] p = Process.GetProcesses();

    foreach (Process pl in p)
    {
        if (!asJob)
        {
            WriteObject(pl);
        }
        else
        {
            job.ChildJobs[0].Output.Add(PSObject.AsPSObject(pl));
        }
    }
} // End DoProcessLogic.
} //End GetProcCommand
}
```

How to Invoke a Cmdlet from Within a Cmdlet

Article • 10/20/2022

This example shows how to invoke a binary cmdlet that derives from `[System.Management.Automation.Cmdlet]` directly from within another binary cmdlet, which allows you to add the functionality of the invoked cmdlet to the binary cmdlet you are developing. In this example, the `Get-Process` cmdlet is invoked to get the processes that are running on the local computer. The call to the `Get-Process` cmdlet is equivalent to the following command. This command retrieves all the processes whose names start with the characters "a" through "t".

PowerShell

```
Get-Process -Name [a-t]*
```

ⓘ Important

You can invoke only those cmdlets that derive directly from the `System.Management.Automation.Cmdlet` class. You can't invoke a cmdlet that derives from the `System.Management.Automation.PSCmdlet` class. For an example, see [How to invoke a PSCmdlet from within a PSCmdlet](#).

To invoke a cmdlet from within a cmdlet

1. Ensure that the assembly that defines the cmdlet to be invoked is referenced and that the appropriate `using` statement is added. In this example, the following namespaces are added.

C#

```
using System.Diagnostics;
using System.Management.Automation; // PowerShell assembly.
using Microsoft.PowerShell.Commands; // PowerShell cmdlets assembly
you want to call.
```

2. In the input processing method of the cmdlet, create a new instance of the cmdlet to be invoked. In this example, an object of type

`Microsoft.PowerShell.Commands.GetProcessCommand` is created along with the string that contains the arguments that are used when the cmdlet is invoked.

```
C#
```

```
GetProcessCommand gp = new GetProcessCommand();
gp.Name = new string[] { "[a-t]*" };
```

3. Call the `System.Management.Automation.Cmdlet.Invoke*` method to invoke the `Get-Process` cmdlet.

```
C#
```

```
foreach (Process p in gp.Invoke<Process>())
{
    Console.WriteLine(p.ToString());
}
```

Example

In this example, the `Get-Process` cmdlet is invoked from within the `System.Management.Automation.Cmdlet.BeginProcessing` method of a cmdlet.

```
C#
```

```
using System;
using System.Diagnostics;
using System.Management.Automation; // PowerShell assembly.
using Microsoft.PowerShell.Commands; // PowerShell cmdlets assembly you
want to call.

namespace SendGreeting
{
    // Declare the class as a cmdlet and specify an
    // appropriate verb and noun for the cmdlet name.
    [Cmdlet(VerbsCommunications.Send, "GreetingInvoke")]
    public class SendGreetingInvokeCommand : Cmdlet
    {
        // Declare the parameters for the cmdlet.
        [Parameter(Mandatory = true)]
        public string Name { get; set; }

        // Override the BeginProcessing method to invoke
        // the Get-Process cmdlet.
        protected override void BeginProcessing()
        {
            GetProcessCommand gp = new GetProcessCommand();
```

```
gp.Name = new string[] { "[a-t]*" };
foreach (Process p in gp.Invoke<Process>())
{
    WriteVerbose(p.ToString());
}
}

// Override the ProcessRecord method to process
// the supplied user name and write out a
// greeting to the user by calling the WriteObject
// method.
protected override void ProcessRecord()
{
    WriteObject("Hello " + Name + "!");
}
}
```

How to invoke a PSCmdlet from within a PSCmdlet

Article • 10/20/2022

This example shows how to invoke a script based cmdlet or binary cmdlet inheriting from `[System.Management.Automation.PSCmdlet]` from within a binary cmdlet. In this example, the new cmdlet `Get-ClipboardReverse` calls `Get-Clipboard` to get the contents of the clipboard. The `Get-ClipboardReverse` reverses the order of the characters and returns the reversed string.

ⓘ Note

The `[PSCmdlet]` class differs from the `[Cmdlet]` class. `[PSCmdlet]` implementations use runspace context information so you must invoke another cmdlet using the PowerShell pipeline API. In `[Cmdlet]` implementations you can call the cmdlet's .NET API directly. For an example, see [How to invoke a Cmdlet from within a Cmdlet](#).

To invoke a cmdlet from within a PSCmdlet

1. Ensure that the namespace for the `[System.Management.Automation.PowerShell]` API is referenced. In this example, the following namespaces are added.

C#

```
using System.Management.Automation; // PowerShell assembly.  
using System.Text;
```

2. To invoke a command from within another binary cmdlet you must use the `[PowerShell]` API to construct a new pipeline and add the cmdlet to be invoked. Call the `System.Management.Automation.PowerShell.Invoke<T>()` method to invoke the pipeline.

C#

```
using var ps = PowerShell.Create(RunspaceMode.CurrentRunspace);  
ps.AddCommand("Get-Clipboard").AddParameter("Raw");  
var output = ps.Invoke<string>();
```

Example

To invoke a script based cmdlet or binary cmdlet inheriting from `[PSCmdlet]` you must build a PowerShell pipeline with the command and parameters you want to execute, then invoke the pipeline.

C#

```
using System;
using System.Management.Automation; // PowerShell assembly.
using System.Text;

namespace ClipboardReverse
{
    [Cmdlet(VerbsCommon.Get, "ClipboardReverse")]
    [OutputType(typeof(string))]
    public class ClipboardReverse : PSCmdlet
    {
        protected override void EndProcessing()
        {
            using var ps = PowerShell.Create(RunspaceMode.CurrentRunspace);
            ps.AddCommand("Get-Clipboard").AddParameter("Raw");
            var output = ps.Invoke<string>();
            if (ps.HadErrors)
            {
                WriteError(new ErrorRecord(ps.Streams.Error[0].Exception,
                    "Get-Clipboard Error",
                    ErrorCategory.NotSpecified, null));
            }
            else
            {
                var sb = new StringBuilder();
                foreach (var text in output)
                {
                    sb.Append(text);
                }

                var reversed = sb.ToString().ToCharArray();
                Array.Reverse(reversed);
                WriteObject(new string(reversed));
            }
        }
    }
}
```

Tutorials for Writing Cmdlets

Article • 09/17/2021

This section contains tutorials for writing cmdlets. These tutorials include the code needed to write the cmdlets, plus an explanation of why the code is needed. These topics will be very helpful for those who are just starting to write cmdlets.

Important

For those who want code examples with less description, see [Cmdlet Samples](#).

In This Section

[GetProc Tutorial](#) - This tutorial describes how to define a cmdlet class and add basic functionality such as adding parameters and reporting errors. The cmdlet described in this tutorial is very similar to the [Get-Process](#) cmdlet provided by Windows PowerShell.

[StopProc Tutorial](#) - This tutorial describes how to define a cmdlet and add functionality such as user prompts, wildcard support, and the use of parameter sets. The cmdlet described here performs the same task as the [Stop-Process](#) cmdlet provided by Windows PowerShell.

[SelectStr Tutorial](#) - This tutorial describes how to define a cmdlet that accesses a data store. The cmdlet described here performs the same task as the [Select-String](#) cmdlet provided by Windows PowerShell.

GetProc Tutorial

Article • 09/15/2023

This section provides a tutorial for creating a Get-Proc cmdlet that is very similar to the [Get-Process](#) cmdlet provided by Windows PowerShell. This tutorial provides fragments of code that illustrate how cmdlets are implemented, and an explanation of the code.

Topics in this Tutorial

The topics in this tutorial are designed to be read sequentially, with each topic building on what was discussed in the previous topic.

- [Creating a Cmdlet without Parameters](#): This section describes how to create a cmdlet that retrieves information from the local computer without the use of parameters, and then writes the information to the pipeline.
- [Adding Parameters that Process Command-Line Input](#): This section describes how to add a parameter to the Get-Proc cmdlet so that the cmdlet can process input based on explicit objects passed to the cmdlet. The implementation described here retrieves processes based on their name, and then writes the information to the pipeline.
- [Adding Parameters that Process Pipeline Input](#): This section describes how to add a parameter to the Get-Proc cmdlet so that the cmdlet can process objects passed to it through the pipeline. The implementation cmdlet described here retrieves processes based on objects passed to the cmdlet, and then writes the information to the pipeline.
- [Adding Non-terminating Error Reporting to Your Cmdlet](#): This section describes how to add non-terminating error reporting to a cmdlet. The implementation described here detects non-terminating errors that occur when processing input, and writes an error record to the error stream.

Creating a Cmdlet without Parameters

Article • 09/17/2021

This section describes how to create a cmdlet that retrieves information from the local computer without the use of parameters, and then writes the information to the pipeline. The cmdlet described here is a Get-Proc cmdlet that retrieves information about the processes of the local computer, and then displays that information at the command line.

ⓘ Note

Be aware that when writing cmdlets, the Windows PowerShell® reference assemblies are downloaded onto disk (by default at C:\Program Files\Reference Assemblies\Microsoft\WindowsPowerShell\v1.0). They are not installed in the Global Assembly Cache (GAC).

Naming the Cmdlet

A cmdlet name consists of a verb that indicates the action the cmdlet takes and a noun that indicates the items that the cmdlet acts upon. Because this sample Get-Proc cmdlet retrieves process objects, it uses the verb "Get", defined by the [System.Management.Automation.VerbsCommon](#) enumeration, and the noun "Proc" to indicate that the cmdlet works on process items.

When naming cmdlets, do not use any of the following characters: # , () {} [] & - ^ \$; : " ' < > | ? @ ` .

Choosing a Noun

You should choose a noun that is specific. It is best to use a singular noun prefixed with a shortened version of the product name. An example cmdlet name of this type is "Get-SQLServer".

Choosing a Verb

You should use a verb from the set of approved cmdlet verb names. For more information about the approved cmdlet verbs, see [Cmdlet Verb Names](#).

Defining the Cmdlet Class

Once you have chosen a cmdlet name, define a .NET class to implement the cmdlet. Here is the class definition for this sample Get-Proc cmdlet:

C#

```
[Cmdlet(VerbsCommon.Get, "Proc")]
public class GetProcCommand : Cmdlet
```

VB

```
<Cmdlet(VerbsCommon.Get, "Proc")> _
Public Class GetProcCommand
    Inherits Cmdlet
```

Notice that previous to the class definition, the [System.Management.Automation.CmdletAttribute](#) attribute, with the syntax `[Cmdlet(verb, noun, ...)]`, is used to identify this class as a cmdlet. This is the only required attribute for all cmdlets, and it allows the Windows PowerShell runtime to call them correctly. You can set attribute keywords to further declare the class if necessary. Be aware that the attribute declaration for our sample GetProcCommand class declares only the noun and verb names for the Get-Proc cmdlet.

ⓘ Note

For all Windows PowerShell attribute classes, the keywords that you can set correspond to properties of the attribute class.

When naming the class of the cmdlet, it is a good practice to reflect the cmdlet name in the class name. To do this, use the form "VerbNounCommand" and replace "Verb" and "Noun" with the verb and noun used in the cmdlet name. As is shown in the previous class definition, the sample Get-Proc cmdlet defines a class called GetProcCommand, which derives from the [System.Management.Automation.Cmdlet](#) base class.

ⓘ Important

If you want to define a cmdlet that accesses the Windows PowerShell runtime directly, your .NET class should derive from the [System.Management.Automation.PSCmdlet](#) base class. For more information about this class, see [Creating a Cmdlet that Defines Parameter Sets](#).

Note

The class for a cmdlet must be explicitly marked as public. Classes that are not marked as public will default to internal and will not be found by the Windows PowerShell runtime.

Windows PowerShell uses the [Microsoft.PowerShell.Commands](#) namespace for its cmdlet classes. It is recommended to place your cmdlet classes in a Commands namespace of your API namespace, for example, xxx.PS.Commands.

Overriding an Input Processing Method

The [System.Management.Automation.Cmdlet](#) class provides three main input processing methods, at least one of which your cmdlet must override. For more information about how Windows PowerShell processes records, see [How Windows PowerShell Works](#).

For all types of input, the Windows PowerShell runtime calls [System.Management.Automation.Cmdlet.BeginProcessing](#) to enable processing. If your cmdlet must perform some preprocessing or setup, it can do this by overriding this method.

Note

Windows PowerShell uses the term "record" to describe the set of parameter values supplied when a cmdlet is called.

If your cmdlet accepts pipeline input, it must override the [System.Management.Automation.Cmdlet.ProcessRecord](#) method, and optionally the [System.Management.Automation.Cmdlet.EndProcessing](#) method. For example, a cmdlet might override both methods if it gathers all input using [System.Management.Automation.Cmdlet.ProcessRecord](#) and then operates on the input as a whole rather than one element at a time, as the `Sort-Object` cmdlet does.

If your cmdlet does not take pipeline input, it should override the [System.Management.Automation.Cmdlet.EndProcessing](#) method. Be aware that this method is frequently used in place of [System.Management.Automation.Cmdlet.BeginProcessing](#) when the cmdlet cannot operate on one element at a time, as is the case for a sorting cmdlet.

Because this sample Get-Proc cmdlet must receive pipeline input, it overrides the `System.Management.Automation.Cmdlet.ProcessRecord` method and uses the default implementations for `System.Management.Automation.Cmdlet.BeginProcessing` and `System.Management.Automation.Cmdlet.EndProcessing`. The `System.Management.Automation.Cmdlet.ProcessRecord` override retrieves processes and writes them to the command line using the `System.Management.Automation.Cmdlet.WriteObject` method.

C#

```
protected override void ProcessRecord()
{
    // Get the current processes
    Process[] processes = Process.GetProcesses();

    // Write the processes to the pipeline making them available
    // to the next cmdlet. The second parameter of this call tells
    // PowerShell to enumerate the array, and send one process at a
    // time to the pipeline.
    WriteObject(processes, true);
}
```

VB

```
Protected Overrides Sub ProcessRecord()

    ' Get the current processes.
    Dim processes As Process()
    processes = Process.GetProcesses()

    ' Write the processes to the pipeline making them available
    ' to the next cmdlet. The second parameter of this call tells
    ' PowerShell to enumerate the array, and send one process at a
    ' time to the pipeline.
    WriteObject(processes, True)

End Sub 'ProcessRecord
```

Things to Remember About Input Processing

- The default source for input is an explicit object (for example, a string) provided by the user on the command line. For more information, see [Creating a Cmdlet to Process Command Line Input](#).
- An input processing method can also receive input from the output object of an upstream cmdlet on the pipeline. For more information, see [Creating a Cmdlet to](#)

Process Pipeline Input. Be aware that your cmdlet can receive input from a combination of command-line and pipeline sources.

- The downstream cmdlet might not return for a long time, or not at all. For that reason, the input processing method in your cmdlet should not hold locks during calls to [System.Management.Automation.Cmdlet.WriteObject](#), especially locks for which the scope extends beyond the cmdlet instance.

ⓘ Important

Cmdlets should never call [System.Console.WriteLine*](#) or its equivalent.

- Your cmdlet might have object variables to clean up when it is finished processing (for example, if it opens a file handle in the [System.Management.Automation.Cmdlet.BeginProcessing](#) method and keeps the handle open for use by [System.Management.Automation.Cmdlet.ProcessRecord](#)). It is important to remember that the Windows PowerShell runtime does not always call the [System.Management.Automation.Cmdlet.EndProcessing](#) method, which should perform object cleanup.

For example, [System.Management.Automation.Cmdlet.EndProcessing](#) might not be called if the cmdlet is canceled midway or if a terminating error occurs in any part of the cmdlet. Therefore, a cmdlet that requires object cleanup should implement the complete [System.IDisposable](#) pattern, including the finalizer, so that the runtime can call both [System.Management.Automation.Cmdlet.EndProcessing](#) and [System.IDisposable.Dispose*](#) at the end of processing.

Code Sample

For the complete C# sample code, see [GetProcessSample01 Sample](#).

Defining Object Types and Formatting

Windows PowerShell passes information between cmdlets using .NET objects. Consequently, a cmdlet might need to define its own type, or the cmdlet might need to extend an existing type provided by another cmdlet. For more information about defining new types or extending existing types, see [Extending Object Types and Formatting](#).

Building the Cmdlet

After implementing a cmdlet, you must register it with Windows PowerShell through a Windows PowerShell snap-in. For more information about registering cmdlets, see [How to Register Cmdlets, Providers, and Host Applications](#).

Testing the Cmdlet

When your cmdlet has been registered with Windows PowerShell, you can test it by running it on the command line. The code for our sample Get-Proc cmdlet is small, but it still uses the Windows PowerShell runtime and an existing .NET object, which is enough to make it useful. Let's test it to better understand what Get-Proc can do and how its output can be used. For more information about using cmdlets from the command line, see the [Getting Started with Windows PowerShell](#).

1. Start Windows PowerShell, and get the current processes running on the computer.

```
PowerShell
Get-Proc
```

The following output appears.

Output							
Handles	NPM(K)	PM(K)	WS(K)	VS(M)	CPU(s)	Id	ProcessName
254	7	7664	12048	66	173.75	1200	QCTRAY
32	2	1372	2628	31	0.04	1860	DLG
271	6	1216	3688	33	0.03	3816	lg
27	2	560	1920	24	0.01	1768	TpScrex
...							

2. Assign a variable to the cmdlet results for easier manipulation.

```
PowerShell
$p=Get-Proc
```

3. Get the number of processes.

```
PowerShell
$p.Length
```

The following output appears.

```
Output
```

```
63
```

4. Retrieve a specific process.

```
PowerShell
```

```
$p[6]
```

The following output appears.

```
Output
```

Handles	NPM(K)	PM(K)	WS(K)	VS(M)	CPU(s)	Id	ProcessName
1033	3	2400	3336	35	0.53	1588	rundll32

5. Get the start time of this process.

```
PowerShell
```

```
$p[6].StartTime
```

The following output appears.

```
Output
```

```
Tuesday, July 26, 2005 9:34:15 AM
```

```
PowerShell
```

```
$p[6].StartTime.DayOfYear
```

```
Output
```

```
207
```

6. Get the processes for which the handle count is greater than 500, and sort the result.

PowerShell

```
$p | Where-Object {$_.HandleCount -gt 500} | Sort-Object HandleCount
```

The following output appears.

Output

Handles	NPM(K)	PM(K)	WS(K)	VS(M)	CPU(s)	Id	ProcessName
568	14	2164	4972	39	5.55	824	svchost
716	7	2080	5332	28	25.38	468	csrss
761	21	33060	56608	440	393.56	3300	WINWORD
791	71	7412	4540	59	3.31	492	winlogon
...							

7. Use the `Get-Member` cmdlet to list the properties available for each process.

PowerShell

```
$p | Get-Member -MemberType Property
```

Output

```
TypeName: System.Diagnostics.Process
```

The following output appears.

Output

Name	MemberType	Definition
BasePriority	Property	System.Int32 BasePriority {get;}
Container	Property	System.ComponentModel.IContainer
Conta...		
EnableRaisingEvents	Property	System.Boolean EnableRaisingEvents
{ge...		
...

Adding Parameters That Process Command-Line Input

Article • 09/17/2021

One source of input for a cmdlet is the command line. This topic describes how to add a parameter to the `Get-Proc` cmdlet (which is described in [Creating Your First Cmdlet](#)) so that the cmdlet can process input from the local computer based on explicit objects passed to the cmdlet. The `Get-Proc` cmdlet described here retrieves processes based on their names, and then displays information about the processes at a command prompt.

Defining the Cmdlet Class

The first step in cmdlet creation is cmdlet naming and the declaration of the .NET Framework class that implements the cmdlet. This cmdlet retrieves process information, so the verb name chosen here is "Get." (Almost any sort of cmdlet that is capable of retrieving information can process command-line input.) For more information about approved cmdlet verbs, see [Cmdlet Verb Names](#).

Here's the class declaration for the `Get-Proc` cmdlet. Details about this definition are provided in [Creating Your First Cmdlet](#).

C#

```
[Cmdlet(VerbsCommon.Get, "proc")]
public class GetProcCommand: Cmdlet
```

VB

```
<Cmdlet(VerbsCommon.Get, "Proc")> _
Public Class GetProcCommand
    Inherits Cmdlet
```

Declaring Parameters

A cmdlet parameter enables the user to provide input to the cmdlet. In the following example, `Get-Proc` and `Get-Member` are the names of pipelined cmdlets, and `MemberType` is a parameter for the `Get-Member` cmdlet. The parameter has the argument "property."

PS> `Get-Proc ; Get-Member -MemberType Property`

To declare parameters for a cmdlet, you must first define the properties that represent the parameters. In the `Get-Proc` cmdlet, the only parameter is `Name`, which in this case represents the name of the .NET Framework process object to retrieve. Therefore, the cmdlet class defines a property of type string to accept an array of names.

Here's the parameter declaration for the `Name` parameter of the `Get-Proc` cmdlet.

C#

```
/// <summary>
/// Specify the cmdlet Name parameter.
/// </summary>
[Parameter(Position = 0)]
[ValidateNotNullOrEmpty]
public string[] Name
{
    get { return processNames; }
    set { processNames = value; }
}
private string[] processNames;

#endregion Parameters
```

VB

```
<Parameter(Position:=0), ValidateNotNullOrEmpty()> _
Public Property Name() As String()
    Get
        Return processNames
    End Get

    Set(ByVal value As String())
        processNames = value
    End Set

End Property
```

To inform the Windows PowerShell runtime that this property is the `Name` parameter, a `System.Management.Automation.ParameterAttribute` attribute is added to the property definition. The basic syntax for declaring this attribute is `[Parameter()]`.

ⓘ Note

A parameter must be explicitly marked as public. Parameters that are not marked as public default to internal and are not found by the Windows PowerShell runtime.

This cmdlet uses an array of strings for the `Name` parameter. If possible, your cmdlet should also define a parameter as an array, because this allows the cmdlet to accept more than one item.

Things to Remember About Parameter Definitions

- Predefined Windows PowerShell parameter names and data types should be reused as much as possible to ensure that your cmdlet is compatible with Windows PowerShell cmdlets. For example, if all cmdlets use the predefined `Id` parameter name to identify a resource, user will easily understand the meaning of the parameter, regardless of what cmdlet they are using. Basically, parameter names follow the same rules as those used for variable names in the common language runtime (CLR). For more information about parameter naming, see [Cmdlet Parameter Names](#).
- Windows PowerShell reserves a few parameter names to provide a consistent user experience. Do not use these parameter names: `WhatIf`, `Confirm`, `Verbose`, `Debug`, `Warn`, `ErrorAction`, `ErrorVariable`, `OutVariable`, and `OutBuffer`. Additionally, the following aliases for these parameter names are reserved: `vb`, `db`, `ea`, `ev`, `ov`, and `ob`.
- `Name` is a simple and common parameter name, recommended for use in your cmdlets. It is better to choose a parameter name like this than a complex name that is unique to a specific cmdlet and hard to remember.
- Parameters are case-insensitive in Windows PowerShell, although by default the shell preserves case. Case-sensitivity of the arguments depends on the operation of the cmdlet. Arguments are passed to a parameter as specified at the command line.
- For examples of other parameter declarations, see [Cmdlet Parameters](#).

Declaring Parameters as Positional or Named

A cmdlet must set each parameter as either a positional or named parameter. Both kinds of parameters accept single arguments, multiple arguments separated by commas, and Boolean settings. A Boolean parameter, also called a *switch*, handles only Boolean settings. The switch is used to determine the presence of the parameter. The recommended default is `false`.

The sample `Get-Proc` cmdlet defines the `Name` parameter as a positional parameter with position 0. This means that the first argument the user enters on the command line is automatically inserted for this parameter. If you want to define a named parameter, for which the user must specify the parameter name from the command line, leave the `Position` keyword out of the attribute declaration.

 **Note**

Unless parameters must be named, we recommend that you make the most-used parameters positional so that users will not have to type the parameter name.

Declaring Parameters as Mandatory or Optional

A cmdlet must set each parameter as either an optional or a mandatory parameter. In the sample `Get-Proc` cmdlet, the `Name` parameter is defined as optional because the `Mandatory` keyword is not set in the attribute declaration.

Supporting Parameter Validation

The sample `Get-Proc` cmdlet adds an input validation attribute, `System.Management.Automation.ValidateNotNullOrEmptyAttribute`, to the `Name` parameter to enable validation that the input is neither `null` nor empty. This attribute is one of several validation attributes provided by Windows PowerShell. For examples of other validation attributes, see [Validating Parameter Input](#).

```
[Parameter(Position = 0)]
[ValidateNotNullOrEmpty]
public string[] Name
```

Overriding an Input Processing Method

If your cmdlet is to handle command-line input, it must override the appropriate input processing methods. The basic input processing methods are introduced in [Creating Your First Cmdlet](#).

The `Get-Proc` cmdlet overrides the `System.Management.Automation.Cmdlet.ProcessRecord` method to handle the `Name` parameter input provided by the user or a script. This method gets the processes for each requested process name, or all for processes if no name is provided. Notice that in `System.Management.Automation.Cmdlet.ProcessRecord`, the call to `System.Management.Automation.Cmdlet.WriteObject` is the output mechanism for sending output objects to the pipeline. The second parameter of this call, `enumerateCollection`, is set to `true` to inform the Windows PowerShell runtime to enumerate the output array of process objects and write one process at a time to the command line.

C#

```
protected override void ProcessRecord()
{
    // If no process names are passed to the cmdlet, get all processes.
    if (processNames == null)
    {
        // Write the processes to the pipeline making them available
        // to the next cmdlet. The second argument of this call tells
        // PowerShell to enumerate the array, and send one process at a
        // time to the pipeline.
        WriteObject(Process.GetProcesses(), true);
    }
    else
    {
        // If process names are passed to the cmdlet, get and write
        // the associated processes.
        foreach (string name in processNames)
        {
            WriteObject(Process.GetProcessesByName(name), true);
        }
    }
}
```

VB

```
Protected Overrides Sub ProcessRecord()

    ' If no process names are passed to the cmdlet, get all processes.
    If processNames Is Nothing Then
        Dim processes As Process()
        processes = Process.GetProcesses()
    End If

    ' If process names are specified, write the processes to the
    ' pipeline to display them or make them available to the next cmdlet.

    For Each name As String In processNames
```

```
'/ The second parameter of this call tells PowerShell to enumerate  
the  
'/ array, and send one process at a time to the pipeline.  
WriteObject(Process.GetProcessesByName(name), $True)  
Next  
  
End Sub 'ProcessRecord
```

Code Sample

For the complete C# sample code, see [GetProcessSample02 Sample](#).

Defining Object Types and Formatting

Windows PowerShell passes information between cmdlets by using .NET Framework objects. Consequently, a cmdlet might need to define its own type, or a cmdlet might need to extend an existing type provided by another cmdlet. For more information about defining new types or extending existing types, see [Extending Object Types and Formatting](#).

Building the Cmdlet

After you implement a cmdlet, you must register it with Windows PowerShell by using a Windows PowerShell snap-in. For more information about registering cmdlets, see [How to Register Cmdlets, Providers, and Host Applications](#).

Testing the Cmdlet

When your cmdlet is registered with Windows PowerShell, you can test it by running it on the command line. Here are two ways to test the code for the sample cmdlet. For more information about using cmdlets from the command line, see [Getting Started with Windows PowerShell](#).

- At the Windows PowerShell prompt, use the following command to list the Internet Explorer process, which is named "IEXPLORE."

```
PowerShell
```

```
Get-Proc -Name iexplore
```

The following output appears.

Output

Handles	NPM(K)	PM(K)	WS(K)	VS(M)	CPU(s)	Id	ProcessName
354	11	10036	18992	85	0.67	3284	iexplore

- To list the Internet Explorer, Outlook, and Notepad processes named "IEXPLORE," "OUTLOOK," and "NOTEPAD," use the following command. If there are multiple processes, all of them are displayed.

PowerShell

```
Get-Proc -Name iexplore, outlook, notepad
```

The following output appears.

Handles	NPM(K)	PM(K)	WS(K)	VS(M)	CPU(s)	Id	ProcessName
732	21	24696	5000	138	2.25	2288	iexplore
715	19	20556	14116	136	1.78	3860	iexplore
3917	62	74096	58112	468	191.56	1848	OUTLOOK
39	2	1024	3280	30	0.09	1444	notepad
39	2	1024	356	30	0.08	3396	notepad

Adding Parameters that Process Pipeline Input

Article • 09/17/2021

One source of input for a cmdlet is an object on the pipeline that originates from an upstream cmdlet. This section describes how to add a parameter to the Get-Proc cmdlet (described in [Creating Your First Cmdlet](#)) so that the cmdlet can process pipeline objects.

This Get-Proc cmdlet uses a `Name` parameter that accepts input from a pipeline object, retrieves process information from the local computer based on the supplied names, and then displays information about the processes at the command line.

Defining the Cmdlet Class

The first step in cmdlet creation is always naming the cmdlet and declaring the .NET class that implements the cmdlet. This cmdlet retrieves process information, so the verb name chosen here is "Get". (Almost any sort of cmdlet that is capable of retrieving information can process command-line input.) For more information about approved cmdlet verbs, see [Cmdlet Verb Names](#).

The following is the definition for this Get-Proc cmdlet. Details of this definition are given in [Creating Your First Cmdlet](#).

C#

```
[Cmdlet(VerbsCommon.Get, "proc")]
public class GetProcCommand : Cmdlet
```

VB

```
<Cmdlet(VerbsCommon.Get, "Proc")> _
Public Class GetProcCommand
    Inherits Cmdlet
```

Defining Input from the Pipeline

This section describes how to define input from the pipeline for a cmdlet. This Get-Proc cmdlet defines a property that represents the `Name` parameter as described in [Adding Parameters that Process Command Line Input](#). (See that topic for general information about declaring parameters.)

However, when a cmdlet needs to process pipeline input, it must have its parameters bound to input values by the Windows PowerShell runtime. To do this, you must add the `ValueFromPipeline` keyword or add the `ValueFromPipelineByPropertyName` keyword to the `System.Management.Automation.ParameterAttribute` attribute declaration. Specify the `ValueFromPipeline` keyword if the cmdlet accesses the complete input object. Specify the `ValueFromPipelineByPropertyName` if the cmdlet accesses only a property of the object.

Here is the parameter declaration for the `Name` parameter of this Get-Proc cmdlet that accepts pipeline input.

C#

```
[Parameter(
    Position = 0,
    ValueFromPipeline = true,
    ValueFromPipelineByPropertyName = true)]
[ValidateNotNullOrEmpty]
public string[] Name
{
    get { return this.processNames; }
    set { this.processNames = value; }
}
```

VB

```
<Parameter(Position:=0, ValueFromPipeline:=True, _
ValueFromPipelineByPropertyName:=True), ValidateNotNullOrEmpty()> _
Public Property Name() As String()
    Get
        Return processNames
    End Get

    Set(ByVal value As String())
        processNames = value
    End Set

End Property
```

The previous declaration sets the `ValueFromPipeline` keyword to `true` so that the Windows PowerShell runtime will bind the parameter to the incoming object if the object is the same type as the parameter, or if it can be coerced to the same type. The `ValueFromPipelineByPropertyName` keyword is also set to `true` so that the Windows PowerShell runtime will check the incoming object for a `Name` property. If the incoming object has such a property, the runtime will bind the `Name` parameter to the `Name` property of the incoming object.

ⓘ Note

The setting of the `ValueFromPipeline` attribute keyword for a parameter takes precedence over the setting for the `ValueFromPipelineByPropertyName` keyword.

Overriding an Input Processing Method

If your cmdlet is to handle pipeline input, it needs to override the appropriate input processing methods. The basic input processing methods are introduced in [Creating Your First Cmdlet](#).

This Get-Proc cmdlet overrides the

`System.Management.Automation.Cmdlet.ProcessRecord` method to handle the `Name` parameter input provided by the user or a script. This method will get the processes for each requested process name or all processes if no name is provided. Notice that within `System.Management.Automation.Cmdlet.ProcessRecord`, the call to `WriteObject(System.Object, System.Boolean)` is the output mechanism for sending output objects to the pipeline. The second parameter of this call, `enumerateCollection`, is set to `true` to tell the Windows PowerShell runtime to enumerate the array of process objects, and write one process at a time to the command line.

C#

```
protected override void ProcessRecord()
{
    // If no process names are passed to the cmdlet, get all processes.
    if (processNames == null)
    {
        // Write the processes to the pipeline making them available
        // to the next cmdlet. The second argument of this call tells
        // PowerShell to enumerate the array, and send one process at a
        // time to the pipeline.
        WriteObject(Process.GetProcesses(), true);
    }
    else
    {
        // If process names are passed to the cmdlet, get and write
        // the associated processes.
        foreach (string name in processNames)
        {
            WriteObject(Process.GetProcessesByName(name), true);
        } // End foreach (string name...).
    }
}
```

VB

```
Protected Overrides Sub ProcessRecord()
    Dim processes As Process()

    '/ If no process names are passed to the cmdlet, get all processes.
    If processNames Is Nothing Then
        processes = Process.GetProcesses()
    Else

        '/ If process names are specified, write the processes to the
        '/ pipeline to display them or make them available to the next
        cmdlet.
        For Each name As String In processNames
            '/ The second parameter of this call tells PowerShell to
            enumerate the
            '/ array, and send one process at a time to the pipeline.
            WriteObject(Process.GetProcessesByName(name), True)
        Next
    End If

End Sub 'ProcessRecord
```

Code Sample

For the complete C# sample code, see [GetProcessSample03 Sample](#).

Defining Object Types and Formatting

Windows PowerShell passes information between cmdlets using .NET objects. Consequently, a cmdlet may need to define its own type, or the cmdlet may need to extend an existing type provided by another cmdlet. For more information about defining new types or extending existing types, see [Extending Object Types and Formatting](#).

Building the Cmdlet

After implementing a cmdlet it must be registered with Windows PowerShell through a Windows PowerShell snap-in. For more information about registering cmdlets, see [How to Register Cmdlets, Providers, and Host Applications](#).

Testing the Cmdlet

When your cmdlet has been registered with Windows PowerShell, test it by running it on the command line. For example, test the code for the sample cmdlet. For more information about using cmdlets from the command line, see the [Getting Started with Windows PowerShell](#).

- At the Windows PowerShell prompt, enter the following commands to retrieve the process names through the pipeline.

```
PowerShell  
PS> type ProcessNames | Get-Proc
```

The following output appears.

Handles	NPM(K)	PM(K)	WS(K)	VS(M)	CPU(s)	Id	ProcessName
809	21	40856	4448	147	9.50	2288	iexplore
737	21	26036	16348	144	22.03	3860	iexplore
39	2	1024	388	30	0.08	3396	notepad
3927	62	71836	26984	467	195.19	1848	OUTLOOK

- Enter the following lines to get the process objects that have a `Name` property from the processes called "IEXPLORE". This example uses the `Get-Process` cmdlet (provided by Windows PowerShell) as an upstream command to retrieve the "IEXPLORE" processes.

```
PowerShell  
PS> Get-Process iexplore | Get-Proc
```

The following output appears.

Handles	NPM(K)	PM(K)	WS(K)	VS(M)	CPU(s)	Id	ProcessName
801	21	40720	6544	142	9.52	2288	iexplore
726	21	25872	16652	138	22.09	3860	iexplore
801	21	40720	6544	142	9.52	2288	iexplore
726	21	25872	16652	138	22.09	3860	iexplore

Adding Non-Terminating Error Reporting to Your Cmdlet

Article • 09/15/2023

Cmdlets can report non-terminating errors by calling the [System.Management.Automation.Cmdlet.WriteError](#) method and still continue to operate on the current input object or on further incoming pipeline objects. This section explains how to create a cmdlet that reports non-terminating errors from its input processing methods.

For non-terminating errors (as well as terminating errors), the cmdlet must pass an [System.Management.Automation.ErrorRecord](#) object identifying the error. Each error record is identified by a unique string called the "error identifier". In addition to the identifier, the category of each error is specified by constants defined by a [System.Management.Automation.ErrorCategory](#) enumeration. The user can view errors based on their category by setting the `$ErrorView` variable to "CategoryView".

For more information about error records, see [Windows PowerShell Error Records](#).

Defining the Cmdlet

The first step in cmdlet creation is always naming the cmdlet and declaring the .NET class that implements the cmdlet. This cmdlet retrieves process information, so the verb name chosen here is "Get". (Almost any sort of cmdlet that is capable of retrieving information can process command-line input.) For more information about approved cmdlet verbs, see [Cmdlet Verb Names](#).

The following is the definition for this `Get-Proc` cmdlet. Details of this definition are given in [Creating Your First Cmdlet](#).

C#

```
[Cmdlet(VerbsCommon.Get, "proc")]
public class GetProcCommand: Cmdlet
```

VB

```
<Cmdlet(VerbsCommon.Get, "Proc")> _
Public Class GetProcCommand
    Inherits Cmdlet
```

Defining Parameters

If necessary, your cmdlet must define parameters for processing input. This Get-Proc cmdlet defines a **Name** parameter as described in [Adding Parameters that Process Command-Line Input](#).

Here is the parameter declaration for the **Name** parameter of this Get-Proc cmdlet.

C#

```
[Parameter(
    Position = 0,
    ValueFromPipeline = true,
    ValueFromPipelineByPropertyName = true
)]
[ValidateNotNullOrEmpty]
public string[] Name
{
    get { return processNames; }
    set { processNames = value; }
}
private string[] processNames;
```

VB

```
<Parameter(Position:=0, ValueFromPipeline:=True, _
ValueFromPipelineByPropertyName:=True), ValidateNotNullOrEmpty()> _
Public Property Name() As String()
    Get
        Return processNames
    End Get

    Set(ByVal value As String())
        processNames = value
    End Set

End Property
```

Overriding Input Processing Methods

All cmdlets must override at least one of the input processing methods provided by the `System.Management.Automation.Cmdlet` class. These methods are discussed in [Creating Your First Cmdlet](#).

 Note

Your cmdlet should handle each record as independently as possible.

This Get-Proc cmdlet overrides the [System.Management.Automation.Cmdlet.ProcessRecord](#) method to handle the **Name** parameter for input provided by the user or a script. This method will get the processes for each requested process name or all processes if no name is provided. Details of this override are given in [Creating Your First Cmdlet](#).

Things to Remember When Reporting Errors

The [System.Management.Automation.ErrorRecord](#) object that the cmdlet passes when writing an error requires an exception at its core. Follow the .NET guidelines when determining the exception to use. Basically, if the error is semantically the same as an existing exception, the cmdlet should use or derive from that exception. Otherwise, it should derive a new exception or exception hierarchy directly from the [System.Exception](#) class.

When creating error identifiers (accessed through the `FullyQualifiedErrorId` property of the `ErrorRecord` class) keep the following in mind.

- Use strings that are targeted for diagnostic purposes so that when inspecting the fully qualified identifier you can determine what the error is and where the error came from.
- A well formed fully qualified error identifier might be as follows.

```
CommandNotFoundException,Microsoft.PowerShell.Commands.GetCommandCommand
```

Notice that in the previous example, the error identifier (the first token) designates what the error is and the remaining part indicates where the error came from.

- For more complex scenarios, the error identifier can be a dot separated token that can be parsed on inspection. This allows you too branch on the parts of the error identifier as well as the error identifier and error category.

The cmdlet should assign specific error identifiers to different code paths. Keep the following information in mind for assignment of error identifiers:

- An error identifier should remain constant throughout the cmdlet life cycle. Do not change the semantics of an error identifier between cmdlet versions.
- Use text for an error identifier that tersely corresponds to the error being reported. Do not use white space or punctuation.

- Have your cmdlet generate only error identifiers that are reproducible. For example, it should not generate an identifier that includes a process identifier. Error identifiers are useful to a user only when they correspond to identifiers that are seen by other users experiencing the same problem.

Unhandled exceptions are not caught by PowerShell in the following conditions:

- If a cmdlet creates a new thread and code running in that thread throws an unhandled exception, PowerShell will not catch the error and will terminate the process.
- If an object has code in its destructor or Dispose methods that causes an unhandled exception, PowerShell will not catch the error and will terminate the process.

Reporting Non-terminating Errors

Any one of the input processing methods can report a non-terminating error to the output stream using the [System.Management.Automation.Cmdlet.WriteError](#) method.

Here is a code example from this Get-Proc cmdlet that illustrates the call to [System.Management.Automation.Cmdlet.WriteError](#) from within the override of the [System.Management.Automation.Cmdlet.ProcessRecord](#) method. In this case, the call is made if the cmdlet cannot find a process for a specified process identifier.

C#

```
protected override void ProcessRecord()
{
    // If no name parameter passed to cmdlet, get all processes.
    if (processNames == null)
    {
        WriteObject(Process.GetProcesses(), true);
    }
    else
    {
        // If a name parameter is passed to cmdlet, get and write
        // the associated processes.
        // Write a non-terminating error for failure to retrieve
        // a process.
        foreach (string name in processNames)
        {
            Process[] processes;

            try
            {
                processes = Process.GetProcessesByName(name);
            }

```

```
        catch (InvalidOperationException ex)
    {
        WriteError(new ErrorRecord(
            ex,
            "NameNotFound",
            ErrorCategory.InvalidOperation,
            name));
        continue;
    }

    WriteObject(processes, true);
} // foreach ...
} // else
}
```

Things to Remember About Writing Non-terminating Errors

For a non-terminating error, the cmdlet must generate a specific error identifier for each specific input object.

A cmdlet frequently needs to modify the PowerShell action produced by a non-terminating error. It can do this by defining the `ErrorAction` and `ErrorVariable` parameters. If defining the `ErrorAction` parameter, the cmdlet presents the user options `System.Management.Automation.ActionPreference`, you can also directly influence the action by setting the `$ErrorActionPreference` variable.

The cmdlet can save non-terminating errors to a variable using the `ErrorVariable` parameter, which is not affected by the setting of `ErrorAction`. Failures can be appended to an existing error variable by adding a plus sign (+) to the front of the variable name.

Code Sample

For the complete C# sample code, see [GetProcessSample04 Sample](#).

Define Object Types and Formatting

PowerShell passes information between cmdlets using .NET objects. Consequently, a cmdlet might need to define its own type, or the cmdlet might need to extend an existing type provided by another cmdlet. For more information about defining new types or extending existing types, see [Extending Object Types and Formatting](#).

Building the Cmdlet

After implementing a cmdlet, you must register it with Windows PowerShell through a Windows PowerShell snap-in. For more information about registering cmdlets, see [How to Register Cmdlets, Providers, and Host Applications](#).

Testing the Cmdlet

When your cmdlet has been registered with PowerShell, you can test it by running it on the command line. Let's test the sample Get-Proc cmdlet to see whether it reports an error:

- Start PowerShell, and use the Get-Proc cmdlet to retrieve the processes named "TEST".

```
PowerShell  
Get-Proc -Name test
```

The following output appears.

```
Get-Proc : Operation is not valid due to the current state of the  
object.  
At line:1 char:9  
+ Get-Proc <<< -Name test
```

StopProc Tutorial

Article • 09/15/2023

This section provides a tutorial for creating the Stop-Proc cmdlet, which is very similar to the [Stop-Process](#) cmdlet provided by Windows PowerShell. This tutorial provides fragments of code that illustrate how cmdlets are implemented, and an explanation of the code.

Topics in this Tutorial

The topics in this tutorial are designed to be read sequentially, with each topic building on what was discussed in the previous topic.

- [Creating a Cmdlet that Modifies the System](#): This section describes how to create a cmdlet that supports system modifications, such as stopping a process running on the computer.
- [Adding User Messages to Your Cmdlet](#): This section describes how to add the ability to write user messages, debug messages, warning messages, and progress information to your cmdlet.
- [Adding Aliases, Wildcard Expansion, and Help to Cmdlet Parameters](#): This section describes how to create a cmdlet that supports parameter aliases, Help, and wildcard expansion.
- [Adding Parameter Sets to Cmdlets](#): This section describes how to add parameter sets to a cmdlet. Parameter sets allow the cmdlet to operate differently based on what parameters are specified by the user.

Creating a Cmdlet that Modifies the System

Article • 09/17/2021

Sometimes a cmdlet must modify the running state of the system, not just the state of the Windows PowerShell runtime. In these cases, the cmdlet should allow the user a chance to confirm whether or not to make the change.

To support confirmation a cmdlet must do two things.

- Declare that the cmdlet supports confirmation when you specify the [System.Management.Automation.CmdletAttribute](#) attribute by setting the `SupportsShouldProcess` keyword to `true`.
- Call [System.Management.Automation.Cmdlet.ShouldProcess](#) during the execution of the cmdlet (as shown in the following example).

By supporting confirmation, a cmdlet exposes the `Confirm` and `WhatIf` parameters that are provided by Windows PowerShell, and also meets the development guidelines for cmdlets (For more information about cmdlet development guidelines, see [Cmdlet Development Guidelines](#)).

Changing the System

The act of "changing the system" refers to any cmdlet that potentially changes the state of the system outside Windows PowerShell. For example, stopping a process, enabling or disabling a user account, or adding a row to a database table are all changes to the system that should be confirmed. In contrast, operations that read data or establish transient connections do not change the system and generally do not require confirmation. Confirmation is also not needed for actions whose effect is limited to inside the Windows PowerShell runtime, such as `Set-Variable`. Cmdlets that might or might not make a persistent change should declare `SupportsShouldProcess` and call [System.Management.Automation.Cmdlet.ShouldProcess](#) only if they are about to make a persistent change.

Note

`ShouldProcess` confirmation applies only to cmdlets. If a command or script modifies the running state of a system by directly calling .NET methods or

properties, or by calling applications outside of Windows PowerShell, this form of confirmation will not be available.

The StopProc Cmdlet

This topic describes a Stop-Proc cmdlet that attempts to stop processes that are retrieved using the Get-Proc cmdlet (described in [Creating Your First Cmdlet](#)).

Defining the Cmdlet

The first step in cmdlet creation is always naming the cmdlet and declaring the .NET class that implements the cmdlet. Because you are writing a cmdlet to change the system, it should be named accordingly. This cmdlet stops system processes, so the verb name chosen here is "Stop", defined by the

[System.Management.Automation.VerbsLifecycle](#) class, with the noun "Proc" to indicate that the cmdlet stops processes. For more information about approved cmdlet verbs, see [Cmdlet Verb Names](#).

The following is the class definition for this Stop-Proc cmdlet.

```
C#  
  
[Cmdlet(VerbsLifecycle.Stop, "Proc",  
        SupportsShouldProcess = true)]  
public class StopProcCommand : Cmdlet
```

Be aware that in the [System.Management.Automation.CmdletAttribute](#) declaration, the `SupportsShouldProcess` attribute keyword is set to `true` to enable the cmdlet to make calls to [System.Management.Automation.Cmdlet.ShouldProcess](#) and [System.Management.Automation.Cmdlet.ShouldContinue](#). Without this keyword set, the `Confirm` and `WhatIf` parameters will not be available to the user.

Extremely Destructive Actions

Some operations are extremely destructive, such as reformatting an active hard disk partition. In these cases, the cmdlet should set `ConfirmImpact` = `ConfirmImpact.High` when declaring the [System.Management.Automation.CmdletAttribute](#) attribute. This setting forces the cmdlet to request user confirmation even when the user has not specified the `Confirm` parameter. However, cmdlet developers should avoid overusing `ConfirmImpact` for operations that are just potentially destructive, such as deleting a

user account. Remember that if `ConfirmImpact` is set to `System.Management.Automation.ConfirmImpact.High`.

Similarly, some operations are unlikely to be destructive, although they do in theory modify the running state of a system outside Windows PowerShell. Such cmdlets can set `ConfirmImpact` to `System.Management.Automation.ConfirmImpact.Low`. This will bypass confirmation requests where the user has asked to confirm only medium-impact and high-impact operations.

Defining Parameters for System Modification

This section describes how to define the cmdlet parameters, including those that are needed to support system modification. See [Adding Parameters that Process CommandLine Input](#) if you need general information about defining parameters.

The Stop-Proc cmdlet defines three parameters: `Name`, `Force`, and `PassThru`.

The `Name` parameter corresponds to the `Name` property of the process input object. Be aware that the `Name` parameter in this sample is mandatory, as the cmdlet will fail if it does not have a named process to stop.

The `Force` parameter allows the user to override calls to `System.Management.Automation.Cmdlet.ShouldContinue`. In fact, any cmdlet that calls `System.Management.Automation.Cmdlet.ShouldContinue` should have a `Force` parameter so that when `Force` is specified, the cmdlet skips the call to `System.Management.Automation.Cmdlet.ShouldContinue` and proceeds with the operation. Be aware that this does not affect calls to `System.Management.Automation.Cmdlet.ShouldProcess`.

The `PassThru` parameter allows the user to indicate whether the cmdlet passes an output object through the pipeline, in this case, after a process is stopped. Be aware that this parameter is tied to the cmdlet itself instead of to a property of the input object.

Here is the parameter declaration for the Stop-Proc cmdlet.

```
C#  
  
[Parameter()  
    Position = 0,  
    Mandatory = true,  
    ValueFromPipeline = true,  
    ValueFromPipelineByPropertyName = true  
)]  
public string[] Name
```

```

{
    get { return processNames; }
    set { processNames = value; }
}
private string[] processNames;

/// <summary>
/// Specify the Force parameter that allows the user to override
/// the ShouldContinue call to force the stop operation. This
/// parameter should always be used with caution.
/// </summary>
[Parameter]
public SwitchParameter Force
{
    get { return force; }
    set { force = value; }
}
private bool force;

/// <summary>
/// Specify the PassThru parameter that allows the user to specify
/// that the cmdlet should pass the process object down the pipeline
/// after the process has been stopped.
/// </summary>
[Parameter]
public SwitchParameter PassThru
{
    get { return passThru; }
    set { passThru = value; }
}
private bool passThru;

```

Overriding an Input Processing Method

The cmdlet must override an input processing method. The following code illustrates the `System.Management.Automation.Cmdlet.ProcessRecord` override used in the sample Stop-Proc cmdlet. For each requested process name, this method ensures that the process is not a special process, tries to stop the process, and then sends an output object if the `PassThru` parameter is specified.

C#

```

protected override void ProcessRecord()
{
    foreach (string name in processNames)
    {
        // For every process name passed to the cmdlet, get the associated
        // process(es). For failures, write a non-terminating error
        Process[] processes;

```

```

try
{
    processes = Process.GetProcessesByName(name);
}
catch (InvalidOperationException ioe)
{
    WriteError(new ErrorRecord(ioe, "Unable to access the target process by
name",
                           ErrorCategory.InvalidOperation, name));
    continue;
}

// Try to stop the process(es) that have been retrieved for a name
foreach (Process process in processes)
{
    string processName;

    try
    {
        processName = process.ProcessName;
    }

    catch (Win32Exception e)
    {
        WriteError(new ErrorRecord(e, "ProcessNameNotFound",
                                   ErrorCategory.ReadError, process));
        continue;
    }

    // Call Should Process to confirm the operation first.
    // This is always false if WhatIf is set.
    if (!ShouldProcess(string.Format("{0} ({1})", processName,
                                    process.Id)))
    {
        continue;
    }
    // Call ShouldContinue to make sure the user really does want
    // to stop a critical process that could possibly stop the computer.
    bool criticalProcess =
        criticalProcessNames.Contains(processName.ToLower());

    if (criticalProcess &&!force)
    {
        string message = String.Format
            ("The process \"{0}\" is a critical process and should not
be stopped. Are you sure you wish to stop the process?",
            processName);

        // It is possible that ProcessRecord is called multiple times
        // when the Name parameter receives objects as input from the
        // pipeline. So to retain YesToAll and NoToAll input that the
        // user may enter across multiple calls to ProcessRecord, this
        // information is stored as private members of the cmdlet.
        if (!ShouldContinue(message, "Warning!",
                           ref yesToAll,

```

```

                    ref noToAll))
{
    continue;
}
} // if (criticalProcess...
// Stop the named process.
try
{
    process.Kill();
}
catch (Exception e)
{
    if ((e is Win32Exception) || (e is SystemException) ||
        (e is InvalidOperationException))
    {
        // This process could not be stopped so write
        // a non-terminating error.
        string message = String.Format("{0} {1} {2}",
            "Could not stop process \\"", processName,
            "\\.");
        WriteError(new ErrorRecord(e, message,
            ErrorCategory.CloseError, process));
        continue;
    } // if ((e is...
    else throw;
} // catch

// If the PassThru parameter argument is
// True, pass the terminated process on.
if (passThru)
{
    WriteObject(process);
}
} // foreach (Process...
} // foreach (string...
} // ProcessRecord

```

Calling the ShouldProcess Method

The input processing method of your cmdlet should call the [System.Management.Automation.Cmdlet.ShouldProcess](#) method to confirm execution of an operation before a change (for example, deleting files) is made to the running state of the system. This allows the Windows PowerShell runtime to supply the correct "WhatIf" and "Confirm" behavior within the shell.

ⓘ Note

If a cmdlet states that it supports should process and fails to make the [System.Management.Automation.Cmdlet.ShouldProcess](#) call, the user might

modify the system unexpectedly.

The call to [System.Management.Automation.Cmdlet.ShouldProcess](#) sends the name of the resource to be changed to the user, with the Windows PowerShell runtime taking into account any command-line settings or preference variables in determining what should be displayed to the user.

The following example shows the call to

[System.Management.Automation.Cmdlet.ShouldProcess](#) from the override of the [System.Management.Automation.Cmdlet.ProcessRecord](#) method in the sample Stop-Proc cmdlet.

```
C#
```

```
if (!ShouldProcess(string.Format("{0} ({1})", processName,
                                 process.Id)))
{
    continue;
}
```

Calling the ShouldContinue Method

The call to the [System.Management.Automation.Cmdlet.ShouldContinue](#) method sends a secondary message to the user. This call is made after the call to [System.Management.Automation.Cmdlet.ShouldProcess](#) returns `true` and if the `Force` parameter was not set to `true`. The user can then provide feedback to say whether the operation should be continued. Your cmdlet calls [System.Management.Automation.Cmdlet.ShouldContinue](#) as an additional check for potentially dangerous system modifications or when you want to provide yes-to-all and no-to-all options to the user.

The following example shows the call to

[System.Management.Automation.Cmdlet.ShouldContinue](#) from the override of the [System.Management.Automation.Cmdlet.ProcessRecord](#) method in the sample Stop-Proc cmdlet.

```
C#
```

```
if (criticalProcess &&!force)
{
    string message = String.Format
        ("The process \"{0}\" is a critical process and should not be
         stopped. Are you sure you wish to stop the process?",
         processName);
```

```
// It is possible that ProcessRecord is called multiple times
// when the Name parameter receives objects as input from the
// pipeline. So to retain YesToAll and NoToAll input that the
// user may enter across multiple calls to ProcessRecord, this
// information is stored as private members of the cmdlet.
if (!ShouldContinue(message, "Warning!",
                     ref yesToAll,
                     ref noToAll))
{
    continue;
}
} // if (criticalProcess...
```

Stopping Input Processing

The input processing method of a cmdlet that makes system modifications must provide a way of stopping the processing of input. In the case of this Stop-Proc cmdlet, a call is made from the [System.Management.Automation.Cmdlet.ProcessRecord](#) method to the [System.Diagnostics.Process.Kill](#)* method. Because the `PassThru` parameter is set to `true`, [System.Management.Automation.Cmdlet.ProcessRecord](#) also calls [System.Management.Automation.Cmdlet.WriteObject](#) to send the process object to the pipeline.

Code Sample

For the complete C# sample code, see [StopProcessSample01 Sample](#).

Defining Object Types and Formatting

Windows PowerShell passes information between cmdlets using .NET objects. Consequently, a cmdlet may need to define its own type, or the cmdlet may need to extend an existing type provided by another cmdlet. For more information about defining new types or extending existing types, see [Extending Object Types and Formatting](#) ↗.

Building the Cmdlet

After implementing a cmdlet, it must be registered with Windows PowerShell through a Windows PowerShell snap-in. For more information about registering cmdlets, see [How to Register Cmdlets, Providers, and Host Applications](#) ↗.

Testing the Cmdlet

When your cmdlet has been registered with Windows PowerShell, you can test it by running it on the command line. Here are several tests that test the Stop-Proc cmdlet. For more information about using cmdlets from the command line, see the [Getting Started with Windows PowerShell](#).

- Start Windows PowerShell and use the Stop-Proc cmdlet to stop processing as shown below. Because the cmdlet specifies the `Name` parameter as mandatory, the cmdlet queries for the parameter.

```
PowerShell
```

```
PS> Stop-Proc
```

The following output appears.

```
Cmdlet Stop-Proc at command pipeline position 1  
Supply values for the following parameters:  
Name[0]:
```

- Now let's use the cmdlet to stop the process named "NOTEPAD". The cmdlet asks you to confirm the action.

```
PowerShell
```

```
PS> Stop-Proc -Name notepad
```

The following output appears.

```
Confirm  
Are you sure you want to perform this action?  
Performing operation "Stop-Proc" on Target "notepad (4996)".  
[Y] Yes [A] Yes to All [N] No [L] No to All [S] Suspend [?] Help  
(default is "Y"): Y
```

- Use Stop-Proc as shown to stop the critical process named "WINLOGON". You are prompted and warned about performing this action because it will cause the operating system to reboot.

PowerShell

```
PS> Stop-Proc -Name Winlogon
```

The following output appears.

Output

```
Confirm  
Are you sure you want to perform this action?  
Performing operation "Stop-Proc" on Target "winlogon (656)".  
[Y] Yes [A] Yes to All [N] No [L] No to All [S] Suspend [?] Help  
(default is "Y"): Y  
Warning!  
The process " winlogon " is a critical process and should not be  
stopped. Are you sure you wish to stop the process?  
[Y] Yes [A] Yes to All [N] No [L] No to All [S] Suspend [?] Help  
(default is "Y"): N
```

- Let's now try to stop the WINLOGON process without receiving a warning. Be aware that this command entry uses the `Force` parameter to override the warning.

PowerShell

```
PS> Stop-Proc -Name winlogon -Force
```

The following output appears.

Output

```
Confirm  
Are you sure you want to perform this action?  
Performing operation "Stop-Proc" on Target "winlogon (656)".  
[Y] Yes [A] Yes to All [N] No [L] No to All [S] Suspend [?] Help  
(default is "Y"): N
```

Cmdlet Samples

Adding User Messages to Your Cmdlet

Article • 09/17/2021

Cmdlets can write several kinds of messages that can be displayed to the user by the Windows PowerShell runtime. These messages include the following types:

- Verbose messages that contain general user information.
- Debug messages that contain troubleshooting information.
- Warning messages that contain a notification that the cmdlet is about to perform an operation that can have unexpected results.
- Progress report messages that contain information about how much work the cmdlet has completed when performing an operation that takes a long time.

There are no limits to the number of messages that your cmdlet can write or the type of messages that your cmdlet writes. Each message is written by making a specific call from within the input processing method of your cmdlet.

Defining the Cmdlet

The first step in cmdlet creation is always naming the cmdlet and declaring the .NET class that implements the cmdlet. Any sort of cmdlet can write user notifications from its input processing methods; so, in general, you can name this cmdlet using any verb that indicates what system modifications the cmdlet performs. For more information about approved cmdlet verbs, see [Cmdlet Verb Names](#).

The Stop-Proc cmdlet is designed to modify the system; therefore, the [System.Management.Automation.CmdletAttribute](#) declaration for the .NET class must include the `SupportsShouldProcess` attribute keyword and be set to `true`.

The following code is the definition for this Stop-Proc cmdlet class. For more information about this definition, see [Creating a Cmdlet that Modifies the System](#).

C#

```
[Cmdlet(VerbsLifecycle.Stop, "proc",
        SupportsShouldProcess = true)]
public class StopProcCommand : Cmdlet
```

Defining Parameters for System Modification

The Stop-Proc cmdlet defines three parameters: `Name`, `Force`, and `PassThru`. For more information about defining these parameters, see [Creating a Cmdlet that Modifies the System](#).

Here is the parameter declaration for the Stop-Proc cmdlet.

C#

```
[Parameter(
    Position = 0,
    Mandatory = true,
    ValueFromPipeline = true,
    ValueFromPipelineByPropertyName = true
)]
public string[] Name
{
    get { return processNames; }
    set { processNames = value; }
}
private string[] processNames;

/// <summary>
/// Specify the Force parameter that allows the user to override
/// the ShouldContinue call to force the stop operation. This
/// parameter should always be used with caution.
/// </summary>
[Parameter]
public SwitchParameter Force
{
    get { return force; }
    set { force = value; }
}
private bool force;

/// <summary>
/// Specify the PassThru parameter that allows the user to specify
/// that the cmdlet should pass the process object down the pipeline
/// after the process has been stopped.
/// </summary>
[Parameter]
public SwitchParameter PassThru
{
    get { return passThru; }
    set { passThru = value; }
}
private bool passThru;
```

Overriding an Input Processing Method

Your cmdlet must override an input processing method, most often it will be [System.Management.Automation.Cmdlet.ProcessRecord](#). This Stop-Proc cmdlet overrides the [System.Management.Automation.Cmdlet.ProcessRecord](#) input processing method. In this implementation of the Stop-Proc cmdlet, calls are made to write verbose messages, debug messages, and warning messages.

 **Note**

For more information about how this method calls the [System.Management.Automation.Cmdlet.ShouldProcess](#) and [System.Management.Automation.Cmdlet.ShouldContinue](#) methods, see [Creating a Cmdlet that Modifies the System](#).

Writing a Verbose Message

The [System.Management.Automation.Cmdlet.WriteVerbose](#) method is used to write general user-level information that is unrelated to specific error conditions. The system administrator can then use that information to continue processing other commands. In addition, any information written using this method should be localized as needed.

The following code from this Stop-Proc cmdlet shows two calls to the [System.Management.Automation.Cmdlet.WriteVerbose](#) method from the override of the [System.Management.Automation.Cmdlet.ProcessRecord](#) method.

C#

```
message = String.Format("Attempting to stop process \'{0}\'.", name);
WriteVerbose(message);
```

C#

```
message = String.Format("Stopped process \'{0}\', pid {1}.",
processName, process.Id);

WriteVerbose(message);
```

Writing a Debug Message

The [System.Management.Automation.Cmdlet.WriteDebug](#) method is used to write debug messages that can be used to troubleshoot the operation of the cmdlet. The call is made from an input processing method.

Note

Windows PowerShell also defines a `Debug` parameter that presents both verbose and debug information. If your cmdlet supports this parameter, it does not need to call `System.Management.Automation.Cmdlet.WriteDebug` in the same code that calls `System.Management.Automation.Cmdlet.WriteVerbose`.

The following two sections of code from the sample Stop-Proc cmdlet show calls to the `System.Management.Automation.Cmdlet.WriteDebug` method from the override of the `System.Management.Automation.Cmdlet.ProcessRecord` method.

This debug message is written immediately before `System.Management.Automation.Cmdlet.ShouldProcess` is called.

```
C#
```

```
message =
    String.Format("Acquired name for pid {0} : \'{1}\'",
        process.Id, processName);
WriteDebug(message);
```

This debug message is written immediately before `System.Management.Automation.Cmdlet.WriteObject` is called.

```
C#
```

```
message =
    String.Format("Writing process \'{0}\' to pipeline",
        processName);
WriteDebug(message);
WriteObject(process);
```

Windows PowerShell automatically routes any `System.Management.Automation.Cmdlet.WriteDebug` calls to the tracing infrastructure and cmdlets. This allows the method calls to be traced to the hosting application, a file, or a debugger without your having to do any extra development work within the cmdlet. The following command-line entry implements a tracing operation.

```
PS> Trace-Expression Stop-Proc -File proc.log -Command Stop-Proc notepad
```

Writing a Warning Message

The [System.Management.Automation.Cmdlet.WriteWarning](#) method is used to write a warning when the cmdlet is about to perform an operation that might have an unexpected result, for example, overwriting a read-only file.

The following code from the sample Stop-Proc cmdlet shows the call to the [System.Management.Automation.Cmdlet.WriteWarning](#) method from the override of the [System.Management.Automation.Cmdlet.ProcessRecord](#) method.

```
C#
```

```
if (criticalProcess)
{
    message =
        String.Format("Stopping the critical process \">{0}\",
                      processName);
    WriteWarning(message);
} // if (criticalProcess...
```

Writing a Progress Message

The [System.Management.Automation.Cmdlet.WriteProgress](#) is used to write progress messages when cmdlet operations take an extended amount of time to complete. A call to [System.Management.Automation.Cmdlet.WriteProgress](#) passes a [System.Management.Automation.ProgressRecord](#) object that is sent to the hosting application for rendering to the user.

 **Note**

This Stop-Proc cmdlet does not include a call to the [System.Management.Automation.Cmdlet.WriteProgress](#) method.

The following code is an example of a progress message written by a cmdlet that is attempting to copy an item.

```
C#
```

```
int myId = 0;
string myActivity = "Copy-item: Copying *.* to C:\abc";
string myStatus = "Copying file bar.txt";
ProgressRecord pr = new ProgressRecord(myId, myActivity, myStatus);
WriteProgress(pr);

pr.RecordType = ProgressRecordType.Completed;
WriteProgress(pr);
```

Code Sample

For the complete C# sample code, see [StopProcessSample02 Sample](#).

Define Object Types and Formatting

Windows PowerShell passes information between cmdlets using .NET objects. Consequently, a cmdlet might need to define its own type, or the cmdlet might need to extend an existing type provided by another cmdlet. For more information about defining new types or extending existing types, see [Extending Object Types and Formatting](#).

Building the Cmdlet

After implementing a cmdlet, it must be registered with Windows PowerShell through a Windows PowerShell snap-in. For more information about registering cmdlets, see [How to Register Cmdlets, Providers, and Host Applications](#).

Testing the Cmdlet

When your cmdlet has been registered with Windows PowerShell, you can test it by running it on the command line. Let's test the sample Stop-Proc cmdlet. For more information about using cmdlets from the command line, see the [Getting Started with Windows PowerShell](#).

- The following command-line entry uses Stop-Proc to stop the process named "NOTEPAD", provide verbose notifications, and print debug information.

```
PowerShell
```

```
PS> Stop-Proc -Name notepad -Verbose -Debug
```

The following output appears.

```
VERBOSE: Attempting to stop process " notepad ".
DEBUG: Acquired name for pid 5584 : "notepad"

Confirm
Continue with this operation?
[Y] Yes  [A] Yes to All  [H] Halt Command  [S] Suspend  [?] Help
```

```
(default is "Y"): Y

Confirm
Are you sure you want to perform this action?
Performing operation "Stop-Proc" on Target "notepad (5584)".
[Y] Yes [A] Yes to All [N] No [L] No to All [S] Suspend [?] Help
(default is "Y"): Y
VERBOSE: Stopped process "notepad", pid 5584.
```

Adding Aliases, Wildcard Expansion, and Help to Cmdlet Parameters

Article • 05/12/2022

This section describes how to add aliases, wildcard expansion, and Help messages to the parameters of the `Stop-Proc` cmdlet (described in [Creating a Cmdlet that Modifies the System](#)).

This `Stop-Proc` cmdlet attempts to stop processes that are retrieved using the `Get-Proc` cmdlet (described in [Creating Your First Cmdlet](#)).

Defining the Cmdlet

The first step in cmdlet creation is always naming the cmdlet and declaring the .NET class that implements the cmdlet. Because you are writing a cmdlet to change the system, it should be named accordingly. Because this cmdlet stops system processes, it uses the verb **Stop**, defined by the `System.Management.Automation.VerbsLifecycle` class, with the noun **Proc** to indicate process. For more information about approved cmdlet verbs, see [Cmdlet Verb Names](#).

The following code is the class definition for this `Stop-Proc` cmdlet.

```
C#  
  
[Cmdlet(VerbsLifecycle.Stop, "proc",  
        SupportsShouldProcess = true)]  
public class StopProcCommand : Cmdlet
```

Defining Parameters for System Modification

Your cmdlet needs to define parameters that support system modifications and user feedback. The cmdlet should define a **Name** parameter or equivalent so that the cmdlet will be able to modify the system by some sort of identifier. In addition, the cmdlet should define the **Force** and **PassThru** parameters. For more information about these parameters, see [Creating a Cmdlet that Modifies the System](#).

Defining a Parameter Alias

A parameter alias can be an alternate name or a well-defined 1-letter or 2-letter short name for a cmdlet parameter. In both cases, the goal of using aliases is to simplify user entry from the command line. Windows PowerShell supports parameter aliases through the [System.Management.Automation.AliasAttribute](#) attribute, which uses the declaration syntax `[Alias()]`.

The following code shows how an alias is added to the **Name** parameter.

```
C#  
  
/// <summary>  
/// Specify the mandatory Name parameter used to identify the  
/// processes to be stopped.  
/// </summary>  
[Parameter(  
    Position = 0,  
    Mandatory = true,  
    ValueFromPipeline = true,  
    ValueFromPipelineByPropertyName = true,  
    HelpMessage = "The name of one or more processes to stop.  
Wildcards are permitted."  
)  
[Alias("ProcessName")]  
public string[] Name  
{  
    get { return processNames; }  
    set { processNames = value; }  
}  
private string[] processNames;
```

In addition to using the [System.Management.Automation.AliasAttribute](#) attribute, the Windows PowerShell runtime performs partial name matching, even if no aliases are specified. For example, if your cmdlet has a **FileName** parameter and that is the only parameter that starts with `F`, the user could enter `Filename`, `Filenam`, `File`, `Fi`, or `F` and still recognize the entry as the **FileName** parameter.

Creating Help for Parameters

Windows PowerShell allows you to create Help for cmdlet parameters. Do this for any parameter used for system modification and user feedback. For each parameter to support Help, you can set the **HelpMessage** attribute keyword in the [System.Management.Automation.ParameterAttribute](#) attribute declaration. This keyword defines the text to display to the user for assistance in using the parameter. You can also set the **HelpMessageBaseName** keyword to identify the base name of a resource to use

for the message. If you set this keyword, you must also set the **HelpMessageResourceId** keyword to specify the resource identifier.

The following code from this `Stop-Proc` cmdlet defines the **HelpMessage** attribute keyword for the **Name** parameter.

```
C#
```

```
/// <summary>
/// Specify the mandatory Name parameter used to identify the
/// processes to be stopped.
/// </summary>
[Parameter(
    Position = 0,
    Mandatory = true,
    ValueFromPipeline = true,
    ValueFromPipelineByPropertyName = true,
    HelpMessage = "The name of one or more processes to stop.
Wildcards are permitted."
)]
```

Overriding an Input Processing Method

Your cmdlet must override an input processing method, most often this will be `System.Management.Automation.Cmdlet.ProcessRecord`. When modifying the system, the cmdlet should call the `System.Management.Automation.Cmdlet.ShouldProcess` and `System.Management.Automation.Cmdlet.ShouldContinue` methods to allow the user to provide feedback before a change is made. For more information about these methods, see [Creating a Cmdlet that Modifies the System](#).

Supporting Wildcard Expansion

To allow the selection of multiple objects, your cmdlet can use the `System.Management.Automation.WildcardPattern` and `System.Management.Automation.WildcardOptions` classes to provide wildcard expansion support for parameter input. Examples of wildcard patterns are `1sa*`, `*.txt`, and `[a-c]*`. Use the back-quote character (`\``) as an escape character when the pattern contains a character that should be used literally.

Wildcard expansions of file and path names are examples of common scenarios where the cmdlet may want to allow support for path inputs when the selection of multiple objects is required. A common case is in the file system, where a user wants to see all files residing in the current folder.

You should need a customized wildcard pattern matching implementation only rarely. In this case, your cmdlet should support either the full POSIX 1003.2, 3.13 specification for wildcard expansion or the following simplified subset:

- **Question mark (?)**. Matches any character at the specified location.
- **Asterisk (*)**. Matches zero or more characters starting at the specified location.
- **Open bracket ([)**. Introduces a pattern bracket expression that can contain characters or a range of characters. If a range is required, a hyphen (-) is used to indicate the range.
- **Close bracket (])**. Ends a pattern bracket expression.
- **Back-quote escape character (`)**. Indicates that the next character should be taken literally. Be aware that when specifying the back-quote character from the command line (as opposed to specifying it programmatically), the back-quote escape character must be specified twice.

Note

For more information about wildcard patterns, see [Supporting Wildcards in Cmdlet Parameters](#).

The following code shows how to set wildcard options and define the wildcard pattern used for resolving the **Name** parameter for this cmdlet.

```
C#
```

```
WildcardOptions options = WildcardOptions.IgnoreCase |  
    WildcardOptions.Compiled;  
WildcardPattern wildcard = new WildcardPattern(name,options);
```

The following code shows how to test whether the process name matches the defined wildcard pattern. Notice that, in this case, if the process name does not match the pattern, the cmdlet continues on to get the next process name.

```
C#
```

```
if (!wildcard.IsMatch(processName))  
{  
    continue;  
}
```

Code Sample

For the complete C# sample code, see [StopProcessSample03 Sample](#).

Define Object Types and Formatting

Windows PowerShell passes information between cmdlets using .NET objects. Consequently, a cmdlet may need to define its own type, or the cmdlet may need to extend an existing type provided by another cmdlet. For more information about defining new types or extending existing types, see [Extending Object Types and Formatting](#).

Building the Cmdlet

After implementing a cmdlet, it must be registered with Windows PowerShell through a Windows PowerShell snap-in. For more information about registering cmdlets, see [How to Register Cmdlets, Providers, and Host Applications](#).

Testing the Cmdlet

When your cmdlet has been registered with Windows PowerShell, you can test it by running it on the command line. Let's test the sample Stop-Proc cmdlet. For more information about using cmdlets from the command line, see the [Getting Started with Windows PowerShell](#).

- Start Windows PowerShell and use `Stop-Proc` to stop a process using the `ProcessName` alias for the `Name` parameter.

```
PowerShell  
PS> Stop-Proc -ProcessName notepad
```

The following output appears.

```
Confirm  
Are you sure you want to perform this action?  
Performing operation "Stop-Proc" on Target "notepad (3496)".  
[Y] Yes [A] Yes to All [N] No [L] No to All [S] Suspend [?] Help  
(default is "Y"): Y
```

- Make the following entry on the command line. Because the `Name` parameter is mandatory, you are prompted for it. Entering `!?` brings up the help text associated

with the parameter.

```
PowerShell
```

```
PS> Stop-Proc
```

The following output appears.

```
Cmdlet Stop-Proc at command pipeline position 1
Supply values for the following parameters:
(Type !? for Help.)
Name[0]: !?
The name of one or more processes to stop. Wildcards are permitted.
Name[0]: notepad
```

- Now make the following entry to stop all processes that match the wildcard pattern `*note*`. You are prompted before stopping each process that matches the pattern.

```
PowerShell
```

```
PS> Stop-Proc -Name *note*
```

The following output appears.

```
Confirm
Are you sure you want to perform this action?
Performing operation "Stop-Proc" on Target "notepad (1112)".
[Y] Yes [A] Yes to All [N] No [L] No to All [S] Suspend [?] Help
(default is "Y"): Y
```

The following output appears.

```
Confirm
Are you sure you want to perform this action?
Performing operation "Stop-Proc" on Target "ONENOTEM (3712)".
[Y] Yes [A] Yes to All [N] No [L] No to All [S] Suspend [?] Help
(default is "Y"): N
```

The following output appears.

Confirm
Are you sure you want to perform this action?
Performing operation "Stop-Proc" on Target "ONENOTE (3592)".
[Y] Yes [A] Yes to All [N] No [L] No to All [S] Suspend [?] Help
(default is "Y"): N

Adding Parameter Sets to a Cmdlet

Article • 09/17/2021

Things to Know About Parameter Sets

Windows PowerShell defines a parameter set as a group of parameters that operate together. By grouping the parameters of a cmdlet, you can create a single cmdlet that can change its functionality based on what group of parameters the user specifies.

An example of a cmdlet that uses two parameter sets to define different functionalities is the `Get-EventLog` cmdlet that is provided by Windows PowerShell. This cmdlet returns different information when the user specifies the `List` or `LogName` parameter. If the `LogName` parameter is specified, the cmdlet returns information about the events in a given event log. If the `List` parameter is specified, the cmdlet returns information about the log files themselves (not the event information they contain). In this case, the `List` and `LogName` parameters identify two separate parameter sets.

Two important things to remember about parameter sets is that the Windows PowerShell runtime uses only one parameter set for a particular input, and that each parameter set must have at least one parameter that is unique for that parameter set.

To illustrate that last point, this `Stop-Proc` cmdlet uses three parameter sets:

`ProcessName`, `ProcessId`, and `InputObject`. Each of these parameter sets has one parameter that is not in the other parameter sets. The parameter sets could share other parameters, but the cmdlet uses the unique parameters `ProcessName`, `ProcessId`, and `InputObject` to identify which set of parameters that the Windows PowerShell runtime should use.

Declaring the Cmdlet Class

The first step in cmdlet creation is always naming the cmdlet and declaring the .NET class that implements the cmdlet. For this cmdlet, the lifecycle verb "Stop" is used because the cmdlet stops system processes. The noun name "Proc" is used because the cmdlet works on processes. In the declaration below, note that the cmdlet verb and noun name are reflected in the name of the cmdlet class.

Note

For more information about approved cmdlet verb names, see [Cmdlet Verb Names](#).

The following code is the class definition for this Stop-Proc cmdlet.

C#

```
[Cmdlet(VerbsLifecycle.Stop, "Proc",
        DefaultParameterSetName = "ProcessId",
        SupportsShouldProcess = true)]
public class StopProcCommand : PSCmdlet
```

VB

```
<Cmdlet(VerbsLifecycle.Stop, "Proc", DefaultParameterSetName:="ProcessId", _
SupportsShouldProcess:=True)> _
Public Class StopProcCommand
    Inherits PSCmdlet
```

Declaring the Parameters of the Cmdlet

This cmdlet defines three parameters needed as input to the cmdlet (these parameters also define the parameter sets), as well as a `Force` parameter that manages what the cmdlet does and a `PassThru` parameter that determines whether the cmdlet sends an output object through the pipeline. By default, this cmdlet does not pass an object through the pipeline. For more information about these last two parameters, see [Creating a Cmdlet that Modifies the System](#).

Declaring the Name Parameter

This input parameter allows the user to specify the names of the processes to be stopped. Note that the `ParameterSetName` attribute keyword of the `System.Management.Automation.ParameterAttribute` attribute specifies the `ProcessName` parameter set for this parameter.

C#

```
[Parameter(
    Position = 0,
    ParameterSetName = "ProcessName",
    Mandatory = true,
    ValueFromPipeline = true,
    ValueFromPipelineByPropertyName = true,
```

```

        HelpMessage = "The name of one or more processes to stop. Wildcards are
permitted."
    )]
[Alias("ProcessName")]
public string[] Name
{
    get { return processNames; }
    set { processNames = value; }
}
private string[] processNames;

```

VB

```

<Parameter(Position:=0, ParameterSetName:="ProcessName", _
Mandatory:=True, _
ValueFromPipeline:=True, ValueFromPipelineByPropertyName:=True, _
HelpMessage:="The name of one or more processes to stop. " & _
    "Wildcards are permitted."), [Alias]("ProcessName")> _
Public Property Name() As String()
    Get
        Return processNames
    End Get
    Set(ByVal value As String())
        processNames = value
    End Set
End Property

Private processNames() As String

```

Note also that the alias "ProcessName" is given to this parameter.

Declaring the Id Parameter

This input parameter allows the user to specify the identifiers of the processes to be stopped. Note that the `ParameterSetName` attribute keyword of the `System.Management.Automation.ParameterAttribute` attribute specifies the `ProcessId` parameter set.

C#

```

[Parameter(
    ParameterSetName = "ProcessId",
    Mandatory = true,
    ValueFromPipelineByPropertyName = true,
    ValueFromPipeline = true
)]
[Alias("ProcessId")]
public int[] Id
{

```

```

    get { return processIds; }
    set { processIds = value; }
}
private int[] processIds;

```

VB

```

<Parameter(ParameterSetName:="ProcessId", _
Mandatory:=True, _
ValueFromPipelineByPropertyName:=True, _
ValueFromPipeline:=True), [Alias]("ProcessId")> _
Public Property Id() As Integer()
    Get
        Return processIds
    End Get
    Set(ByVal value As Integer())
        processIds = value
    End Set
End Property
Private processIds() As Integer

```

Note also that the alias "ProcessId" is given to this parameter.

Declaring the InputObject Parameter

This input parameter allows the user to specify an input object that contains information about the processes to be stopped. Note that the `ParameterSetName` attribute keyword of the `System.Management.Automation.ParameterAttribute` attribute specifies the `InputObject` parameter set for this parameter.

C#

```

[Parameter(
    ParameterSetName = "InputObject",
    Mandatory = true,
    ValueFromPipeline = true)]
public Process[] InputObject
{
    get { return inputObject; }
    set { inputObject = value; }
}
private Process[] inputObject;

```

VB

```

<Parameter(ParameterSetName:="InputObject", _
Mandatory:=True, ValueFromPipeline:=True)> _
Public Property InputObject() As Process()

```

```
Get
    Return myInputObject
End Get
Set(ByVal value As Process())
    myInputObject = value
End Set
End Property
Private myInputObject() As Process
```

Note also that this parameter has no alias.

Declaring Parameters in Multiple Parameter Sets

Although there must be a unique parameter for each parameter set, parameters can belong to more than one parameter set. In these cases, give the shared parameter a [System.Management.Automation.ParameterAttribute](#) attribute declaration for each set to which that the parameter belongs. If a parameter is in all parameter sets, you only have to declare the parameter attribute once and do not need to specify the parameter set name.

Overriding an Input Processing Method

Every cmdlet must override an input processing method, most often this will be the [System.Management.Automation.Cmdlet.ProcessRecord](#) method. In this cmdlet, the [System.Management.Automation.Cmdlet.ProcessRecord](#) method is overridden so that the cmdlet can process any number of processes. It contains a Select statement that calls a different method based on which parameter set the user has specified.

```
C#
protected override void ProcessRecord()
{
    switch (ParameterSetName)
    {
        case "ProcessName":
            ProcessByName();
            break;

        case "ProcessId":
            ProcessById();
            break;

        case "InputObject":
            foreach (Process process in inputObject)
            {
                SafeStopProcess(process);
            }
    }
}
```

```
        break;

    default:
        throw new ArgumentException("Bad ParameterSet Name");
    } // switch (ParameterSetName...
} // ProcessRecord
```

VB

```
Protected Overrides Sub ProcessRecord()
    Select Case ParameterSetName
        Case "ProcessName"
            ProcessByName()

        Case "ProcessId"
            ProcessById()

        Case "InputObject"
            Dim process As Process
            For Each process In myInputObject
                SafeStopProcess(process)
            Next process

        Case Else
            Throw New ArgumentException("Bad ParameterSet Name")
    End Select

End Sub 'ProcessRecord ' ProcessRecord
```

The Helper methods called by the Select statement are not described here, but you can see their implementation in the complete code sample in the next section.

Code Sample

For the complete C# sample code, see [StopProcessSample04 Sample](#).

Defining Object Types and Formatting

Windows PowerShell passes information between cmdlets using .NET objects. Consequently, a cmdlet might need to define its own type, or the cmdlet might need to extend an existing type provided by another cmdlet. For more information about defining new types or extending existing types, see [Extending Object Types and Formatting](#).

Building the Cmdlet

After implementing a cmdlet, you must register it with Windows PowerShell through a Windows PowerShell snap-in. For more information about registering cmdlets, see [How to Register Cmdlets, Providers, and Host Applications](#).

Testing the Cmdlet

When your cmdlet has been registered with Windows PowerShell, test it by running it on the command line. Here are some tests that show how the `ProcessId` and `InputObject` parameters can be used to test their parameter sets to stop a process.

- With Windows PowerShell started, run the `Stop-Proc` cmdlet with the `ProcessId` parameter set to stop a process based on its identifier. In this case, the cmdlet is using the `ProcessId` parameter set to stop the process.

```
PS> Stop-Proc -Id 444
Confirm
Are you sure you want to perform this action?
Performing operation "Stop-Proc" on Target "notepad (444)".
[Y] Yes [A] Yes to All [N] No [L] No to All [S] Suspend [?] Help
(default is "Y"): Y
```

- With Windows PowerShell started, run the `Stop-Proc` cmdlet with the `InputObject` parameter set to stop processes on the Notepad object retrieved by the `Get-Process` command.

```
PS> Get-Process notepad | Stop-Proc
Confirm
Are you sure you want to perform this action?
Performing operation "Stop-Proc" on Target "notepad (444)".
[Y] Yes [A] Yes to All [N] No [L] No to All [S] Suspend [?] Help
(default is "Y"): N
```

Creating a Cmdlet to Access a Data Store

Article • 09/17/2021

This section describes how to create a cmdlet that accesses stored data by way of a Windows PowerShell provider. This type of cmdlet uses the Windows PowerShell provider infrastructure of the Windows PowerShell runtime and, therefore, the cmdlet class must derive from the [System.Management.Automation.PSCmdlet](#) base class.

The Select-Str cmdlet described here can locate and select strings in a file or object. The patterns used to identify the string can be specified explicitly through the `Path` parameter of the cmdlet or implicitly through the `Script` parameter.

The cmdlet is designed to use any Windows PowerShell provider that derives from [System.Management.Automation.Provider.IContentCmdletProvider](#). For example, the cmdlet can specify the FileSystem provider or the Variable provider that is provided by Windows PowerShell. For more information about Windows PowerShell providers, see [Designing Your Windows PowerShell provider](#).

Defining the Cmdlet Class

The first step in cmdlet creation is always naming the cmdlet and declaring the .NET class that implements the cmdlet. This cmdlet detects certain strings, so the verb name chosen here is "Select", defined by the [System.Management.Automation.VerbsCommon](#) class. The noun name "Str" is used because the cmdlet acts upon strings. In the declaration below, note that the cmdlet verb and noun name are reflected in the name of the cmdlet class. For more information about approved cmdlet verbs, see [Cmdlet Verb Names](#).

The .NET class for this cmdlet must derive from the [System.Management.Automation.PSCmdlet](#) base class, because it provides the support needed by the Windows PowerShell runtime to expose the Windows PowerShell provider infrastructure. Note that this cmdlet also makes use of the .NET Framework regular expressions classes, such as [System.Text.RegularExpressions.Regex](#).

The following code is the class definition for this Select-Str cmdlet.

```
C#
```

```
[Cmdlet(VerbsCommon.Select, "Str",
DefaultParameterSetName="PatternParameterSet")]
```

```
public class SelectStringCommand : PSCmdlet
```

This cmdlet defines a default parameter set by adding the `DefaultParameterSetName` attribute keyword to the class declaration. The default parameter set `PatternParameterSet` is used when the `Script` parameter is not specified. For more information about this parameter set, see the `Pattern` and `Script` parameter discussion in the following section.

Defining Parameters for Data Access

This cmdlet defines several parameters that allow the user to access and examine stored data. These parameters include a `Path` parameter that indicates the location of the data store, a `Pattern` parameter that specifies the pattern to be used in the search, and several other parameters that support how the search is performed.

ⓘ Note

For more information about the basics of defining parameters, see [Adding Parameters that Process Command Line Input](#).

Declaring the Path Parameter

To locate the data store, this cmdlet must use a Windows PowerShell path to identify the Windows PowerShell provider that is designed to access the data store. Therefore, it defines a `Path` parameter of type string array to indicate the location of the provider.

C#

```
[Parameter(
    Position = 0,
    ParameterSetName = "ScriptParameterSet",
    Mandatory = true)]
[Parameter(
    Position = 0,
    ParameterSetName = "PatternParameterSet",
    ValueFromPipeline = true,
    Mandatory = true)]
    [Alias("PSPath")]
public string[] Path
{
    get { return paths; }
    set { paths = value; }
```

```
}
```

```
private string[] paths;
```

Note that this parameter belongs to two different parameter sets and that it has an alias.

Two [System.Management.Automation.ParameterAttribute](#) attributes declare that the `Path` parameter belongs to the `ScriptParameterSet` and the `PatternParameterSet`. For more information about parameter sets, see [Adding Parameter Sets to a Cmdlet](#).

The [System.Management.Automation.AliasAttribute](#) attribute declares a `PSPath` alias for the `Path` parameter. Declaring this alias is strongly recommended for consistency with other cmdlets that access Windows PowerShell providers. For more information about Windows PowerShell paths, see "PowerShell Path Concepts" in [How Windows PowerShell Works](#).

Declaring the Pattern Parameter

To specify the patterns to search for, this cmdlet declares a `Pattern` parameter that is an array of strings. A positive result is returned when any of the patterns are found in the data store. Note that these patterns can be compiled into an array of compiled regular expressions or an array of wildcard patterns used for literal searches.

```
C#
```

```
[Parameter(
    Position = 1,
    ParameterSetName = "PatternParameterSet",
    Mandatory = true)]
public string[] Pattern
{
    get { return patterns; }
    set { patterns = value; }
}
private string[] patterns;
private Regex[] regexPattern;
private WildcardPattern[] wildcardPattern;
```

When this parameter is specified, the cmdlet uses the default parameter set `PatternParameterSet`. In this case, the cmdlet uses the patterns specified here to select strings. In contrast, the `Script` parameter could also be used to provide a script that contains the patterns. The `Script` and `Pattern` parameters define two separate parameter sets, so they are mutually exclusive.

Declaring Search Support Parameters

This cmdlet defines the following support parameters that can be used to modify the search capabilities of the cmdlet.

The `Script` parameter specifies a script block that can be used to provide an alternate search mechanism for the cmdlet. The script must contain the patterns used for matching and return a `System.Management.Automation.PSObject` object. Note that this parameter is also the unique parameter that identifies the `ScriptParameterSet` parameter set. When the Windows PowerShell runtime sees this parameter, it uses only parameters that belong to the `ScriptParameterSet` parameter set.

```
C#  
  
[Parameter(  
    Position = 1,  
    ParameterSetName = "ScriptParameterSet",  
    Mandatory = true)]  
public ScriptBlock Script  
{  
    set { script = value; }  
    get { return script; }  
}  
ScriptBlock script;
```

The `SimpleMatch` parameter is a switch parameter that indicates whether the cmdlet is to explicitly match the patterns as they are supplied. When the user specifies the parameter at the command line (`true`), the cmdlet uses the patterns as they are supplied. If the parameter is not specified (`false`), the cmdlet uses regular expressions. The default for this parameter is `false`.

```
C#  
  
[Parameter]  
public SwitchParameter SimpleMatch  
{  
    get { return simpleMatch; }  
    set { simpleMatch = value; }  
}  
private bool simpleMatch;
```

The `CaseSensitive` parameter is a switch parameter that indicates whether a case-sensitive search is performed. When the user specifies the parameter at the command line (`true`), the cmdlet checks for the uppercase and lowercase of characters when comparing patterns. If the parameter is not specified (`false`), the cmdlet does not distinguish between uppercase and lowercase. For example "MyFile" and "myfile" would both be returned as positive hits. The default for this parameter is `false`.

C#

```
[Parameter]
public SwitchParameter CaseSensitive
{
    get { return caseSensitive; }
    set { caseSensitive = value; }
}
private bool caseSensitive;
```

The `Exclude` and `Include` parameters identify items that are explicitly excluded from or included in the search. By default, the cmdlet will search all items in the data store. However, to limit the search performed by the cmdlet, these parameters can be used to explicitly indicate items to be included in the search or omitted.

C#

```
[Parameter]
public SwitchParameter CaseSensitive
{
    get { return caseSensitive; }
    set { caseSensitive = value; }
}
private bool caseSensitive;
```

C#

```
[Parameter]
[ValidateNotNullOrEmpty]
public string[] Include
{
    get
    {
        return includeStrings;
    }
    set
    {
        includeStrings = value;

        this.include = new WildcardPattern[includeStrings.Length];
        for (int i = 0; i < includeStrings.Length; i++)
        {
            this.include[i] = new WildcardPattern(includeStrings[i],
WildcardOptions.IgnoreCase);
        }
    }
}
```

```
internal string[] includeStrings = null;
internal WildcardPattern[] include = null;
```

Declaring Parameter Sets

This cmdlet uses two parameter sets (`ScriptParameterSet` and `PatternParameterSet`, which is the default) as the names of two parameter sets used in data access.

`PatternParameterSet` is the default parameter set and is used when the `Pattern` parameter is specified. `ScriptParameterSet` is used when the user specifies an alternate search mechanism through the `Script` parameter. For more information about parameter sets, see [Adding Parameter Sets to a Cmdlet](#).

Overriding Input Processing Methods

Cmdlets must override one or more of the input processing methods for the `System.Management.Automation.PSCmdlet` class. For more information about the input processing methods, see [Creating Your First Cmdlet](#).

This cmdlet overrides the `System.Management.Automation.Cmdlet.BeginProcessing` method to build an array of compiled regular expressions at startup. This increases performance during searches that do not use simple matching.

C#

```
protected override void BeginProcessing()
{
    WriteDebug("Validating patterns.");
    if (patterns != null)
    {
        foreach(string pattern in patterns)
        {
            if (pattern == null)
                ThrowTerminatingError(new ErrorRecord(
                    new ArgumentNullException(
                        "Search pattern cannot be null."),
                    "NullSearchPattern",
                    ErrorCategory.InvalidArgument,
                    pattern));
        }
    }

    WriteVerbose("Search pattern(s) are valid.");

    // If a simple match is not specified, then
    // compile the regular expressions once.
    if (!simpleMatch)
```

```

{
    WriteDebug("Compiling search regular expressions.");

    RegexOptions regexOptions = RegexOptions.Compiled;
    if (!caseSensitive)
        regexOptions |= RegexOptions.Compiled;
    regexPattern = new Regex[patterns.Length];

    for (int i = 0; i < patterns.Length; i++)
    {
        try
        {
            regexPattern[i] = new Regex(patterns[i], regexOptions);
        }
        catch (ArgumentException ex)
        {
            ThrowTerminatingError(new ErrorRecord(
                ex,
                "InvalidRegularExpression",
                ErrorCategory.InvalidArgument,
                patterns[i]
            ));
        }
    }
} //Loop through patterns to create RegEx objects.

WriteVerbose("Pattern(s) compiled into regular expressions.");
}// If not a simple match.

// If a simple match is specified, then compile the
// wildcard patterns once.
else
{
    WriteDebug("Compiling search wildcards.");

    WildcardOptions wildcardOptions = WildcardOptions.Compiled;

    if (!caseSensitive)
    {
        wildcardOptions |= WildcardOptions.IgnoreCase;
    }

    wildcardPattern = new WildcardPattern[patterns.Length];
    for (int i = 0; i < patterns.Length; i++)
    {
        wildcardPattern[i] =
            new WildcardPattern(patterns[i], wildcardOptions);
    }

    WriteVerbose("Pattern(s) compiled into wildcard expressions.");
} // If match is a simple match.
}// If valid patterns are available.
}// End of function BeginProcessing().

```

This cmdlet also overrides the `System.Management.Automation.Cmdlet.ProcessRecord` method to process the string selections that the user makes on the command line. It writes the results of string selection in the form of a custom object by calling a private `MatchString` method.

```
C#  
  
protected override void ProcessRecord()  
{  
    UInt64 lineNumber = 0;  
    MatchInfo result;  
    ArrayList nonMatches = new ArrayList();  
  
    // Walk the list of paths and search the contents for  
    // any of the specified patterns.  
    foreach (string psPath in paths)  
    {  
        // Once the filepaths are expanded, we may have more than one  
        // path, so process all referenced paths.  
        foreach(PathInfo path in  
            SessionState.Path.GetResolvedPSPPathFromPSPPath(psPath)  
        )  
        {  
            WriteVerbose("Processing path " + path.Path);  
  
            // Check if the path represents one of the items to be  
            // excluded. If so, continue to next path.  
            if (!MeetsIncludeExcludeCriteria(path.ProviderPath))  
                continue;  
  
            // Get the content reader for the item(s) at the  
            // specified path.  
            Collection<IContentReader> readerCollection = null;  
            try  
            {  
                readerCollection =  
                    this.InvokeProvider.Content.GetReader(path.Path);  
            }  
            catch (PSNotSupportedException ex)  
            {  
                WriteError(new ErrorRecord(ex,  
                    "ContentAccessNotSupported",  
                    ErrorCategory.NotImplemented,  
                    path.Path)  
            );  
            return;  
        }  
  
        foreach(IContentReader reader in readerCollection)  
        {  
            // Reset the line number for this path.  
            lineNumber = 0;
```

```

// Read in a single block (line in case of a file)
// from the object.
IList items = reader.Read(1);

// Read and process one block(line) at a time until
// no more blocks(lines) exist.
while (items != null && items.Count == 1)
{
    // Increment the line number each time a line is
    // processed.
    lineNumber++;

    String message = String.Format("Testing line {0} : {1}",
                                    lineNumber, items[0]));

    WriteDebug(message);

    result = SelectString(items[0]);

    if (result != null)
    {
        result.Path = path.Path;
        result.LineNumber = lineNumber;

        WriteObject(result);
    }
    else
    {
        // Add the block(line) that did not match to the
        // collection of non matches , which will be stored
        // in the SessionState variable $NonMatches
        nonMatches.Add(items[0]);
    }

    // Get the next line from the object.
    items = reader.Read(1);

} // While loop for reading one line at a time.
}// Foreach loop for reader collection.
}// Foreach loop for processing referenced paths.
}// Foreach loop for walking of path list.

// Store the list of non-matches in the
// session state variable $NonMatches.
try
{
    this.SessionState.PSVariable.Set("NonMatches", nonMatches);
}
catch (SessionStateUnauthorizedAccessException ex)
{
    WriteError(new ErrorRecord(ex,
                               "CannotWriteVariableNonMatches",
                               ErrorCategory.InvalidOperation,
                               nonMatches));
}

```

```
}

} // End of protected override void ProcessRecord().
```

Accessing Content

Your cmdlet must open the provider indicated by the Windows PowerShell path so that it can access the data. The [System.Management.Automation.SessionState](#) object for the runspace is used for access to the provider, while the [System.Management.Automation.PSCmdlet.InvokeProvider*](#) property of the cmdlet is used to open the provider. Access to content is provided by retrieval of the [System.Management.Automation.ProviderIntrinsics](#) object for the provider opened.

This sample Select-Str cmdlet uses the [System.Management.Automation.ProviderIntrinsics.Content*](#) property to expose the content to scan. It can then call the [System.Management.Automation.ContentCmdletProviderIntrinsics.GetReader*](#) method, passing the required Windows PowerShell path.

Code Sample

The following code shows the implementation of this version of this Select-Str cmdlet. Note that this code includes the cmdlet class, private methods used by the cmdlet, and the Windows PowerShell snap-in code used to register the cmdlet. For more information about registering the cmdlet, see [Building the Cmdlet](#).

Building the Cmdlet

After implementing a cmdlet, you must register it with Windows PowerShell through a Windows PowerShell snap-in. For more information about registering cmdlets, see [How to Register Cmdlets, Providers, and Host Applications](#).

Testing the Cmdlet

When your cmdlet has been registered with Windows PowerShell, you can test it by running it on the command line. The following procedure can be used to test the sample Select-Str cmdlet.

1. Start Windows PowerShell, and search the Notes file for occurrences of lines with the expression ".NET". Note that the quotation marks around the name of the path are required only if the path consists of more than one word.

PowerShell

```
Select-Str -Path "notes" -Pattern ".NET" -SimpleMatch=$false
```

The following output appears.

Output

```
IgnoreCase      : True
LineNumber      : 8
Line            : Because Windows PowerShell works directly with .NET
objects, there is often a .NET object
Path            : C:\PowerShell-Progs\workspace\Samples\SelectStr\notes
Pattern         : .NET
IgnoreCase      : True
LineNumber      : 21
Line            : You should normally define the class for a cmdlet in a
.NET namespace
Path            : C:\PowerShell-Progs\workspace\Samples\SelectStr\notes
Pattern         : .NET
```

2. Search the Notes file for occurrences of lines with the word "over", followed by any other text. The `SimpleMatch` parameter is using the default value of `false`. The search is case-insensitive because the `CaseSensitive` parameter is set to `false`.

PowerShell

```
Select-Str -Path notes -Pattern "over*" -SimpleMatch -
CaseSensitive:$false
```

The following output appears.

Output

```
IgnoreCase      : True
LineNumber      : 45
Line            : Override StopProcessing
Path            : C:\PowerShell-Progs\workspace\Samples\SelectStr\notes
Pattern         : over*
IgnoreCase      : True
LineNumber      : 49
Line            : overriding the StopProcessing method
Path            : C:\PowerShell-Progs\workspace\Samples\SelectStr\notes
Pattern         : over*
```

3. Search the Notes file using a regular expression as the pattern. The cmdlet searches for alphabetical characters and blank spaces enclosed in parentheses.

PowerShell

```
Select-Str -Path notes -Pattern "\([A-Za-z:blank:]" -SimpleMatch:$false
```

The following output appears.

Output

```
IgnoreCase      : True
LineNumber     : 1
Line           : Advisory Guidelines (Consider Following)
Path           : C:\PowerShell-Progs\workspace\Samples\SelectStr\notes
Pattern        : \([A-Za-z:blank:]
IgnoreCase      : True
LineNumber     : 53
Line           : If your cmdlet has objects that are not disposed of
(written to the pipeline)
Path           : C:\PowerShell-Progs\workspace\Samples\SelectStr\notes
Pattern        : \([A-Za-z:blank:]
```

4. Perform a case-sensitive search of the Notes file for occurrences of the word "Parameter".

PowerShell

```
Select-Str -Path notes -Pattern Parameter -CaseSensitive
```

The following output appears.

Output

```
IgnoreCase      : False
LineNumber     : 6
Line           : Support an InputObject Parameter
Path           : C:\PowerShell-Progs\workspace\Samples\SelectStr\notes
Pattern        : Parameter
IgnoreCase      : False
LineNumber     : 30
Line           : Support Force Parameter
Path           : C:\PowerShell-Progs\workspace\Samples\SelectStr\notes
Pattern        : Parameter
```

5. Search the Variable provider shipped with Windows PowerShell for variables that have numerical values from 0 through 9.

PowerShell

```
Select-Str -Path * -Pattern "[0-9]"
```

The following output appears.

Output

```
IgnoreCase      : True
LineNumber      : 1
Line            : 64
Path            : Variable:\MaximumHistoryCount
Pattern         : [0-9]
```

6. Use a script block to search the file `SelectStrCommandSample.cs` for the string "Pos". The `-cmatch` operator performs a case-insensitive pattern match.

PowerShell

```
Select-Str -Path "SelectStrCommandSample.cs" -Script { if ($args[0] -cmatch "Pos"){ return $true } return $false }
```

The following output appears.

Output

```
IgnoreCase      : True
LineNumber      : 37
Line            : Position = 0.
Path            : C:\PowerShell-
Progs\workspace\Samples\SelectStr\SelectStrCommandSample.cs
Pattern         :
```

Cmdlet Samples

Article • 09/15/2023

This section describes sample code that is provided in the Windows PowerShell 2.0 SDK.

In This Section

- [GetProcessSample01 Sample](#): This sample shows how to write a cmdlet that retrieves the processes on the local computer.
- [GetProcessSample02 Sample](#): This sample shows how to write a cmdlet that retrieves the processes on the local computer. It provides a Name parameter that can be used to specify the processes to be retrieved.
- [GetProcessSample03 Sample](#): This sample shows how to write a cmdlet that retrieves the processes on the local computer. It provides a Name parameter that can accept an object from the pipeline or a value from a property of an object whose property name is the same as the parameter name.
- [GetProcessSample04 Sample](#): This sample shows how to write a cmdlet that retrieves the processes on the local computer. It generates a non-terminating error if an error occurs while retrieving a process.
- [GetProcessSample05 Sample](#): This sample shows a complete version of the Get-Proc cmdlet.
- [StopProcessSample01 Sample](#): This sample shows how to write a cmdlet that requests feedback from the user before it attempts to stop a process, and how to implement a `PassThru` parameter that indicates that the user wants the cmdlet to return an object.
- [StopProcessSample02 Sample](#): This sample shows how to write a cmdlet that writes debug, verbose, and warning messages while stopping processes on the local computer.
- [StopProcessSample03 Sample](#): This sample shows how to write a cmdlet whose parameters have aliases and that support wildcard characters.
- [StopProcessSample04 Sample](#): This sample shows how to write a cmdlet that declares parameter sets, specifies the default parameter set, and can accept an input object.

- **Events01 Sample:** This sample shows how to create a cmdlet that allows the user to register for events raised by `System.IO.FileSystemWatcher`. With this cmdlet users can, for example, register an action to execute when a file is created under a specific directory. This sample derives from the `Microsoft.PowerShell.Commands.ObjectEventRegistrationBase` base class.

GetProcessSample01 Sample

Article • 04/10/2024

This sample shows how to implement a cmdlet that retrieves the processes on the local computer. This cmdlet is a simplified version of the `Get-Process` cmdlet that is provided by Windows PowerShell 2.0.

How to build the sample by using Visual Studio

1. With the Windows PowerShell 2.0 SDK installed, navigate to the GetProcessSample01 folder. The default location is `C:\Program Files (x86)\Microsoft SDKs\Windows\v7.0\Samples\sysmgmt\WindowsPowerShell\csharp\GetProcessSample01`.
2. Double-click the icon for the solution (.sln) file. This opens the sample project in Microsoft Visual Studio.
3. In the **Build** menu, select **Build Solution** to build the library for the sample in the default `\bin` or `\bin\debug` folders.

How to run the sample

1. Open a Command Prompt window.
2. Navigate to the directory containing the sample .dll file.
3. Run `installutil "GetProcessSample01.dll"`.
4. Start Windows PowerShell.
5. Run the following command to add the snap-in to the shell.

```
Add-PSSnapin GetProcPSSnapIn01
```

6. Enter the following command to run the cmdlet. `Get-Proc`

```
Get-Proc
```

This is a sample output that results from following these steps.

```
Output
```

Id	Name	State	HasMoreData	Location
--	-----	-----	-----	-----

1	26932870-d3b...	NotStarted	False	

```
Write-Host "A f..."
```

PowerShell

```
Set-Content $Env:TEMP\test.txt "This is a test file"
```

Output

```
A file was created in the TEMP directory
```

Requirements

This sample requires Windows PowerShell 1.0 or later.

Demonstrates

This sample demonstrates the following.

- Creating a basic sample cmdlet.
- Defining a cmdlet class by using the Cmdlet attribute.
- Creating a snap-in that works with both Windows PowerShell 1.0 and Windows PowerShell 2.0. Subsequent samples use modules instead of snap-ins so they require Windows PowerShell 2.0.

Example

This sample shows how to create a simple cmdlet and its snap-in.

C#

```
using System;
using System.Diagnostics;
using System.Management.Automation;           //Windows PowerShell
namespace
using System.ComponentModel;
```

```
namespace Microsoft.Samples.PowerShell.Commands

GetProcessSample02 Sample

Article • 09/15/2023

This sample shows how to write a cmdlet that retrieves the processes on the local computer. It provides a `Name` parameter that can be used to specify the processes to be retrieved. This cmdlet is a simplified version of the `Get-Process` cmdlet provided by Windows PowerShell 2.0.

How to build the sample using Visual Studio

1. With the Windows PowerShell 2.0 SDK installed, navigate to the GetProcessSample02 folder. The default location is `C:\Program Files (x86)\Microsoft SDKs\Windows\v7.0\Samples\sysmgmt\WindowsPowerShell\csharp\GetProcessSample02.`
2. Double-click the icon for the solution (.sln) file. This opens the sample project in Visual Studio.
3. In the **Build** menu, select **Build Solution** to build the library for the sample in the default `\bin` or `\bin\debug` folders.

How to run the sample

1. Create the following module folder:
`[user]\Documents\WindowsPowerShell\Modules\GetProcessSample02`
2. Copy the sample assembly to the module folder.
3. Start Windows PowerShell.
4. Run the following command to load the assembly into Windows PowerShell:
`Import-Module getprocesssample02`
5. Run the following command to run the cmdlet:
`Get-Proc`

Requirements

This sample requires Windows PowerShell 2.0.

Demonstrates

This sample demonstrates the following.

- Declaring a cmdlet class using the Cmdlet attribute.
- Declaring a cmdlet parameter using the Parameter attribute.
- Specifying the position of the parameter.
- Declaring a validation attribute for the parameter input.

Example

This sample shows an implementation of the Get-Proc cmdlet that includes a `Name` parameter.

C#

```
namespace Microsoft.Samples.PowerShell.Commands
{
    using System;
    using System.Diagnostics;
    using System.Management.Automation; // Windows PowerShell namespace

    #region GetProcCommand

    /// <summary>
    /// This class implements the Get-Proc cmdlet.
    /// </summary>
    [Cmdlet(VerbsCommon.Get, "Proc")]
    public class GetProcCommand : Cmdlet
    {
        #region Parameters

        /// <summary>
        /// The names of the processes retrieved by the cmdlet.
        /// </summary>
        private string[] processNames;

        /// <summary>
        /// Gets or sets the list of process names on which
        /// the Get-Proc cmdlet will work.
        /// </summary>
        [Parameter(Position = 0)]
        [ValidateNotNullOrEmpty]
        public string[] Name
```

```

{
    get { return this.processNames; }
    set { this.processNames = value; }
}

#endregion Parameters

#region Cmdlet Overrides

/// <summary>
/// The ProcessRecord method calls the Process.GetProcesses
/// method to retrieve the processes specified by the Name
/// parameter. Then, the WriteObject method writes the
/// associated process objects to the pipeline.
/// </summary>
protected override void ProcessRecord()
{
    // If no process names are passed to the cmdlet, get all
    // processes.
    if (this.processNames == null)
    {
        WriteObject(Process.GetProcesses(), true);
    }
    else
    {
        // If process names are passed to cmdlet, get and write
        // the associated processes.
        foreach (string name in this.processNames)
        {
            WriteObject(Process.GetProcessesByName(name), true);
        }
    } // End if (processNames...).
} // End ProcessRecord.
#endregion Cmdlet Overrides
} // End GetProcCommand class.
#endregion GetProcCommand
}

GetProcessSample03 Sample

Article • 03/24/2025

This sample shows how to implement a cmdlet that retrieves the processes on the local computer. It provides a `Name` parameter that can accept an object from the pipeline or a value from a property of an object whose property name is the same as the parameter name. This cmdlet is a simplified version of the `Get-Process` cmdlet provided by Windows PowerShell 2.0.

How to build the sample using Visual Studio

1. With the Windows PowerShell 2.0 SDK installed, navigate to the GetProcessSample03 folder. The default location is `C:\Program Files (x86)\Microsoft SDKs\Windows\v7.0\Samples\sysmgmt\WindowsPowerShell\csharp\GetProcessSample03`.
2. Double-click the icon for the solution (.sln) file. This opens the sample project in Visual Studio.
3. In the **Build** menu, select **Build Solution** to build the library for the sample in the default `\bin` or `\bin\debug` folders.

How to run the sample

1. Create the following module folder:
`[user]\Documents\WindowsPowerShell\Modules\GetProcessSample03`
2. Copy the sample assembly to the module folder.
3. Start Windows PowerShell.
4. Run the following command to load the assembly into Windows PowerShell:
`Import-Module getprocesssample03`
5. Run the following command to run the cmdlet:
`Get-Proc`

Requirements

This sample requires Windows PowerShell 2.0.

Demonstrates

This sample demonstrates the following.

- Declaring a cmdlet class using the Cmdlet attribute.
- Declaring a cmdlet parameter using the Parameter attribute.
- Specifying the position of the parameter.
- Specifying that the parameter takes input from the pipeline. The input can be taken from an object or a value from a property of an object whose property name is the same as the parameter name.
- Declaring a validation attribute for the parameter input.

Example

This sample shows an implementation of the Get-Proc cmdlet that includes a `Name` parameter that accepts input from the pipeline.

C#

```
namespace Microsoft.Samples.PowerShell.Commands
{
    using System;
    using System.Diagnostics;
    using System.Management.Automation; // Windows PowerShell
    namespace
        #region GetProcCommand

        /// <summary>
        /// This class implements the Get-Proc cmdlet.
        /// </summary>
        [Cmdlet(VerbsCommon.Get, "Proc")]
        public class GetProcCommand : Cmdlet
        {
            #region Parameters

            /// <summary>
            /// The names of the processes retrieved by the cmdlet.
            /// </summary>
            private string[] processNames;

            /// <summary>
            /// Gets or sets the names of the
        }
}
```

```

/// process that the cmdlet will retrieve.
/// </summary>
[Parameter(
    Position = 0,
    ValueFromPipeline = true,
    ValueFromPipelineByPropertyName = true)]
[ValidateNotNullOrEmpty]
public string[] Name
{
    get { return this.processNames; }
    set { this.processNames = value; }
}

#endregion Parameters

#region Cmdlet Overrides

/// <summary>
/// The ProcessRecord method calls the Process.GetProcesses
/// method to retrieve the processes specified by the Name
/// parameter. Then, the WriteObject method writes the
/// associated processes to the pipeline.
/// </summary>
protected override void ProcessRecord()
{
    // If no process names are passed to the cmdlet, get all
    // processes.
    if (this.processNames == null)
    {
        WriteObject(Process.GetProcesses(), true);
    }
    else
    {
        // If process names are passed to the cmdlet, get and write
        // the associated processes.
        foreach (string name in this.processNames)
        {
            WriteObject(Process.GetProcessesByName(name), true);
        }
    } // End if (processNames ...)
} // End ProcessRecord.

GetProcessSample04 Sample

Article • 03/24/2025

This sample shows how to implement a cmdlet that retrieves the processes on the local computer. It generates a non-terminating error if an error occurs while retrieving a process. This cmdlet is a simplified version of the `Get-Process` cmdlet provided by Windows PowerShell 2.0.

How to build the sample using Visual Studio

1. With the Windows PowerShell 2.0 SDK installed, navigate to the GetProcessSample04 folder. The default location is `C:\Program Files (x86)\Microsoft SDKs\Windows\v7.0\Samples\sysmgmt\WindowsPowerShell\csharp\GetProcessSample04`.
2. Double-click the icon for the solution (.sln) file. This opens the sample project in Visual Studio.
3. In the **Build** menu, select **Build Solution** to build the library for the sample in the default `\bin` or `\bin\debug` folders.

How to run the sample

1. Create the following module folder:

```
[user]\Documents\WindowsPowerShell\Modules\GetProcessSample04
```

2. Copy the sample assembly to the module folder.
3. Start Windows PowerShell.
4. Run the following command to load the assembly into Windows PowerShell:

```
Import-Module getprocesssample04
```

5. Run the following command to run the cmdlet:

```
Get-Proc
```

Requirements

This sample requires Windows PowerShell 2.0.

Demonstrates

This sample demonstrates the following.

- Declaring a cmdlet class using the Cmdlet attribute.
- Declaring a cmdlet parameter using the Parameter attribute.
- Specifying the position of the parameter.
- Specifying that the parameter takes input from the pipeline. The input can be taken from an object or a value from a property of an object whose property name is the same as the parameter name.
- Declaring a validation attribute for the parameter input.
- Trapping a non-terminating error and writing an error message to the error stream.

Example

This sample shows how to create a cmdlet that handles non-terminating errors and writes error messages to the error stream.

C#

```
namespace Microsoft.Samples.PowerShell.Commands
{
    using System;
    using System.Diagnostics;
    using System.Management.Automation;      // Windows PowerShell
namespace.
    #region GetProcCommand

    /// <summary>
    /// This class implements the Get-Proc cmdlet.
    /// </summary>
    [Cmdlet(VerbsCommon.Get, "Proc")]
    public class GetProcCommand : Cmdlet
    {
        #region Parameters

        /// <summary>
        /// The names of the processes to act on.
        /// </summary>
        private string[] processNames;

        /// <summary>
        /// Gets or sets the list of process names on
        /// which the Get-Proc cmdlet will work.
    }
}
```

```

/// </summary>
[Parameter(
    Position = 0,
    ValueFromPipeline = true,
    ValueFromPipelineByPropertyName = true)]
[ValidateNotNullOrEmpty]
public string[] Name
{
    get { return this.processNames; }
    set { this.processNames = value; }
}

#endregion Parameters

#region Cmdlet Overrides

/// <summary>
/// The ProcessRecord method calls the Process.GetProcesses
/// method to retrieve the processes specified by the Name
/// parameter. Then, the WriteObject method writes the
/// associated processes to the pipeline.
/// </summary>
protected override void ProcessRecord()
{
    // If no process names are passed to cmdlet, get all
    // processes.
    if (this.processNames == null)
    {
        WriteObject(Process.GetProcesses(), true);
    }
    else
    {
        // If process names are passed to the cmdlet, get and write
        // the associated processes.
        // If a non-terminating error occurs while retrieving
processes,
        // call the WriteError method to send an error record to the
        // error stream.
        foreach (string name in this.processNames)
        {
            Process[] processes;

            try
            {
                processes = Process.GetProcessesByName(name);
            }
            catch (InvalidOperationException ex)
            {
                WriteError(new ErrorRecord(
                    ex,
                    "UnableToAccessProcessByName",
                    ErrorCategory.InvalidOperation,
                    name));
                continue;
            }
        }
    }
}

```

```
        WriteObject(processes, true);
    } // foreach (string name...
} // else
} // ProcessRecord

#endregion Overrides
} // End GetProcCommand class.

#endregion GetProcCommand
}

GetProcessSample05 Sample

Article • 09/15/2023

This sample shows a complete version of the Get-Proc cmdlet.

How to build the sample using Visual Studio.

1. Open Windows Explorer and navigate to the GetProcessSample05 directory under the Samples directory.

With the Windows PowerShell 2.0 SDK installed, navigate to the GetProcessSample05 folder. The default location is `C:\Program Files (x86)\Microsoft SDKs\Windows\v7.0\Samples\sysmgmt\WindowsPowerShell\csharp\GetProcessSample05`.

2. Double-click the icon for the solution (.sln) file. This opens the sample project in Visual Studio.
3. In the **Build** menu, select **Build Solution** to build the library for the sample in the default `\bin` or `\bin\debug` folders.

How to run the sample

1. Create the following module folder:

```
[user]\Documents\WindowsPowerShell\Modules\GetProcessSample05
```

2. Copy the sample assembly to the module folder.
3. Start Windows PowerShell.
4. Run the following command to load the assembly into Windows PowerShell:

```
Import-Module getprocesssample05
```

5. Run the following command to run the cmdlet:

```
Get-Proc
```

Requirements

This sample requires Windows PowerShell 2.0.

Demonstrates

This sample demonstrates the following.

- Declaring a cmdlet class using the Cmdlet attribute.
- Declaring a cmdlet parameter using the Parameter attribute.
- Specifying positions for parameters.
- Specifying that parameters can take input from the pipeline. The input can be taken from an object or a value from a property of an object whose property name is the same as the parameter name.
- Declaring a validation attribute for the parameter input.
- Handling errors and exceptions.
- Writing debug messages.

Example

This sample shows how to create a cmdlet that displays a list of specified processes.

C#

```
namespace Microsoft.Samples.PowerShell.Commands
{
    using System;
    using System.Collections.Generic;
    using System.Diagnostics;
    using System.Management.Automation;      // Windows PowerShell namespace.
    using System.Security.Permissions;
    using Win32Exception = System.ComponentModel.Win32Exception;
    #region GetProcCommand

        /// <summary>
        /// This class implements the Get-Proc cmdlet.
        /// </summary>

StopProcessSample01 Sample

Article • 09/15/2023

This sample shows how to write a cmdlet that requests feedback from the user before it attempts to stop a process, and how to implement a `PassThru` parameter indicating that the user wants the cmdlet to return an object. This cmdlet is similar to the `Stop-Process` cmdlet provided by Windows PowerShell 2.0.

How to build the sample by using Visual Studio

1. With the Windows PowerShell 2.0 SDK installed, navigate to the StopProcessSample01 folder. The default location is `C:\Program Files (x86)\Microsoft SDKs\Windows\v7.0\Samples\sysmgmt\WindowsPowerShell\csharp\StopProcessSample01`.
2. Double-click the icon for the solution (.sln) file. This opens the sample project in Microsoft Visual Studio.
3. In the **Build** menu, select **Build Solution** to build the library for the sample in the default `\bin` or `\bin\debug` folders.

How to run the sample

1. Create the following module folder:
`[user]\Documents\WindowsPowerShell\Modules\StopProcessSample01`
2. Copy the sample assembly to the module folder.
3. Start Windows PowerShell.
4. Run the following command to load the assembly into Windows PowerShell:
`Import-Module stopprocesssample01`
5. Run the following command to run the cmdlet:
`Stop-Proc`

Requirements

This sample requires Windows PowerShell 2.0.

Demonstrates

This sample demonstrates the following.

- Declaring a cmdlet class by using the `Cmdlet` attribute.
- Declaring a cmdlet parameters by using the `Parameter` attribute.
- Calling the `ShouldProcess` method to request confirmation.
- Implementing a `PassThru` parameter that indicates if the user wants the cmdlet to return an object. By default, this cmdlet does not return an object to the pipeline.

Example

This sample shows how to implement a `PassThru` parameter that indicates that the user wants the cmdlet to return an object, and how to request user feedback by calls to the `ShouldProcess` and `ShouldContinue` methods.

C#

```
using System;
using System.Diagnostics;
using System.Collections;
using Win32Exception = System.ComponentModel.Win32Exception;
using System.Management.Automation;    // Windows PowerShell namespace
using System.Globalization;

namespace Microsoft.Samples.PowerShell.Commands
{
    #region StopProcCommand

        /// <summary>
        /// This class implements the Stop-Proc cmdlet.
        /// </summary>
        [Cmdlet(VerbsLifecycle.Stop, "Proc",
            SupportsShouldProcess = true)]
        public class StopProcCommand : Cmdlet
    {
        #region Parameters

            /// <summary>
            /// This parameter provides the list of process names on
            /// which the Stop-Proc cmdlet will work.
            /// </summary>
            [Parameter(
```

```

StopProcessSample02 Sample

Article • 09/15/2023

This sample shows how to write a cmdlet that writes debug (WriteDebug), verbose (WriteVerbose), and warning (WriteWarning) messages while stopping processes on the local computer. This cmdlet is similar to the `Stop-Process` cmdlet provided by Windows PowerShell 2.0.

How to build the sample by using Visual Studio

1. Open Windows Internet Explorer and navigate to the StopProcessSample02 directory under the Samples directory.

With the Windows PowerShell 2.0 SDK installed, navigate to the StopProcessSample02 folder. The default location is `C:\Program Files (x86)\Microsoft SDKs\Windows\v7.0\Samples\sysmgmt\WindowsPowerShell\csharp\StopProcessSample02`.

2. Double-click the icon for the solution (.sln) file. This opens the sample project in Microsoft Visual Studio.
3. In the **Build** menu, select **Build Solution** to build the library for the sample in the default `\bin` or `\bin\debug` folders.

How to run the sample

1. Create the following module folder:

```
[user]\Documents\WindowsPowerShell\Modules\StopProcessSample02
```

2. Copy the sample assembly to the module folder.
3. Start Windows PowerShell.
4. Run the following command to load the assembly into Windows PowerShell:

```
Import-Module stopprocesssample02
```

5. Run the following command to run the cmdlet:

```
Stop-Proc
```

Requirements

This sample requires Windows PowerShell 2.0.

Demonstrates

This sample demonstrates the following.

- Declaring a cmdlet class by using the `Cmdlet` attribute.
- Declaring a cmdlet parameters by using the `Parameter` attribute.
- Writing verbose messages. For more information about the method used to write verbose messages, see [System.Management.Automation.Cmdlet.WriteVerbose](#).
- Writing error messages. For more information about the method used to write error messages, see [System.Management.Automation.Cmdlet.WriteError](#).
- Writing warning messages. For more information about the method used to write warning messages, see [System.Management.Automation.Cmdlet.WriteWarning](#).

Example

This sample shows how to write debug, verbose, and warning messages by using the `WriteDebug`, `WriteVerbose`, and `WriteWarning` methods.

C#

```
using System;
using System.Diagnostics;
using System.Collections;
using Win32Exception = System.ComponentModel.Win32Exception;
using System.Management.Automation; //Windows PowerShell
namespace
using System.Globalization;

StopProcessSample03 Sample

Article • 09/15/2023

This sample shows how to write a cmdlet whose parameters have aliases and whose parameters support wildcard characters. This cmdlet is similar to the `Stop-Process` cmdlet provided by Windows PowerShell 2.0.

How to build the sample by using Visual Studio

1. With the Windows PowerShell 2.0 SDK installed, navigate to the StopProcessSample03 folder. The default location is `C:\Program Files (x86)\Microsoft SDKs\Windows\v7.0\Samples\sysmgmt\WindowsPowerShell\csharp\StopProcessSample03`.
2. Double-click the icon for the solution (.sln) file. This opens the sample project in Microsoft Visual Studio.
3. In the **Build** menu, select **Build Solution** to build the library for the sample in the default `\bin` or `\bin\debug` folders.

How to run the sample

1. Create the following module folder:
`[user]\Documents\WindowsPowerShell\Modules\StopProcessSample03`
2. Copy the sample assembly to the module folder.
3. Start Windows PowerShell.
4. Run the following command to load the assembly into Windows PowerShell:

```
Import-Module stopprocesssample03
```

5. Run the following command to run the cmdlet:

```
Stop-Proc
```

Requirements

This sample requires Windows PowerShell 2.0.

Demonstrates

This sample demonstrates the following.

- Declaring a cmdlet class by using the Cmdlet attribute.
- Declaring a cmdlet parameters by using the Parameter attribute.
- Adding aliases to parameter declarations..
- Adding wildcard support to parameters.

Example

This sample shows how to declare parameter aliases and support wildcards.

C#

```
using System;
using System.Diagnostics;
using System.Collections;
using Win32Exception = System.ComponentModel.Win32Exception;
using System.Management.Automation; //Windows PowerShell
namespace
using System.Globalization;

namespace Microsoft.Samples.PowerShell.Commands
{

    #region StopProcCommand

        /// <summary>
        /// This class implements the Stop-Proc cmdlet.
        /// </summary>
        [Cmdlet(VerbsLifecycle.Stop, "Proc",
            SupportsShouldProcess = true)]
        public class StopProcCommand : Cmdlet
    {
        #region Parameters

            /// <summary>
            /// This parameter provides the list of process names on
            /// which the Stop-Proc cmdlet will work.
            /// </summary>
            [Parameter(
                Position = 0,
                Mandatory = true,
                ValueFromPipeline = true,
```

```

        ValueFromPipelineByPropertyName = true,
        HelpMessage = "The name of one or more processes to stop.
Wildcards are permitted."
    )]
[Alias("ProcessName")]
public string[] Name
{
    get { return processNames; }
    set { processNames = value; }
}
private string[] processNames;

/// <summary>
/// This parameter overrides the ShouldContinue call to force
/// the cmdlet to stop its operation. This parameter should always
/// be used with caution.
/// </summary>
[Parameter]
public SwitchParameter Force
{
    get { return force; }

StopProcessSample04 Sample

Article • 09/15/2023

This sample shows how to write a cmdlet that declares parameter sets, specifies the default parameter set, and can accept an input object. This cmdlet is similar to the `Stop-Process` cmdlet provided by Windows PowerShell 2.0.

How to build the sample by using Visual Studio

1. With the Windows PowerShell 2.0 SDK installed, navigate to the StopProcessSample04 folder. The default location is `C:\Program Files (x86)\Microsoft SDKs\Windows\v7.0\Samples\sysmgmt\WindowsPowerShell\csharp\StopProcessSample04`.
2. Double-click the icon for the solution (.sln) file. This opens the sample project in Microsoft Visual Studio.
3. In the **Build** menu, select **Build Solution** to build the library for the sample in the default `\bin` or `\bin\debug` folders.

How to run the sample

1. Create the following module folder:
`[user]\Documents\WindowsPowerShell\Modules\StopProcessSample04`
2. Copy the sample assembly to the module folder.
3. Start Windows PowerShell.
4. Run the following command to load the assembly into Windows PowerShell:

```
Import-Module stopprocesssample04
```

5. Run the following command to run the cmdlet:

```
Stop-Proc
```

Requirements

This sample requires Windows PowerShell 2.0.

Demonstrates

This sample demonstrates the following.

- Declaring a cmdlet class by using the Cmdlet attribute.
- Declaring a cmdlet parameters by using the Parameter attribute.
- Adding a parameter that accepts input object.
- Adding parameters to parameter sets
- Specifying the default parameter set.

Example

The following code shows an implementation of the Stop-Proc cmdlet that declare parameter sets, specifies the default parameter set, and can accept an input object.

This sample shows the input object, how to declare parameter sets, and how to specify the default parameter set to use.

C#

```
using System;
using System.Diagnostics;
using System.Collections;
using Win32Exception = System.ComponentModel.Win32Exception;
using System.Management.Automation; //Windows PowerShell
namespace
using System.Globalization;

namespace Microsoft.Samples.PowerShell.Commands
{
    #region StopProcCommand

    /// <summary>
    /// This class implements the Stop-Proc cmdlet.
    /// </summary>
    [Cmdlet(VerbsLifecycle.Stop, "Proc",
        DefaultParameterSetName = "ProcessId",
        SupportsShouldProcess = true)]
    public class StopProcCommand : PSCmdlet
    {
        #region Parameters
```

```

/// <summary>
/// This parameter provides the list of process names on
/// which the Stop-Proc cmdlet will work.
/// </summary>
[Parameter(
    Position = 0,
    ParameterSetName = "ProcessName",
    Mandatory = true,
    ValueFromPipeline = true,
    ValueFromPipelineByPropertyName = true,
    HelpMessage = "The name of one or more processes to stop.
Wildcards are permitted."
)]

Events01 Sample

Article • 09/15/2023

This sample shows how to create a cmdlet that allows the user to register for events that are raised by [System.IO.FileSystemWatcher](#). With this cmdlet, users can register an action to execute when a file is created under a specific directory. This sample derives from the [Microsoft.PowerShell.Commands.ObjectEventRegistrationBase](#) base class.

How to build the sample by using Visual Studio

1. With the Windows PowerShell 2.0 SDK installed, navigate to the Events01 folder.
The default location is `C:\Program Files (x86)\Microsoft
SDKs\Windows\v7.0\Samples\sysmgmt\WindowsPowerShell\csharp\Events01`.
2. Double-click the icon for the solution (.sln) file. This opens the sample project in Microsoft Visual Studio.
3. In the **Build** menu, select **Build Solution** to build the library for the sample in the default `\bin` or `\bin\debug` folders.

How to run the sample

1. Create the following module folder:
`[user]\Documents\WindowsPowerShell\Modules\events01`
2. Copy the library file for the sample to the module folder.
3. Start Windows PowerShell.
4. Run the following command to load the cmdlet into Windows PowerShell:

```
PowerShell  
  
Import-Module events01
```

5. Use the Register-FileSystemEvent cmdlet to register an action that will write a message when a file is created under the TEMP directory.

```
PowerShell
```

```
Register-FileSystemEvent $Env:TEMP Created -Filter "*.txt" -Action {  
    Write-Host "A file was created in the TEMP directory" }
```

6. Create a file under the TEMP directory and note that the action is executed (the message is displayed).

This is a sample output that results by following these steps.

Output				
Id	Name	State	HasMoreData	Location
Command				
--	-----	-----	-----	-----

1	26932870-d3b...	NotStarted	False	
Write-Host "A f...				

PowerShell	
<pre>Set-Content \$Env:TEMP\test.txt "This is a test file"</pre>	
Output	
A file was created in the TEMP directory	

Requirements

This sample requires Windows PowerShell 2.0.

Demonstrates

This sample demonstrates the following.

How to write a cmdlet for event registration

The cmdlet derives from the

[Microsoft.PowerShell.Commands.ObjectEventRegistrationBase](#) class, which provides support for parameters common to the `Register-*Event` cmdlets. Cmdlets that are derived from [Microsoft.PowerShell.Commands.ObjectEventRegistrationBase](#) need only

to define their particular parameters and override the `GetSourceObject` and `GetSourceObjectEventName` abstract methods.

Example

This sample shows how to register for events raised by `System.IO.FileSystemWatcher`.

C#

```
namespace Sample
{
    using System;
    using System.IO;
    using System.Management.Automation;
    using System.Management.Automation.Runspaces;
    using Microsoft.PowerShell.Commands;

    [Cmdlet(VerbsLifecycle.Register, "FileSystemEvent")]
    public class RegisterObjectEventCommand : ObjectEventRegistrationBase
    {

Writing a Windows PowerShell Module

Article • 09/17/2021

This document is written for administrators, script developers, and cmdlet developers who need to package and distribute their Windows PowerShell cmdlets. By using Windows PowerShell modules, you can package and distribute your Windows PowerShell solutions without using a compiled language.

Windows PowerShell modules enable you to partition, organize, and abstract your Windows PowerShell code into self-contained, reusable units. With these reusable units, you can easily share your modules directly with others. If you are a script developer, you can also repackage third-party modules to create custom script-based applications. Modules, similar to modules in other scripting languages such as Perl and Python, enable production-ready scripting solutions that use reusable, redistributable components, with the added benefit of enabling you to repackage and abstract multiple components to create custom solutions.

At their most basic, Windows PowerShell will treat any valid Windows PowerShell script code saved in a `.psm1` file as a module. PowerShell will also automatically treat any binary cmdlet assembly as a module. However, you can also use a module (or more specifically, a module manifest) to bundle an entire solution together. The following scenarios describe typical uses for Windows PowerShell modules.

Libraries

Modules can be used to package and distribute cohesive libraries of functions that perform common tasks. Typically, the names of these functions share one or more nouns that reflect the common task that they are used for. These functions can also be similar to .NET Framework classes in that they can have public and private members. For example, a library can contain a set of functions for file transfers. In this case, the noun reflecting the common task might be "file."

Configuration

Modules can be used to customize your environment by adding specific cmdlets, providers, functions, and variables.

Compiled Code Development and Distribution

Cmdlet and provider developers can use modules to test and distribute their compiled code without needing to create snap-ins. They can import the assembly that contains the compiled code as a module (a binary module) without needing to create and register snap-ins.

Understanding a Windows PowerShell Module

Article • 09/17/2021

A *module* is a set of related Windows PowerShell functionalities, grouped together as a convenient unit (usually saved in a single directory). By defining a set of related script files, assemblies, and related resources as a module, you can reference, load, persist, and share your code much easier than you would otherwise.

The main purpose of a module is to allow the modularization (ie, reuse and abstraction) of Windows PowerShell code. For example, the most basic way of creating a module is to simply save a Windows PowerShell script as a `.psm1` file. Doing so allows you to control (ie, make public or private) the functions and variables contained in the script. Saving the script as a `.psm1` file also allows you to control the scope of certain variables. Finally, you can also use cmdlets such as [Install-Module](#) to organize, install, and use your script as building blocks for larger solutions.

Module Components and Types

A module is made up of four basic components:

1. Some sort of code file - usually either a PowerShell script or a managed cmdlet assembly.
2. Anything else that the above code file may need, such as additional assemblies, help files, or scripts.
3. A manifest file that describes the above files, as well as stores metadata such as author and versioning information.
4. A directory that contains all of the above content, and is located where PowerShell can reasonably find it.

ⓘ Note

None of these components, by themselves, are actually necessary. For example, a module can technically be only a script stored in a `.psm1` file. You can also have a module that is nothing but a manifest file, which is used mainly for organizational purposes. You can also write a script that dynamically creates a module, and as such doesn't actually need a directory to

store anything in. The following sections describe the types of modules you can get by mixing and matching the different possible parts of a module together.

Script Modules

As the name implies, a *script module* is a file (`.psm1`) that contains any valid Windows PowerShell code. Script developers and administrators can use this type of module to create modules whose members include functions, variables, and more. At heart, a script module is simply a Windows PowerShell script with a different extension, which allows administrators to use import, export, and management functions on it.

In addition, you can use a manifest file to include other resources in your module, such as data files, other dependent modules, or runtime scripts. Manifest files are also useful for tracking metadata such as authoring and versioning information.

Finally, a script module, like any other module that isn't dynamically created, needs to be saved in a folder that PowerShell can reasonably discover. Usually, this is on the PowerShell module path; but if necessary you can explicitly describe where your module is installed. For more information, see [How to Write a PowerShell Script Module](#).

Binary Modules

A **binary module** is a .NET Framework assembly (`.dll`) that contains compiled code, such as C#. Cmdlet developers can use this type of module to share cmdlets, providers, and more. (Existing snap-ins can also be used as binary modules.) Compared to a script module, a binary module allows you to create cmdlets that are faster or use features (such as multithreading) that are not as easy to code in Windows PowerShell scripts.

As with script modules, you can include a manifest file to describe additional resources that your module uses, and to track metadata about your module. Similarly, you probably should install your binary module in a folder somewhere along the PowerShell module path. For more information, see How to [How to Write a PowerShell Binary Module](#).

Manifest Modules

A **manifest module** is a module that uses a manifest file to describe all of its components, but doesn't have any sort of core assembly or script. (Formally, a manifest module leaves the `ModuleToProcess` or `RootModule` element of the manifest empty.) However, you can still use the other features of a module, such as the ability to load up

dependent assemblies or automatically run certain pre-processing scripts. You can also use a manifest module as a convenient way to package up resources that other modules will use, such as nested modules, assemblies, types, or formats. For more information, see [How to Write a PowerShell Module Manifest](#).

Dynamic Modules

A **dynamic module** is a module that is not loaded from, or saved to, a file. Instead, they are created dynamically by a script, using the [New-Module](#) cmdlet. This type of module enables a script to create a module on demand that does not need to be loaded or saved to persistent storage. By its nature, a dynamic module is intended to be short-lived, and therefore cannot be accessed by the [Get-Module](#) cmdlet. Similarly, they usually do not need module manifests, nor do they likely need permanent folders to store their related assemblies.

Module Manifests

A **module manifest** is a `.psd1` file that contains a hash table. The keys and values in the hash table do the following things:

- Describe the contents and attributes of the module.
- Define the prerequisites.
- Determine how the components are processed.

Manifests are not required for a module. Modules can reference script files (`.ps1`), script module files (`.psm1`), manifest files (`.psd1`), formatting and type files (`.ps1xml`), cmdlet and provider assemblies (`.dll`), resource files, Help files, localization files, or any other type of file or resource that is bundled as part of the module. For an internationalized script, the module folder also contains a set of message catalog files. If you add a manifest file to the module folder, you can reference the multiple files as a single unit by referencing the manifest.

The manifest itself describes the following categories of information:

- Metadata about the module, such as the module version number, the author, and the description.
- Prerequisites needed to import the module, such as the Windows PowerShell version, the common language runtime (CLR) version, and the required modules.
- Processing directives, such as the scripts, formats, and types to process.

- Restrictions on the members of the module to export, such as the aliases, functions, variables, and cmdlets to export.

For more information, see [How to Write a PowerShell Module Manifest](#).

Storing and Installing a Module

Once you have created a script, binary, or manifest module, you can save your work in a location that others may access it. For example, your module can be stored in the system folder where Windows PowerShell is installed, or it can be stored in a user folder.

Generally speaking, you can determine where you should install your module by using one of the paths stored in the `$Env:PSModulePath` variable. Using one of these paths means that PowerShell can automatically find and load your module when a user makes a call to it in their code. If you store your module somewhere else, you can explicitly let PowerShell know by passing in the location of your module as a parameter when you call `Install-Module`.

Regardless, the path of the folder is referred to as the **base** of the module (`ModuleBase`), and the name of the script, binary, or manifest module file should be the same as the module folder name, with the following exceptions:

- Dynamic modules that are created by the `New-Module` cmdlet can be named using the `Name` parameter of the cmdlet.
- Modules imported from assembly objects by the `Import-Module -Assembly` command are named according to the following syntax: `"dynamic_code_module_" + assembly.GetName()`.

For more information, see [Installing a PowerShell Module](#) and [about_PSMODULEPATH](#).

Module Cmdlets and Variables

The following cmdlets and variables are provided by Windows PowerShell for the creation and management of modules.

New-Module cmdlet This cmdlet creates a new dynamic module that exists only in memory. The module is created from a script block, and its exported members, such as its functions and variables, are immediately available in the session and remain available until the session is closed.

[New-ModuleManifest](#) cmdlet This cmdlet creates a new module manifest (`.psd1`) file, populates its values, and saves the manifest file to the specified path. This cmdlet can also be used to create a module manifest template that can be filled in manually.

[Import-Module](#) cmdlet This cmdlet adds one or more modules to the current session.

[Get-Module](#) cmdlet This cmdlet retrieves information about the modules that have been or that can be imported into the current session.

[Export-ModuleMember](#) cmdlet This cmdlet specifies the module members (such as cmdlets, functions, variables, and aliases) that are exported from a script module (`.psm1`) file or from a dynamic module created by using the [New-Module](#) cmdlet.

[Remove-Module](#) cmdlet This cmdlet removes modules from the current session.

[Test-ModuleManifest](#) cmdlet This cmdlet verifies that a module manifest accurately describes the components of a module by verifying that the files that are listed in the module manifest file (`.psd1`) actually exist in the specified paths.

`$PSScriptRoot` This variable contains the directory from which the script module is being executed. It enables scripts to use the module path to access other resources.

`$Env:PSModulePath` This environment variable contains a list of the directories in which Windows PowerShell modules are stored. Windows PowerShell uses the value of this variable when importing modules automatically and updating Help topics for modules.

How to Write a PowerShell Script Module

Article • 06/09/2022

A script module is any valid PowerShell script saved in a `.psm1` extension. This extension allows the PowerShell engine to use rules and module cmdlets on your file. Most of these capabilities are there to help you install your code on other systems, as well as manage scoping. You can also use a module manifest file, which describes more complex installations and solutions.

Writing a PowerShell script module

To create a script module, save a valid PowerShell script to a `.psm1` file. The script and the directory where it's stored must use the same name. For example, a script named `MyPsScript.psm1` is stored in a directory named `MyPsScript`.

The module's directory needs to be in a path specified in `$Env:PSModulePath`. The module's directory can contain any resources that are needed to run the script, and a module manifest file that describes to PowerShell how your module works.

Create a basic PowerShell module

The following steps describe how to create a PowerShell module.

1. Save a PowerShell script with a `.psm1` extension. Use the same name for the script and the directory where the script is saved.

Saving a script with the `.psm1` extension means that you can use the module cmdlets, such as [Import-Module](#). The module cmdlets exist primarily so that you can import and export your code onto other user's systems. The alternate solution would be to load your code on other systems and then dot-source it into active memory, which isn't a scalable solution. For more information, see [Understanding a Windows PowerShell Module](#). By default, when users import your `.psm1` file, all functions in your script are accessible, but variables aren't.

An example PowerShell script, entitled `Show-Calendar`, is available at the end of this article.

```

function Show-Calendar {
    param(
        [datetime] $Start = [datetime]::Today,
        [datetime] $End = $Start,
        $FirstDayOfWeek,
        [int[]] $HighlightDay,
        [string[]] $HighlightDate = [datetime]::Today.ToString('yyyy-MM-
dd')
    )

    #actual code for the function goes here see the end of the topic
    #for the complete code sample
}

```

2. To control user access to certain functions or variables, call [Export-ModuleMember](#) at the end of your script.

The example code at the bottom of the article has only one function, which by default would be exposed. However, it's recommended you explicitly call out which functions you wish to expose, as described in the following code:

```

PowerShell

function Show-Calendar {
}
Export-ModuleMember -Function Show-Calendar

```

You can restrict what's imported using a module manifest. For more information, see [Importing a PowerShell Module](#) and [How to Write a PowerShell Module Manifest](#).

3. If you have modules that your own module needs to load, you can use [Import-Module](#), at the top of your module.

The [Import-Module](#) cmdlet imports a targeted module onto a system, and can be used at a later point in the procedure to install your own module. The sample code at the bottom of this article doesn't use any import modules. But if it did, they would be listed at the top of the file, as shown in the following code:

```

PowerShell

Import-Module GenericModule

```

4. To describe your module to the PowerShell Help system, you can either use standard help comments inside the file, or create an additional Help file.

The code sample at the bottom of this article includes the help information in the comments. You could also write expanded XML files that contain additional help content. For more information, see [Writing Help for Windows PowerShell Modules](#).

5. If you have additional modules, XML files, or other content you want to package with your module, you can use a module manifest.

A module manifest is a file that contains the names of other modules, directory layouts, versioning numbers, author data, and other pieces of information.

PowerShell uses the module manifest file to organize and deploy your solution. For more information, see [How to write a PowerShell module manifest](#).

6. To install and run your module, save the module to one of the appropriate PowerShell paths, and use `Import-Module`.

The paths where you can install your module are located in the `$Env:PSModulePath` global variable. For example, a common path to save a module on a system would be `%SystemRoot%/users/<user>/Documents/PowerShell/Modules/<moduleName>`. Be sure to create a directory for your module that uses the same name as the script module, even if it's only a single `.psm1` file. If you didn't save your module to one of these paths, you would have to specify the module's location in the `Import-Module` command. Otherwise, PowerShell wouldn't be able to find the module.

 **Note**

Starting with PowerShell 3.0, if you've placed your module in one of the PowerShell module paths, you don't need to explicitly import it. Your module is automatically loaded when a user calls your function. For more information about the module path, see [Importing a PowerShell Module](#) and [about_PSMODULEPATH](#).

7. To remove a module from active service in the current PowerShell session, use [Remove-Module](#).

 **Note**

`Remove-Module` removes a module from the current PowerShell session, but doesn't uninstall the module or delete the module's files.

Show-Calendar code example

The following example is a script module that contains a single function named `Show-Calendar`. This function displays a visual representation of a calendar. The sample contains the PowerShell Help strings for the synopsis, description, parameter values, and code. When the module is imported, the `Export-ModuleMember` command ensures that the `Show-Calendar` function is exported as a module member.

PowerShell

```
<#
.SYNOPSIS
    Displays a visual representation of a calendar.

.DESCRIPTION
    Displays a visual representation of a calendar. This function supports
    multiple months
    and lets you highlight specific date ranges or days.

.PARAMETER Start
    The first month to display.

.PARAMETER End
    The last month to display.

.PARAMETER FirstDayOfWeek
    The day of the month on which the week begins.

.PARAMETER HighlightDay
    Specific days (numbered) to highlight. Used for date ranges like (25..31).
    Date ranges are specified by the Windows PowerShell range syntax. These
    dates are
    enclosed in square brackets.

.PARAMETER HighlightDate
    Specific days (named) to highlight. These dates are surrounded by
    asterisks.

.EXAMPLE
    # Show a default display of this month.
    Show-Calendar

.EXAMPLE
    # Display a date range.
    Show-Calendar -Start "March, 2010" -End "May, 2010"

.EXAMPLE
    # Highlight a range of days.
    Show-Calendar -HighlightDay (1..10 + 22) -HighlightDate "2008-12-25"
#>
function Show-Calendar {
    param(
        [datetime] $Start = [datetime]::Today,
        [datetime] $End = $Start,
```

```

$FirstDayOfWeek,
[int[]] $HighlightDay,
[string[]] $HighlightDate = [datetime]::Today.ToString('yyyy-MM-dd')
)

## Determine the first day of the start and end months.
$Start = New-Object DateTime $Start.Year,$Start.Month,1
$End = New-Object DateTime $End.Year,$End.Month,1

## Convert the highlighted dates into real dates.
[datetime[]] $HighlightDate = [datetime[]] $HighlightDate

## Retrieve the DateTimeFormat information so that the
## calendar can be manipulated.
$dateTimeFormat = (Get-Culture).DateTimeFormat
if($FirstDayOfWeek)
{
    $dateTimeFormat.FirstDayOfWeek = $FirstDayOfWeek
}

$currentDay = $Start

## Process the requested months.
while($Start -le $End)
{
    ## Return to an earlier point in the function if the first day of the
    month
    ## is in the middle of the week.
    while($currentDay.DayOfWeek -ne $dateTimeFormat.FirstDayOfWeek)
    {
        $currentDay = $currentDay.AddDays(-1)
    }

    ## Prepare to store information about this date range.
    $currentWeek = New-Object PsObject
    $dayNames = @()
    $weeks = @()

    ## Continue processing dates until the function reaches the end of the
    month.
    ## The function continues until the week is completed with
    ## days from the next month.
    while(($currentDay -lt $Start.AddMonths(1)) -or
          ($currentDay.DayOfWeek -ne $dateTimeFormat.FirstDayOfWeek))
    {
        ## Determine the day names to use to label the columns.
        $dayName = "{0:ddd}" -f $currentDay
        if($dayNames -notcontains $dayName)
        {
            $dayNames += $dayName
        }

        ## Pad the day number for display, highlighting if necessary.
        $displayDay = " {0,2} " -f $currentDay.Day

```

```

## Determine whether to highlight a specific date.
if($HighlightDate)
{
    $compareDate = New-Object DateTime $currentDay.Year,
                  $currentDay.Month,$currentDay.Day
    if($HighlightDate -contains $compareDate)
    {
        $displayDay = "*" + ("{0,2}" -f $currentDay.Day) + "*"
    }
}

## Otherwise, highlight as part of a date range.
if($HighlightDay -and ($HighlightDay[0] -eq $currentDay.Day))
{
    $displayDay = "[" + ("{0,2}" -f $currentDay.Day) + "]"
    $null,$HighlightDay = $HighlightDay
}

## Add the day of the week and the day of the month as note
properties.
$currentWeek | Add-Member NoteProperty $dayName $displayDay

## Move to the next day of the month.
$currentDay = $currentDay.AddDays(1)

## If the function reaches the next week, store the current week
## in the week list and continue.
if($currentDay.DayOfWeek -eq $dateTimeFormat.FirstDayOfWeek)
{
    $weeks += $currentWeek
    $currentWeek = New-Object PsObject
}
}

## Format the weeks as a table.
$calendar = $weeks | Format-Table $dayNames -AutoSize | Out-String

## Add a centered header.
$width = ($calendar.Split("`n") | Measure-Object -Maximum
Length).Maximum
$header = "{0:MMMM yyyy}" -f $Start
$padding = " " * (($width - $header.Length) / 2)
$displayCalendar = "`n" + $padding + $header + "`n " + $calendar
$displayCalendar.TrimEnd()

## Move to the next month.
$Start = $Start.AddMonths(1)

}

}

Export-ModuleMember -Function Show-Calendar

```

How to Write a PowerShell Binary Module

06/12/2025

A binary module can be any assembly (.dll) that contains cmdlet classes. By default, all the cmdlets in the assembly are imported when the binary module is imported. However, you can restrict the cmdlets that are imported by creating a module manifest whose root module is the assembly. (For example, the **CmdletsToExport** key of the manifest can be used to export only those cmdlets that are needed.) In addition, a binary module can contain additional files, a directory structure, and other pieces of useful management information that a single cmdlet cannot.

The following procedure describes how to create and install a PowerShell binary module.

How to create and install a PowerShell binary module

1. Create a binary PowerShell solution (such as a cmdlet written in C#), with the capabilities you need, and ensure that it runs properly.

From a code perspective, the core of a binary module is a cmdlet assembly. In fact, PowerShell treats a single cmdlet assembly as a module for loading and unloading, with no additional effort on the part of the developer. For more information about writing a cmdlet, see [Writing a Windows PowerShell Cmdlet](#).

2. If necessary, create the rest of your solution: (additional cmdlets, XML files, and so on) and describe them with a module manifest.

In addition to describing the cmdlet assemblies in your solution, a module manifest can describe how you want your module exported and imported, what cmdlets will be exposed, and what additional files will go into the module. As stated previously however, PowerShell can treat a binary cmdlet like a module with no additional effort. As such, a module manifest is useful mainly for combining multiple files into a single package, or for explicitly controlling publication for a given assembly. For more information, see [How to Write a PowerShell Module Manifest](#).

The following code is a simplified C# example that contains three cmdlets in the same file that can be used as a module.

C#

```
using System.Management.Automation;           // Windows PowerShell
namespace.
```

```

namespace ModuleCmdlets
{
    [Cmdlet(VerbsDiagnostic.Test, "BinaryModuleCmdlet1")]
    public class TestBinaryModuleCmdlet1Command : Cmdlet
    {
        protected override void BeginProcessing()
        {
            WriteObject("BinaryModuleCmdlet1 exported by the ModuleCmdlets
module.");
        }
    }

    [Cmdlet(VerbsDiagnostic.Test, "BinaryModuleCmdlet2")]
    public class TestBinaryModuleCmdlet2Command : Cmdlet
    {
        protected override void BeginProcessing()
        {
            WriteObject("BinaryModuleCmdlet2 exported by the ModuleCmdlets
module.");
        }
    }

    [Cmdlet(VerbsDiagnostic.Test, "BinaryModuleCmdlet3")]
    public class TestBinaryModuleCmdlet3Command : Cmdlet
    {
        protected override void BeginProcessing()
        {
            WriteObject("BinaryModuleCmdlet3 exported by the ModuleCmdlets
module.");
        }
    }
}

```

3. Package your solution, and save the package to somewhere in the PowerShell module path.

The `$env:PSModulePath` global environment variable describes the default paths that PowerShell uses to locate your module. For example, a common path to save a module on a system would be `%SystemRoot%\Users\<user>\Documents\WindowsPowerShell\Modules\<moduleName>`. If you don't use the default paths, you need to explicitly state the location of your module during installation. Be sure to create a folder to save your module in, as you may need the folder to store multiple assemblies and files for your solution.

Technically, you don't need to install your module anywhere on the `$env:PSModulePath` - those are simply the default locations that PowerShell will look for your module. However, it's considered best practice to do so, unless you have a good reason for storing your

module somewhere else. For more information, see [Installing a PowerShell Module](#) and [about_PSMODULEPATH](#).

4. Import your module into PowerShell with a call to [Import-Module](#).

Calling to [Import-Module](#) loads your module into active memory. If you are using PowerShell 3.0 and later, invoking a command from your module in code also imports it. For more information, see [Importing a PowerShell Module](#).

Module initialization and cleanup code

If your module needs to do something upon import or removal such as a discovery task or initialization, you can implement the [IModuleAssemblyInitializer](#) and [IModuleAssemblyCleanup](#) interfaces.

 Note

This pattern is discouraged unless absolutely necessary. To keep PowerShell performant, you should lazily load things at the point your commands are called rather than on import.

Importing snap-in assemblies as modules

Cmdlets and providers that exist in snap-in assemblies can be loaded as binary modules. When the snap-in assemblies are loaded as binary modules, the cmdlets and providers in the snap-in are available to the user, but the snap-in class in the assembly is ignored, and the snap-in isn't registered. As a result, the snap-in cmdlets provided by Windows PowerShell can't detect the snap-in even though the cmdlets and providers are available to the session.

In addition, any formatting or types files that are referenced by the snap-in can't be imported as part of a binary module. To import the formatting and types files you must create a module manifest. See, [How to Write a PowerShell Module Manifest](#).

How to write a PowerShell module manifest

Article • 02/06/2024

After you've written your PowerShell module, you can add an optional module manifest that includes information about the module. For example, you can describe the author, specify files in the module (such as nested modules), run scripts to customize the user's environment, load type and formatting files, define system requirements, and limit the members that the module exports.

Creating a module manifest

A **module manifest** is a PowerShell data file (`.psd1`) that describes the contents of a module and determines how a module is processed. The manifest file is a text file that contains a hash table of keys and values. You link a manifest file to a module by naming the manifest the same as the module, and storing the manifest in the module's root directory.

For simple modules that contain only a single `.psm1` or binary assembly, a module manifest is optional. But, the recommendation is to use a module manifest whenever possible, as they're useful to help you organize your code and maintain versioning information. And, a module manifest is required to export an assembly that is installed in the [Global Assembly Cache](#). A module manifest is also required for modules that support the Updatable Help feature. Updatable Help uses the **HelpInfoUri** key in the module manifest to find the Help information (HelpInfo XML) file that contains the location of the updated help files for the module. For more information about Updatable Help, see [Supporting Updatable Help](#).

To create and use a module manifest

1. The best practice to create a module manifest is to use the [New-ModuleManifest](#) cmdlet. You can use parameters to specify one or more of the manifest's default keys and values. The only requirement is to name the file. `New-ModuleManifest` creates a module manifest with your specified values, and includes the remaining keys and their default values. If you need to create multiple modules, use `New-ModuleManifest` to create a module manifest template that can be modified for your different modules. For an example of a default module manifest, see the [Sample module manifest](#).

```
New-ModuleManifest -Path C:\myModuleName.psd1 -ModuleVersion "2.0" -Author  
"YourNameHere"
```

An alternative is to manually create the module manifest's hash table using the minimal information required, the **ModuleVersion**. You save the file with the same name as your module and use the `.psd1` file extension. You can then edit the file and add the appropriate keys and values.

2. Add any additional elements that you want in the manifest file.

To edit the manifest file, use any text editor you prefer. But, the manifest file is a script file that contains code, so you may wish to edit it in a scripting or development environment, such as Visual Studio Code. All elements of a manifest file are optional, except for the **ModuleVersion** number.

For descriptions of the keys and values you can include in a module manifest, see the [Module manifest elements](#) table. For more information, see the parameter descriptions in the [New-ModuleManifest](#) cmdlet.

3. To address any scenarios that might not be covered by the base module manifest elements, you have the option to add additional code to your module manifest.

For security concerns, PowerShell only runs a small subset of the available operations in a module manifest file. Generally, you can use the `if` statement, arithmetic and comparison operators, and the basic PowerShell data types.

4. After you've created your module manifest, you can test it to confirm that any paths described in the manifest are correct. To test your module manifest, use [Test-ModuleManifest](#).

```
Test-ModuleManifest myModuleName.psd1
```

5. Be sure that your module manifest is located in the top level of the directory that contains your module.

When you copy your module onto a system and import it, PowerShell uses the module manifest to import your module.

6. Optionally, you can directly test your module manifest with a call to [Import-Module](#) by dot-sourcing the manifest itself.

```
Import-Module .\myModuleName.psd1
```

Module manifest elements

The following table describes the elements you can include in a module manifest.

[+] Expand table

Element	Default	Description
RootModule Type: <code>String</code>	<code><empty string></code>	<p>Script module or binary module file associated with this manifest. Previous versions of PowerShell called this element the ModuleToProcess.</p> <p>Possible types for the root module can be empty, which creates a Manifest module, the name of a script module (<code>.psm1</code>), or the name of a binary module (<code>.exe</code> or <code>.d11</code>). Placing the name of a module manifest (<code>.psd1</code>) or a script file (<code>.ps1</code>) in this element causes an error.</p> <p>Example: <code>RootModule = 'ScriptModule.psm1'</code></p>
ModuleVersion Type: <code>Version</code>	<code>'0.0.1'</code>	<p>Version number of this module. If a value isn't specified, <code>New-ModuleManifest</code> uses the default. The string must be able to convert to the type <code>Version</code> for example <code>#.#.#.#</code>. <code>Import-Module</code> loads the first module it finds on the <code>\$PSModulePath</code> that matches the name, and has at least as high a ModuleVersion, as the MinimumVersion parameter. To import a specific version, use the <code>Import-Module</code> cmdlet's RequiredVersion parameter.</p> <p>Example: <code>ModuleVersion = '1.0'</code></p>
GUID Type: <code>GUID</code>	<code>'<GUID>'</code>	<p>ID used to uniquely identify this module. If a value isn't specified, <code>New-ModuleManifest</code> autogenerates the value. You can't currently import a module by GUID.</p> <p>Example: <code>GUID = 'cfc45206-1e49-459d-a8ad-5b571ef94857'</code></p>
Author Type: <code>String</code>	<code>'<Current user>'</code>	<p>Author of this module. If a value isn't specified, <code>New-ModuleManifest</code> uses the current user.</p> <p>Example: <code>Author = 'AuthorNameHere'</code></p>
CompanyName Type: <code>String</code>	<code>'Unknown'</code>	<p>Company or vendor of this module. If a value isn't specified, <code>New-ModuleManifest</code> uses the default.</p> <p>Example: <code>CompanyName = 'Fabrikam'</code></p>
Copyright Type: <code>String</code>	<code>'(c)<Author>. All rights reserved.'</code>	<p>Copyright statement for this module. If a value isn't specified, <code>New-ModuleManifest</code> uses the default with the current user as the <code><Author></code>. To specify an author, use the Author parameter.</p>

Element	Default	Description
		Example: <code>Copyright = '2019 AuthorName. All rights reserved.'</code>
Description Type: <code>String</code>	<code><empty string></code>	<p>Description of the functionality provided by this module.</p> <p>Example: <code>Description = 'This is the module's description.'</code></p>
PowerShellVersion Type: <code>Version</code>	<code><empty string></code>	<p>Minimum version of the PowerShell engine required by this module. Valid values are 1.0, 2.0, 3.0, 4.0, 5.0, 5.1, 6.0, 6.1, 6.2, 7.0 and 7.1.</p> <p>Example: <code>PowerShellVersion = '5.0'</code></p>
PowerShellHostName Type: <code>String</code>	<code><empty string></code>	<p>Name of the PowerShell host required by this module. This name is provided by PowerShell. To find the name of a host program, in the program, type: <code>\$Host.Name</code>.</p> <p>Example: <code>PowerShellHostName = 'ConsoleHost'</code></p>
PowerShellHostVersion Type: <code>Version</code>	<code><empty string></code>	<p>Minimum version of the PowerShell host required by this module.</p> <p>Example: <code>PowerShellHostVersion = '2.0'</code></p>
DotNetFrameworkVersion Type: <code>Version</code>	<code><empty string></code>	<p>Minimum version of Microsoft .NET Framework required by this module. This prerequisite is valid for the PowerShell Desktop edition only, such as Windows PowerShell 5.1, and only applies to .NET Framework versions lower than 4.5.</p> <p>Example: <code>DotNetFrameworkVersion = '3.5'</code></p>
CLRVersion Type: <code>Version</code>	<code><empty string></code>	<p>Minimum version of the common language runtime (CLR) required by this module. This prerequisite is valid for the PowerShell Desktop edition only, such as Windows PowerShell 5.1, and only applies to .NET Framework versions lower than 4.5.</p> <p>Example: <code>CLRVersion = '3.5'</code></p>
ProcessorArchitecture Type: <code>ProcessorArchitecture</code>	<code><empty string></code>	<p>Processor architecture (None, X86, Amd64) required by this module. Valid values are x86, AMD64, Arm, IA64, MSIL, and None (unknown or unspecified).</p> <p>Example: <code>ProcessorArchitecture = 'x86'</code></p>
RequiredModules Type: <code>Object[]</code>	<code>@()</code>	<p>Modules that must be imported into the global environment prior to importing this module. This loads any modules listed unless they've already been loaded. For example, some modules may already be loaded by a different module. It's</p>

Element	Default	Description
		<p>possible to specify a specific version to load using <code>RequiredVersion</code> rather than <code>ModuleVersion</code>. When <code>ModuleVersion</code> is used it will load the newest version available with a minimum of the version specified. You can combine strings and hash tables in the parameter value.</p> <p>Example: <code>RequiredModules = @("MyModule", @{ModuleName="MyDependentModule"; ModuleVersion="2.0"; GUID="cfc45206-1e49-459d-a8ad-5b571ef94857"})</code></p> <p>Example: <code>RequiredModules = @("MyModule", @{ModuleName="MyDependentModule"; RequiredVersion="1.5"; GUID="cfc45206-1e49-459d-a8ad-5b571ef94857"})</code></p>
RequiredAssemblies	@()	<p>Assemblies that must be loaded prior to importing this module. Specifies the assembly (.dll) file names that the module requires.</p> <p>PowerShell loads the specified assemblies before updating types or formats, importing nested modules, or importing the module file that is specified in the value of the <code>RootModule</code> key. Use this parameter to list all the assemblies that the module requires.</p> <p>Example: <code>RequiredAssemblies = @("assembly1.dll", "assembly2.dll", "assembly3.dll")</code></p>
ScriptsToProcess	@()	<p>Script (.ps1) files that are run in the caller's session state when the module is imported. This could be the global session state or, for nested modules, the session state of another module. You can use these scripts to prepare an environment just as you might use a log in script.</p> <p>These scripts are run before any of the modules listed in the manifest are loaded.</p> <p>Example: <code>ScriptsToProcess = @("script1.ps1", "script2.ps1", "script3.ps1")</code></p>
TypesToProcess	@()	<p>Type files (.ps1xml) to be loaded when importing this module.</p> <p>Example: <code>TypesToProcess = @("type1.ps1xml", "type2.ps1xml", "type3.ps1xml")</code></p>
FormatsToProcess	@()	<p>Format files (.ps1xml) to be loaded when importing this module.</p>

Element	Default	Description
		<p>Example: <code>FormatsToProcess = @("format1.ps1xml", "format2.ps1xml", "format3.ps1xml")</code></p>
NestedModules Type: <code>Object[]</code>	<code>@()</code>	<p>Modules to import as nested modules of the module specified in RootModule (alias:ModuleToProcess). Adding a module name to this element is similar to calling <code>Import-Module</code> from within your script or assembly code. The main difference by using a manifest file is that it's easier to see what you're loading. And, if a module fails to load, you will not yet have loaded your actual module.</p> <p>In addition to other modules, you may also load script (<code>.ps1</code>) files here. These files will execute in the context of the root module. This is equivalent to dot sourcing the script in your root module.</p> <p>Example: <code>NestedModules = @("script.ps1", @{ModuleName="MyModule"; ModuleVersion="1.0.0.0"; GUID="50cdb55f-5ab7-489f-9e94-4ec21ff51e59"})</code></p>
FunctionsToExport Type: <code>String[]</code>	<code>@()</code>	<p>Specifies the functions to export from this module, for best performance, do not use wildcards and do not delete the entry, use an empty array if there are no functions to export. By default, no functions are exported. You can use this key to list the functions that are exported by the module.</p> <p>The module exports the functions to the caller's session state. The caller's session state can be the global session state or, for nested modules, the session state of another module. When chaining nested modules, all functions that are exported by a nested module will be exported to the global session state unless a module in the chain restricts the function by using the FunctionsToExport key. If the manifest exports aliases for the functions, this key can remove functions whose aliases are listed in the AliasesToExport key, but this key cannot add function aliases to the list.</p> <p>Example: <code>FunctionsToExport = @("function1", "function2", "function3")</code></p>
CmdletsToExport Type: <code>String[]</code>	<code>@()</code>	<p>Specifies the cmdlets to export from this module, for best performance, do not use wildcards and do not delete the entry, use an empty array if there are no cmdlets to export. By default, no cmdlets are exported. You can use this key to list the cmdlets that are exported by the module.</p>

Element	Default	Description
		<p>The caller's session state can be the global session state or, for nested modules, the session state of another module. When you're chaining nested modules, all cmdlets that are exported by a nested module will be exported to the global session state unless a module in the chain restricts the cmdlet by using the CmdletsToExport key.</p> <p>If the manifest exports aliases for the cmdlets, this key can remove cmdlets whose aliases are listed in the AliasesToExport key, but this key cannot add cmdlet aliases to the list.</p> <p>Example: <code>CmdletsToExport = @("Get-MyCmdlet", "Set-MyCmdlet", "Test-MyCmdlet")</code></p>
VariablesToExport Type: <code>String[]</code>	<code>'*'</code>	<p>Specifies the variables that the module exports to the caller's session state. Wildcard characters are permitted. By default, all variables (<code>'*'</code>) are exported. You can use this key to restrict the variables that are exported by the module.</p> <p>The caller's session state can be the global session state or, for nested modules, the session state of another module. When you are chaining nested modules, all variables that are exported by a nested module will be exported to the global session state unless a module in the chain restricts the variable by using the VariablesToExport key.</p> <p>If the manifest also exports aliases for the variables, this key can remove variables whose aliases are listed in the AliasesToExport key, but this key cannot add variable aliases to the list.</p> <p>Example: <code>VariablesToExport = @('\$MyVariable1', '\$MyVariable2', '\$MyVariable3')</code></p>
AliasesToExport Type: <code>String[]</code>	<code>@()</code>	<p>Specifies the aliases to export from this module, for best performance, do not use wildcards and do not delete the entry, use an empty array if there are no aliases to export. By default, no aliases are exported. You can use this key to list the aliases that are exported by the module.</p> <p>The module exports the aliases to caller's session state. The caller's session state can be the global session state or, for nested modules, the session state of another module. When you are chaining nested modules, all aliases that are exported by a nested module will be ultimately exported to the global session state unless a module in the chain restricts the alias by using the AliasesToExport key.</p>

Element	Default	Description
		Example: <code>AliasesToExport = @("MyAlias1", "MyAlias2", "MyAlias3")</code>
DscResourcesToExport Type: <code>String[]</code>	<code>@()</code>	Specifies DSC resources to export from this module. Wildcards are permitted. Example: <code>DscResourcesToExport = @("DscResource1", "DscResource2", "DscResource3")</code>
ModuleList Type: <code>Object[]</code>	<code>@()</code>	Specifies all the modules that are packaged with this module. These modules can be entered by name, using a comma-separated string, or as a hash table with ModuleName and GUID keys. The hash table can also have an optional ModuleVersion key. The ModuleList key is designed to act as a module inventory. These modules are not automatically processed. Example: <code>ModuleList = @("SampleModule", "MyModule", @{ModuleName="MyModule"; ModuleVersion="1.0.0.0"; GUID="50cdb55f-5ab7-489f-9e94-4ec21ff51e59"})</code>
FileList Type: <code>String[]</code>	<code>@()</code>	List of all files packaged with this module. As with ModuleList , FileList is an inventory list, and isn't otherwise processed. Example: <code>FileList = @("File1", "File2", "File3")</code>
PrivateData Type: <code>Object</code>	<code>@{...}</code>	Specifies any private data that needs to be passed to the root module specified by the RootModule (alias: ModuleToProcess) key. PrivateData is a hash table that comprises several elements: Tags , LicenseUri , ProjectURI , IconURI , ReleaseNotes , Prerelease , RequireLicenseAcceptance , and ExternalModuleDependencies .
Tags Type: <code>String[]</code>	<code>@()</code>	Tags help with module discovery in online galleries. Example: <code>Tags = "PackageManagement", "PowerShell", "Manifest"</code>
LicenseUri Type: <code>Uri</code>	<code><empty string></code>	A URL to the license for this module. Example: <code>LicenseUri = 'https://www.contoso.com/license'</code>
ProjectUri Type: <code>Uri</code>	<code><empty string></code>	A URL to the main website for this project. Example: <code>ProjectUri = 'https://www.contoso.com/project'</code>

Element	Default	Description
IconUri Type: Uri	<empty string>	A URL to an icon representing this module. Example: IconUri = ' https://www.contoso.com/icons/icon.png '
ReleaseNotes Type: String	<empty string>	Specifies the module's release notes. Example: ReleaseNotes = 'The release notes provide information about the module.'
PreRelease Type: String	<empty string>	This parameter was added in PowerShellGet 1.6.6. A PreRelease string that identifies the module as a prerelease version in online galleries. Example: PreRelease = 'alpha'
RequireLicenseAcceptance Type: Boolean	\$false	This parameter was added in PowerShellGet 1.5. Flag to indicate whether the module requires explicit user acceptance for install, update, or save. Example: RequireLicenseAcceptance = \$false
ExternalModuleDependencies Type: String[]	@()	This parameter was added in PowerShellGet v2. A list of external modules that this module is dependent upon. Example: ExternalModuleDependencies = @("ExtModule1", "ExtModule2", "ExtModule3")
HelpInfoURI Type: String	<empty string>	HelpInfo URI of this module. Example: HelpInfoURI = ' https://www.contoso.com/help '
DefaultCommandPrefix Type: String	<empty string>	Default prefix for commands exported from this module. Override the default prefix using Import-Module -Prefix. Example: DefaultCommandPrefix = 'My'

Sample module manifest

The following sample module manifest was created with `New-ModuleManifest` in PowerShell 7 and contains the default keys and values.

```
PowerShell

#
# Module manifest for module 'SampleModuleManifest'
#
# Generated by: User01
#
# Generated on: 10/15/2019
```

```
#  
  
#{@  
  
# Script module or binary module file associated with this manifest.  
# RootModule = ''  
  
# Version number of this module.  
ModuleVersion = '0.0.1'  
  
# Supported PSEditions  
# CompatiblePSEditions = @()  
  
# ID used to uniquely identify this module  
GUID = 'b632e90c-df3d-4340-9f6c-3b832646bf87'  
  
# Author of this module  
Author = 'User01'  
  
# Company or vendor of this module

Installing a PowerShell Module

Article • 11/15/2022

After you have created your PowerShell module, you will likely want to install the module on a system, so that you or others may use it. Generally speaking, this consists of copying the module files (ie, the `.psm1`, or the binary assembly, the module manifest, and any other associated files) onto a directory on that computer. For a very small project, this may be as simple as copying and pasting the files with Windows Explorer onto a single remote computer; however, for larger solutions you may wish to use a more sophisticated installation process. Regardless of how you get your module onto the system, PowerShell can use a number of techniques that will let users find and use your modules. Therefore, the main issue for installation is ensuring that PowerShell will be able to find your module. For more information, see [Importing a PowerShell Module](#).

Rules for Installing Modules

The following information pertains to all modules, including modules that you create for your own use, modules that you get from other parties, and modules that you distribute to others.

Install Modules in PSModulePath

Whenever possible, install all modules in a path that is listed in the **PSModulePath** environment variable or add the module path to the **PSModulePath** environment variable value.

The **PSModulePath** environment variable (`$Env:PSModulePath`) contains the locations of Windows PowerShell modules. Cmdlets rely on the value of this environment variable to find modules.

By default, the **PSModulePath** environment variable value contains the following system and user module directories, but you can add to and edit the value.

- `$PSHOME\Modules` (`%windir%\System32\WindowsPowerShell\v1.0\Modules`)

Warning

This location is reserved for modules that ship with Windows. Do not install modules to this location.

- `$HOME\Documents\WindowsPowerShell\Modules`
`(%HOMEDRIVE%%HOMEPATH%\Documents\WindowsPowerShell\Modules)`
- `$Env:ProgramFiles\WindowsPowerShell\Modules`
`(%ProgramFiles%\WindowsPowerShell\Modules)`

To get the value of the **PSModulePath** environment variable, use either of the following commands.

PowerShell

```
$Env:PSModulePath  
[Environment]::GetEnvironmentVariable("PSModulePath")
```

To add a module path to value of the **PSModulePath** environment variable value, use the following command format. This format uses the **SetEnvironmentVariable** method of the **System.Environment** class to make a session-independent change to the **PSModulePath** environment variable.

PowerShell

```
#Save the current value in the $p variable.  
$p = [Environment]::GetEnvironmentVariable("PSModulePath")  
  
#Add the new path to the $p variable. Begin with a semi-colon  
#separator.  
$p += ";C:\Program Files (x86)\MyCompany\Modules\"  
  
#Add the paths in $p to the PSModulePath value.  
[Environment]::SetEnvironmentVariable("PSModulePath",$p)
```

Important

Once you have added the path to **PSModulePath**, you should broadcast an environment message about the change. Broadcasting the change allows other applications, such as the shell, to pick up the change. To broadcast the change, have your product installation code send a **WM_SETTINGCHANGE** message with `lParam` set to the string "Environment". Be sure to send the message after your module installation code has updated **PSModulePath**.

Use the Correct Module Directory Name

A well-formed module is a module that is stored in a directory that has the same name as the base name of at least one file in the module directory. If a module is not well-formed, Windows PowerShell does not recognize it as a module.

The "base name" of a file is the name without the file name extension. In a well-formed module, the name of the directory that contains the module files must match the base name of at least one file in the module.

For example, in the sample Fabrikam module, the directory that contains the module files is named "Fabrikam" and at least one file has the "Fabrikam" base name. In this case, both Fabrikam.psd1 and Fabrikam.dll have the "Fabrikam" base name.

```
C:\Program Files
  Fabrikam Technologies
    Fabrikam Manager
      Modules
        Fabrikam
          Fabrikam.psd1 (module manifest)
          Fabrikam.dll (module assembly)
```

Effect of Incorrect Installation

If the module is not well-formed and its location is not included in the value of the **PSModulePath** environment variable, basic discovery features of Windows PowerShell, such as the following, do not work.

- The Module Auto-Loading feature cannot import the module automatically.
- The `ListAvailable` parameter of the [Get-Module](#) cmdlet cannot find the module.
- The [Import-Module](#) cmdlet cannot find the module. To import the module, you must provide the full path to the root module file or module manifest file.

Additional features, such as the following, do not work unless the module is imported into the session. In well-formed modules in the **PSModulePath** environment variable, these features work even when the module is not imported into the session.

- The [Get-Command](#) cmdlet cannot find commands in the module.
- The [Update-Help](#) and [Save-Help](#) cmdlets cannot update or save help for the module.

- The `Show-Command` cmdlet cannot find and display the commands in the module.

The commands in the module are missing from the `Show-Command` window in Windows PowerShell Integrated Scripting Environment (ISE).

Where to Install Modules

This section explains where in the file system to install Windows PowerShell modules. The location depends on how the module is used.

Installing Modules for a Specific User

If you create your own module or get a module from another party, such as a Windows PowerShell community website, and you want the module to be available for your user account only, install the module in your user-specific Modules directory.

```
$HOME\Documents\WindowsPowerShell\Modules\<Module Folder>\<Module Files>
```

The user-specific Modules directory is added to the value of the `PSModulePath` environment variable by default.

Installing Modules for all Users in Program Files

If you want a module to be available to all user accounts on the computer, install the module in the Program Files location.

```
$Env:ProgramFiles\WindowsPowerShell\Modules\<Module Folder>\<Module Files>
```

ⓘ Note

The Program Files location is added to the value of the `PSModulePath` environment variable by default in Windows PowerShell 4.0 and later. For earlier versions of Windows PowerShell, you can manually create the Program Files location (`%ProgramFiles%\WindowsPowerShell\Modules`) and add this path to your `PSModulePath` environment variable as described above.

Installing Modules in a Product Directory

If you are distributing the module to other parties, use the default Program Files location described above, or create your own company-specific or product-specific subdirectory of the `%ProgramFiles%` directory.

For example, Fabrikam Technologies, a fictitious company, is shipping a Windows PowerShell module for their Fabrikam Manager product. Their module installer creates a Modules subdirectory in the Fabrikam Manager product subdirectory.

```
C:\Program Files  
  Fabrikam Technologies  
    Fabrikam Manager  
      Modules  
        Fabrikam  
          Fabrikam.psd1 (module manifest)  
          Fabrikam.dll (module assembly)
```

To enable the Windows PowerShell module discovery features to find the Fabrikam module, the Fabrikam module installer adds the module location to the value of the **PSModulePath** environment variable.

```
PowerShell  
  
$p = [Environment]::GetEnvironmentVariable("PSModulePath")  
$p += ";C:\Program Files\Fabrikam Technologies\Fabrikam Manager\Modules\"  
[Environment]::SetEnvironmentVariable("PSModulePath",$p)
```

Installing Modules in the Common Files Directory

If a module is used by multiple components of a product or by multiple versions of a product, install the module in a module-specific subdirectory of the `%ProgramFiles%\Common Files\Modules` subdirectory.

In the following example, the Fabrikam module is installed in a Fabrikam subdirectory of the `%ProgramFiles%\Common Files\Modules` subdirectory. Note that each module resides in its own subdirectory in the Modules subdirectory.

```
C:\Program Files  
  Common Files  
    Modules  
      Fabrikam  
        Fabrikam.psd1 (module manifest)  
        Fabrikam.dll (module assembly)
```

Then, the installer assures the value of the **PSModulePath** environment variable includes the path of the `Common Files\Modules` subdirectory.

PowerShell

```
$m = $Env:ProgramFiles + '\Common Files\Modules'  
$p = [Environment]::GetEnvironmentVariable("PSModulePath")  
$q = $p -split ';'  
if ($q -notcontains $m) {  
    $q += ";$m"  
}  
$p = $q -join ';'  
[Environment]::SetEnvironmentVariable("PSModulePath", $p)
```

Installing Multiple Versions of a Module

To install multiple versions of the same module, use the following procedure.

1. Create a directory for each version of the module. Include the version number in the directory name.
2. Create a module manifest for each version of the module. In the value of the **ModuleVersion** key in the manifest, enter the module version number. Save the manifest file (.psd1) in the version-specific directory for the module.
3. Add the module root folder path to the value of the **PSModulePath** environment variable, as shown in the following examples.

To import a particular version of the module, the end-user can use the `MinimumVersion` or `RequiredVersion` parameters of the [Import-Module](#) cmdlet.

For example, if the Fabrikam module is available in versions 8.0 and 9.0, the Fabrikam module directory structure might resemble the following.

```
C:\Program Files  
Fabrikam Manager  
  Fabrikam8  
    Fabrikam  
      Fabrikam.psd1 (module manifest: ModuleVersion = "8.0")  
      Fabrikam.dll (module assembly)  
  Fabrikam9  
    Fabrikam  
      Fabrikam.psd1 (module manifest: ModuleVersion = "9.0")  
      Fabrikam.dll (module assembly)
```

The installer adds both of the module paths to the **PSModulePath** environment variable value.

PowerShell

```
$p = [Environment]::GetEnvironmentVariable("PSModulePath")
$p += ";C:\Program Files\Fabrikam\Fabrikam8;C:\Program
Files\Fabrikam\Fabrikam9"
[Environment]::SetEnvironmentVariable("PSModulePath",$p)
```

When these steps are complete, the [ListAvailable](#) parameter of the [Get-Module](#) cmdlet gets both of the Fabrikam modules. To import a particular module, use the [MinimumVersion](#) or [RequiredVersion](#) parameters of the [Import-Module](#) cmdlet.

If both modules are imported into the same session, and the modules contain cmdlets with the same names, the cmdlets that are imported last are effective in the session.

Handling Command Name Conflicts

Command name conflicts can occur when the commands that a module exports have the same name as commands in the user's session.

When a session contains two commands that have the same name, Windows PowerShell runs the command type that takes precedence. When a session contains two commands that have the same name and the same type, Windows PowerShell runs the command that was added to the session most recently. To run a command that is not run by default, users can qualify the command name with the module name.

For example, if the session contains a [Get-Date](#) function and the [Get-Date](#) cmdlet, Windows PowerShell runs the function by default. To run the cmdlet, preface the command with the module name, such as:

PowerShell

```
Microsoft.PowerShell.Utility\Get-Date
```

To prevent name conflicts, module authors can use the [DefaultCommandPrefix](#) key in the module manifest to specify a noun prefix for all commands exported from the module.

Users can use the [Prefix](#) parameter of the [Import-Module](#) cmdlet to use an alternate prefix. The value of the [Prefix](#) parameter takes precedence over the value of the [DefaultCommandPrefix](#) key.

Supporting paths on non-Windows systems

Non-Windows platforms use the colon (:) character as a path separator and a forward-slash (/) character as a directory separator. The `[System.IO.Path]` class has static members that can be used to make your code work on any platform:

- `[System.IO.Path]::PathSeparator` - returns the character used to separate paths in a PATH environment variable for the host platform
- `[System.IO.Path]::DirectorySeparatorChar` - returns the character used to separate directory names with a path for the host platform

Use these static properties to in place of the ; and \ characters when you are constructing path strings.

Modules and Snap-ins

Article • 09/17/2021

Cmdlets can be added to a session using modules (introduced by Windows PowerShell 2.0) or snap-ins. Once the cmdlet is added to the session it can be run programmatically by a host application or interactively at the command line.

We recommend that you use modules as the delivery method for adding cmdlets to a session for the following reasons:

- Modules allow you to add cmdlets by loading the assembly where the cmdlet is defined. There is no need to implement a snap-in class.
- Modules allow you to add other resources, such as variables, functions, scripts, types and formatting files, and more.
- Snap-ins can be used only to add cmdlets and providers to the session.

How to Import Cmdlets Using Modules

Article • 09/17/2021

This article describes how to import cmdlets to a PowerShell session by using a binary module.

ⓘ Note

The members of modules can include cmdlets, providers, functions, variables, aliases, and much more. Snap-ins can contain only cmdlets and providers.

How to load cmdlets using a module

1. Create a module folder that has the same name as the assembly file in which the cmdlets are implemented. In this procedure, the module folder is created in the Windows `system32` folder.

```
%SystemRoot%\system32\WindowsPowerShell\v1.0\Modules\mymodule
```

2. Make sure that the `PSModulePath` environment variable includes the path to your new module folder. By default, the system folder is already added to the `PSModulePath` environment variable. To view the `PSModulePath`, type:
`$Env:PSModulePath`.

3. Copy the cmdlet assembly into the module folder.
4. Add a module manifest file (`.psd1`) in the module's root folder. PowerShell uses the module manifest to import your module. For more information, see [How to Write a PowerShell Module Manifest](#).
5. Run the following command to add the cmdlets to the session:

```
Import-Module [Module_Name]
```

This procedure can be used to test your cmdlets. It adds all the cmdlets in the assembly to the session. For more information about modules, see [Writing a Windows PowerShell Module](#).

How to Create a Windows PowerShell Snap-in

Article • 03/24/2025

A Windows PowerShell snap-in provides a mechanism for registering sets of cmdlets and another Windows PowerShell provider with the shell, thus extending the functionality of the shell. A Windows PowerShell snap-in can register all the cmdlets and providers in a single assembly, or it can register a specific list of cmdlets and providers.

Snap-in assemblies should be installed in a protected directory, just as they would be with other operating systems. Otherwise, malicious users can replace an assembly with unsafe code.

Windows PowerShell Snap-in Classes

All Windows PowerShell snap-in classes derive from the [System.Management.Automation.PSSnapIn](#) or [System.Management.Automation.CustomPSSnapIn](#) classes.

Examples

[Writing a Windows PowerShell Snap-in](#): This example shows how to create a snap-in that is used to register all the cmdlets and providers in an assembly.

[Writing a Custom Windows PowerShell Snap-in](#): This example shows how to create a custom snap-in that is used to register a specific set of cmdlets and providers that might or might not exist in a single assembly.

Writing a Windows PowerShell Snap-in

Article • 09/17/2021

This example shows how to write a Windows PowerShell snap-in that can be used to register all the cmdlets and Windows PowerShell providers in an assembly.

With this type of snap-in, you do not select which cmdlets and providers you want to register. To write a snap-in that allows you to select what is registered, see [Writing a Custom Windows PowerShell Snap-in](#).

Writing a Windows PowerShell Snap-in

1. Add the RunInstallerAttribute attribute.
2. Create a public class that derives from the [System.Management.Automation.PSSnapIn](#) class.

In this example, the class name is "GetProcPSSnapIn01".

3. Add a public property for the name of the snap-in (required). When naming snap-ins, do not use any of the following characters: #, ., , (,), {, }, [,], &, -, /, \, \$, ;, :, ", ', <, >, |, ?, @, ^, *

In this example, the name of the snap-in is "GetProcPSSnapIn01".

4. Add a public property for the vendor of the snap-in (required).

In this example, the vendor is "Microsoft".

5. Add a public property for the vendor resource of the snap-in (optional).

In this example, the vendor resource is "GetProcPSSnapIn01,Microsoft".

6. Add a public property for the description of the snap-in (required).

In this example, the description is "This is a Windows PowerShell snap-in that registers the Get-Proc cmdlet".

7. Add a public property for the description resource of the snap-in (optional).

In this example, the vendor resource is "GetProcPSSnapIn01,This is a Windows PowerShell snap-in that registers the Get-Proc cmdlet".

Example

This example shows how to write a Windows PowerShell snap-in that can be used to register the Get-Proc cmdlet in the Windows PowerShell shell. Be aware that in this example, the complete assembly would contain only the GetProcPSSnapIn01 snap-in class and the `Get-Proc` cmdlet class.

C#

```
[RunInstaller(true)]
public class GetProcPSSnapIn01 : PSSnapIn
{
    /// <summary>
    /// Create an instance of the GetProcPSSnapIn01 class.
    /// </summary>
    public GetProcPSSnapIn01()
        : base()
    {

    }

    /// <summary>
    /// Specify the name of the PowerShell snap-in.
    /// </summary>
    public override string Name
    {
        get
        {
            return "GetProcPSSnapIn01";
        }
    }

    /// <summary>
    /// Specify the vendor for the PowerShell snap-in.
    /// </summary>
    public override string Vendor
    {
        get
        {
            return "Microsoft";
        }
    }

    /// <summary>
    /// Specify the localization resource information for the vendor.
    /// Use the format: resourceBaseName, VendorName.
    /// </summary>
    public override string VendorResource
    {
        get
        {
            return "GetProcPSSnapIn01, Microsoft";
        }
    }
}
```

```
}

/// <summary>
/// Specify a description of the PowerShell snap-in.
/// </summary>
public override string Description
{
    get
    {
        return "This is a PowerShell snap-in that includes the Get-Proc
cmdlet.";
    }
}

/// <summary>
/// Specify the localization resource information for the description.
/// Use the format: resourceBaseName,Description.
/// </summary>
public override string DescriptionResource
{
    get
    {
        return "GetProcPSSnapIn01,This is a PowerShell snap-in that includes
the Get-Proc cmdlet.";
    }
}
```

Writing a Custom Windows PowerShell Snap-in

Article • 09/17/2021

This example shows how to write a Windows PowerShell snap-in that registers specific cmdlets.

With this type of snap-in, you specify which cmdlets, providers, types, or formats to register. For more information about how to write a snap-in that registers all the cmdlets and providers in an assembly, see [Writing a Windows PowerShell Snap-in](#).

To write a Windows PowerShell Snap-in that registers specific cmdlets.

1. Add the RunInstallerAttribute attribute.
2. Create a public class that derives from the [System.Management.Automation.CustomPSSnapIn](#) class.

In this example, the class name is "CustomPSSnapinTest".

3. Add a public property for the name of the snap-in (required). When naming snap-ins, do not use any of the following characters: #, ., , (,), {, }, [,], &, -, /, \, \$, ;, :, ", ', <, >, |, ?, @, `*, *

In this example, the name of the snap-in is "CustomPSSnapInTest".

4. Add a public property for the vendor of the snap-in (required).

In this example, the vendor is "Microsoft".

5. Add a public property for the vendor resource of the snap-in (optional).

In this example, the vendor resource is "CustomPSSnapInTest,Microsoft".

6. Add a public property for the description of the snap-in (required).

In this example, the description is: "This is a custom Windows PowerShell snap-in that includes the `Test-Helloworld` and `Test-CustomSnapinTest` cmdlets".

7. Add a public property for the description resource of the snap-in (optional).

In this example, the vendor resource is:

CustomPSSnapInTest, This is a custom Windows PowerShell snap-in that includes the Test-HelloWorld and Test-CustomSnapinTest cmdlets".

8. Specify the cmdlets that belong to the custom snap-in (optional) using the [System.Management.Automation.Runspaces.CmdletConfigurationEntry](#) class. The information added here includes the name of the cmdlet, its .NET type, and the cmdlet Help file name (the format of the cmdlet Help file name should be `name.dll-help.xml`).

This example adds the Test-HelloWorld and TestCustomSnapinTest cmdlets.

9. Specify the providers that belong to the custom snap-in (optional).

This example does not specify any providers.

10. Specify the types that belong to the custom snap-in (optional).

This example does not specify any types.

11. Specify the formats that belong to the custom snap-in (optional).

This example does not specify any formats.

Example

This example shows how to write a Custom Windows PowerShell snap-in that can be used to register the `Test-HelloWorld` and `Test-CustomSnapinTest` cmdlets. Be aware that in this example, the complete assembly could contain other cmdlets and providers that would not be registered by this snap-in.

C#

```
[RunInstaller(true)]
public class CustomPSSnapinTest : CustomPSSnapIn
{
    /// <summary>
    /// Creates an instance of CustomPSSnapInTest class.
    /// </summary>
    public CustomPSSnapinTest()
        : base()
    {

    }

    /// <summary>
    /// Specify the name of the custom PowerShell snap-in.
    /// </summary>
    public override string Name
    {
```

```
get
{
    return "CustomPSSnapInTest";
}
}

/// <summary>
/// Specify the vendor for the custom PowerShell snap-in.
/// </summary>
public override string Vendor
{
    get
    {
        return "Microsoft";
    }
}

/// <summary>
/// Specify the localization resource information for the vendor.
/// Use the format: resourceName,resourceName.
/// </summary>
public override string VendorResource
{
    get
    {
        return "CustomPSSnapInTest,Microsoft";
    }
}

/// <summary>
/// Specify a description of the custom PowerShell snap-in.
/// </summary>
public override string Description
{
    get
    {
        return "This is a custom PowerShell snap-in that includes the Test-
HelloWorld and Test-CustomSnapinTest cmdlets.";
    }
}

/// <summary>
/// Specify the localization resource information for the description.
/// Use the format: resourceName,Description.
/// </summary>
public override string DescriptionResource
{
    get
    {
        return "CustomPSSnapInTest,This is a custom PowerShell snap-in that
includes the Test-Helloworld and Test-CustomSnapinTest cmdlets.";
    }
}

/// <summary>
```

```
/// Specify the cmdlets that belong to this custom PowerShell snap-in.
/// </summary>
private Collection<CmdletConfigurationEntry> _cmdlets;
public override Collection<CmdletConfigurationEntry> Cmdlets
{
    get
    {
        if (_cmdlets == null)
        {
            _cmdlets = new Collection<CmdletConfigurationEntry>();
            _cmdlets.Add(new CmdletConfigurationEntry("test-customsnapintest",
typeof(TestCustomSnapinTest), "TestCmdletHelp.dll-help.xml"));
            _cmdlets.Add(new CmdletConfigurationEntry("test-helloworld",
typeof(TestHelloWorld), "HelloWorldHelp.dll-help.xml"));
        }

        return _cmdlets;
    }
}

/// <summary>
/// Specify the providers that belong to this custom PowerShell snap-in.
/// </summary>
private Collection<ProviderConfigurationEntry> _providers;
public override Collection<ProviderConfigurationEntry> Providers
{
    get
    {
        if (_providers == null)
        {
            _providers = new Collection<ProviderConfigurationEntry>();
        }

        return _providers;
    }
}

/// <summary>
/// Specify the types that belong to this custom PowerShell snap-in.
/// </summary>
private Collection<TypeConfigurationEntry> _types;
public override Collection<TypeConfigurationEntry> Types
{
    get
    {
        if (_types == null)
        {
            _types = new Collection<TypeConfigurationEntry>();
        }

        return _types;
    }
}

/// <summary>
```

```
/// Specify the formats that belong to this custom PowerShell snap-in.  
/// </summary>  
private Collection<FormatConfigurationEntry> _formats;  
public override Collection<FormatConfigurationEntry> Formats  
{  
    get  
    {  
        if (_formats == null)  
        {  
            _formats = new Collection<FormatConfigurationEntry>();  
        }  
  
        return _formats;  
    }  
}  
}
```

For more information about registering snap-ins, see [How to Register Cmdlets, Providers, and Host Applications](#) in the [Windows PowerShell Programmer's Guide](#).

[Windows PowerShell Shell SDK](#)

Importing a PowerShell Module

Article • 09/17/2021

Once you have installed a module on a system, you will likely want to import the module. Importing is the process that loads the module into active memory, so that a user can access that module in their PowerShell session. In PowerShell 2.0, you can import a newly-installed PowerShell module with a call to [Import-Module](#) cmdlet. In PowerShell 3.0, PowerShell is able to implicitly import a module when one of the functions or cmdlets in the module is called by a user. Note that both versions assume that you install your module in a location where PowerShell is able to find it; for more information, see [Installing a PowerShell Module](#). You can use a module manifest to restrict what parts of your module are exported, and you can use parameters of the `Import-Module` call to restrict what parts are imported.

Importing a Snap-In (PowerShell 1.0)

Modules did not exist in PowerShell 1.0: instead, you had to register and use snap-ins. However, it is not recommended that you use this technology at this point, as modules are generally easier to install and import. For more information, see [How to Create a Windows PowerShell Snap-in](#).

Importing a Module with Import-Module (PowerShell 2.0)

PowerShell 2.0 uses the appropriately-named [Import-Module](#) cmdlet to import modules. When this cmdlet is run, Windows PowerShell searches for the specified module within the directories specified in the `PSModulePath` variable. When the specified directory is found, Windows PowerShell searches for files in the following order: module manifest files (`.psd1`), script module files (`.psm1`), binary module files (`.dll`). For more information about adding directories to the search, see [about_PSModulePath](#). The following code describes how to import a module:

```
PowerShell
Import-Module myModule
```

Assuming that `myModule` was located in the `PSModulePath`, PowerShell would load `myModule` into active memory. If `myModule` was not located on a `PSModulePath` path,

you could still explicitly tell PowerShell where to find it:

```
PowerShell
```

```
Import-Module -Name C:\myRandomDirectory\myModule -Verbose
```

You can also use the `-Verbose` parameter to identify what is being exported out of the module, and what is being imported into active memory. Both exports and imports restrict what is exposed to the user: the difference is who is controlling the visibility. Essentially, exports are controlled by code within the module. In contrast, imports are controlled by the `Import-Module` call. For more information, see [Restricting Members That Are Imported](#), below.

Implicitly Importing a Module (PowerShell 3.0)

Beginning in Windows PowerShell 3.0, modules are imported automatically when any cmdlet or function in the module is used in a command. This feature works on any module in a directory that is included in the value of the **PSModulePath** environment variable. If you do not save your module on a valid path however, you can still load them using the explicit `Import-Module` option, described above.

The following actions trigger automatic importing of a module, also known as "module auto-loading."

- Using a cmdlet in a command. For example, typing `Get-ExecutionPolicy` imports the Microsoft.PowerShell.Security module that contains the `Get-ExecutionPolicy` cmdlet.
- Using the `Get-Command` cmdlet to get the command. For example, typing `Get-Command Get-JobTrigger` imports the **PSScheduledJob** module that contains the `Get-JobTrigger` cmdlet. A `Get-Command` command that includes wildcard characters is considered to be discovery and does not trigger importing of a module.
- Using the `Get-Help` cmdlet to get help for a cmdlet. For example, typing `Get-Help Get-WinEvent` imports the Microsoft.PowerShell.Diagnostics module that contains the `Get-WinEvent` cmdlet.

To support automatic importing of modules, the `Get-Command` cmdlet gets all cmdlets and functions in all installed modules, even if the module is not imported into the session. For more information, see the help topic for the `Get-Command` cmdlet.

The Importing Process

When a module is imported, a new session state is created for the module, and a `System.Management.Automation.PSModuleInfo` object is created in memory. A session-state is created for each module that is imported (this includes the root module and any nested modules). The members that are exported from the root module, including any members that were exported to the root module by any nested modules, are then imported into the caller's session state.

The metadata of members that are exported from a module have a `ModuleName` property. This property is populated with the name of the module that exported them.

⚠️ Warning

If the name of an exported member uses an unapproved verb or if the name of the member uses restricted characters, a warning is displayed when the [Import-Module](#) cmdlet is run.

By default, the [Import-Module](#) cmdlet does not return any objects to the pipeline. However, the cmdlet supports a `PassThru` parameter that can be used to return a `System.Management.Automation.PSModuleInfo` object for each module that is imported. To send output to the host, users should run the [Write-Host](#) cmdlet.

Restricting the Members That Are Imported

When a module is imported by using the [Import-Module](#) cmdlet, by default, all exported module members are imported into the session, including any commands exported to the module by a nested module. By default, variables and aliases are not exported. To restrict the members that are exported, use a [module manifest](#). To restrict the members that are imported, use the following parameters of the `Import-Module` cmdlet.

- **Function:** This parameter restricts the functions that are exported. (If you are using a module manifest, see the `FunctionsToExport` key.)
- **`Cmdlet`:** This parameter restricts the cmdlets that are exported (If you are using a module manifest, see the `CmdletsToExport` key.)
- **Variable:** This parameter restricts the variables that are exported (If you are using a module manifest, see the `VariablesToExport` key.)
- **Alias:** This parameter restricts the aliases that are exported (If you are using a module manifest, see the `AliasesToExport` key.)

[Writing a Windows PowerShell Module](#)

Windows PowerShell Provider Quickstart

Article • 03/24/2025

This topic explains how to create a Windows PowerShell provider that has basic functionality of creating a new drive. For general information about providers, see [Windows PowerShell Provider Overview](#). For examples of providers with more complete functionality, see [Provider Samples](#).

Writing a basic provider

The most basic functionality of a Windows PowerShell provider is to create and remove drives. In this example, we implement the

`System.Management.Automation.Provider.DriveCmdletProvider.NewDrive*` and `System.Management.Automation.Provider.DriveCmdletProvider.RemoveDrive*` methods of the `System.Management.Automation.Provider.DriveCmdletProvider` class. You will also see how to declare a provider class.

When you write a provider, you can specify default drives—drives that are created automatically when the provider is available. You also define a method to create new drives that use that provider.

The examples provided in this topic are based on the [AccessDBProviderSample02](#) sample, which is part of a larger sample that represents an Access database as a Windows PowerShell drive.

Setting up the project

In Visual Studio, create a Class Library project named `AccessDBProviderSample`. Complete the following steps to configure your project so that Windows PowerShell will start, and the provider will be loaded into the session, when you build and start your project.

Configure the provider project

1. Add the `System.Management.Automation` assembly as a reference to your project.
2. Click **Project > AccessDBProviderSample Properties > Debug**. In **Start project**, click **Start external program**, and navigate to the Windows PowerShell executable (typically `C:\Windows\System32\WindowsPowerShell\v1.0\powershell.exe`).

3. Under **Start Options**, enter the following into the **Command line arguments** box:

```
-NoExit -Command "[Reflection.Assembly]::LoadFrom(AccessDBProviderSample.dll') | Import-Module"
```

Declaring the provider class

Our provider derives from the

[System.Management.Automation.Provider.DriveCmdletProvider](#) class. Most providers that provide real functionality (accessing and manipulating items, navigating the data store, and getting and setting content of items) derive from the

[System.Management.Automation.Provider.NavigationCmdletProvider](#) class.

In addition to specifying that the class derives from

[System.Management.Automation.Provider.DriveCmdletProvider](#), you must decorate it with the [System.Management.Automation.Provider.CmdletProviderAttribute](#) as shown in the example.

C#

```
namespace Microsoft.Samples.PowerShell.Providers
{
    using System;
    using System.Data;
    using System.Data.Odbc;
    using System.IO;
    using System.Management.Automation;
    using System.Management.Automation.Provider;

    #region AccessDBProvider

    [CmdletProvider("AccessDB", ProviderCapabilities.None)]
    public class AccessDBProvider : DriveCmdletProvider
    {

    }
}
```

Implementing NewDrive

The [System.Management.Automation.Provider.DriveCmdletProvider.NewDrive*](#) method is called by the Windows PowerShell engine when a user calls the [Microsoft.PowerShell.Commands.NewPSDriveCommand](#) cmdlet specifying the name of your provider. The PSDriveInfo parameter is passed by the Windows PowerShell engine, and the method returns the new drive to the Windows PowerShell engine. This method must be declared within the class created above.

The method first checks to make sure both the drive object and the drive root that were passed in exist, returning `null` if either of them do not. It then uses a constructor of the internal class `AccessDBPSDriveInfo` to create a new drive and a connection to the Access database the drive represents.

C#

```
protected override PSDriveInfo NewDrive(PSDriveInfo drive)
{
    // Check if the drive object is null.
    if (drive == null)
    {
        WriteError(new ErrorRecord(
            new ArgumentNullException("drive"),
            "NullDrive",
            ErrorCategory.InvalidArgument,
            null));

        return null;
    }

    // Check if the drive root is not null or empty
    // and if it is an existing file.
    if (String.IsNullOrEmpty(drive.Root) || (File.Exists(drive.Root) ==
false))
    {
        WriteError(new ErrorRecord(
            new ArgumentException("drive.Root"),
            "NoRoot",
            ErrorCategory.InvalidArgument,
            drive));

        return null;
    }

    // Create a new drive and create an ODBC connection to the new drive.
    AccessDBPSDriveInfo accessDBPSDriveInfo = new
AccessDBPSDriveInfo(drive);
    OdbcConnectionStringBuilder builder = new
OdbcConnectionStringBuilder();

    builder.Driver = "Microsoft Access Driver (*.mdb)";
    builder.Add("DBQ", drive.Root);

    OdbcConnection conn = new OdbcConnection(builder.ConnectionString);
    conn.Open();
    accessDBPSDriveInfo.Connection = conn;

    return accessDBPSDriveInfo;
}
```

The following is the AccessDBPSDriveInfo internal class that includes the constructor used to create a new drive, and contains the state information for the drive.

```
C#  
  
internal class AccessDBPSDriveInfo : PSDriveInfo  
{  
    /// <summary>  
    /// A reference to the connection to the database.  
    /// </summary>  
    private OdbcConnection connection;  
  
    /// <summary>  
    /// Initializes a new instance of the AccessDBPSDriveInfo class.  
    /// The constructor takes a single argument.  
    /// </summary>  
    /// <param name="driveInfo">Drive defined by this provider</param>  
    public AccessDBPSDriveInfo(PSDriveInfo driveInfo)  
        : base(driveInfo)  
    {  
    }  
  
    /// <summary>  
    /// Gets or sets the ODBC connection information.  
    /// </summary>  
    public OdbcConnection Connection  
    {  
        get { return this.connection; }  
        set { this.connection = value; }  
    }  
}
```

Implementing RemoveDrive

The [System.Management.Automation.Provider.DriveCmdletProvider.RemoveDrive](#)* method is called by the Windows PowerShell engine when a user calls the [Microsoft.PowerShell.Commands.RemovePSDriveCommand](#) cmdlet. The method in this provider closes the connection to the Access database.

```
C#  
  
protected override PSDriveInfo RemoveDrive(PSDriveInfo drive)  
{  
    // Check if drive object is null.  
    if (drive == null)  
    {  
        WriteError(new ErrorRecord(  
            new ArgumentNullException("drive"),  
            "NullDrive",  
            ErrorCategory.InvalidArgument,
```

```
        drive));  
  
    return null;  
}  
  
// Close the ODBC connection to the drive.  
AccessDBPSDriveInfo accessDBPSDriveInfo = drive as  
AccessDBPSDriveInfo;  
  
if (accessDBPSDriveInfo == null)  
{  
    return null;  
}  
  
accessDBPSDriveInfo.Connection.Close();  
  
return accessDBPSDriveInfo;  
}
```

Windows PowerShell Provider Overview

Article • 09/17/2021

A Windows PowerShell provider allows any data store to be exposed like a file system as if it were a mounted drive. For example, the built-in Registry provider allows you to navigate the registry like you would navigate the `c` drive of your computer. A provider can also override the `Item` cmdlets (for example, `Get-Item`, `Set-Item`, etc.) such that the data in your data store can be treated like files and directories are treated when navigating a file system. For more information about providers and drives, and the built-in providers in Windows PowerShell, see [about_Providers](#).

Providers and Drives

A Provider defines the logic that is used to access, navigate, and edit a data store, while a drive specifies a specific entry point to a data store (or a portion of a data store) that is of the type defined by the provider. For example, the Registry provider allows you to access hives and keys in a registry, and the HKLM and HKCU drives specify the corresponding hives within the registry. The HKLM and HKCU drives both use the Registry provider.

When you write a provider, you can specify default drives—drives that are created automatically when the provider is available. You also define a method to create new drives that use that provider.

Type of Providers

There are several types of providers, each of which provides a different level of functionality. A provider is implemented as a class that derives from one of the descendants of the [System.Management.Automation.SessionStateCategory CmdletProvider](#) class. For information about the different types of providers, see [Provider types](#).

Provider cmdlets

Providers can implement methods that correspond to cmdlets, creating custom behaviors for those cmdlets when used in a drive for that provider. Depending on the type of provider, different sets of cmdlets are available. For a complete list of the cmdlets available for customization in providers, see [Provider cmdlets](#).

Provider paths

Users navigate provider drives like file systems. Because of this, they expect the syntax of paths to correspond to the paths used in file system navigation. When a user runs a provider cmdlet, they specify a path to the item to be accessed. The path that is specified can be interpreted in several ways. A provider should support one or more of the following path types.

Drive-qualified paths

A drive-qualified path is a combination of the item name, the container and subcontainers in which the item is located, and the Windows PowerShell drive through which the item is accessed. (Drives are defined by the provider that is used to access the data store. This path starts with the drive name followed by a colon (:). For example:

```
Get-ChildItem C:
```

Provider-qualified paths

To allow the Windows PowerShell engine to initialize and uninitialized your provider, the provider must support a provider-qualified path. For example, the user can initialize and uninitialized the FileSystem provider because it defines the following provider-qualified path: `FileSystem::\\uncshare\abc\bar`.

Provider-direct paths

To allow remote access to your Windows PowerShell provider, it should support a provider-direct path to pass directly to the Windows PowerShell provider for the current location. For example, the registry Windows PowerShell provider can use `\\server\regkeypath` as a provider-direct path.

Provider-internal paths

To allow the provider cmdlet to access data using non-Windows PowerShell application programming interfaces (APIs), your Windows PowerShell provider should support a provider-internal path. This path is indicated after the ":" in the provider-qualified path. For example, the provider-internal path for the FileSystem Windows PowerShell provider is `\\uncshare\abc\bar`.

Overriding cmdlet parameters

The behavior of some provider-specific cmdlets can be overridden by a provider. For a list of parameters that can be overridden, and how to override them in your provider class, see [Provider cmdlet parameters](#)

Dynamic parameters

Providers can define dynamic parameters that are added to a provider cmdlet when the user specifies a certain value for one of the static parameters of the cmdlet. A provider does this by implementing one or more dynamic parameter methods. For a list of cmdlet parameters that can be used to add dynamic parameter, and the methods used to implement them, see [Provider cmdlet dynamic parameters](#).

Provider capabilities

The [System.Management.Automation.Provider.ProviderCapabilities](#) enumeration defines a number of capabilities that providers can support. These include the ability to use wildcards, filter items, and support transactions. To specify capabilities for a provider, add a list of values of the [System.Management.Automation.Provider.ProviderCapabilities](#) enumeration, combined with a logical `OR` operation, as the [System.Management.Automation.Provider.CmdletProviderAttribute.ProviderCapabilities*](#) property (the second parameter of the attribute) of the [System.Management.Automation.Provider.CmdletProviderAttribute](#) attribute for your provider class. For example, the following attribute specifies that the provider supports the [System.Management.Automation.Provider.ProviderCapabilities ShouldProcess](#) and [System.Management.Automation.Provider.ProviderCapabilities Transactions](#) capabilities.

```
C#
```

```
[CmdletProvider(RegistryProvider.ProviderName,  
ProviderCapabilities.ShouldProcess | ProviderCapabilities.Transactions)]
```

Provider cmdlet help

When writing a provider, you can implement your own Help for the provider cmdlets that you support. This includes a single help topic for each provider cmdlet or multiple versions of a help topic for cases where the provider cmdlet acts differently based on the use of dynamic parameters. To support provider cmdlet-specific help, your provider must implement the [System.Management.Automation.Provider.ICmdletProviderSupportsHelp](#) interface.

The Windows PowerShell engine calls the [System.Management.Automation.Provider.ICmdletProviderSupportsHelp.GetHelpMaml](#)* method to display the Help topic for your provider cmdlets. The engine provides the name of the cmdlet that the user specified when running the `Get-Help` cmdlet and the current path of the user. The current path is required if your provider implements different versions of the same provider cmdlet for different drives. The method must return a string that contains the XML for the cmdlet Help.

The content for the Help file is written using PSMAML XML. This is the same XML schema that is used for writing Help content for stand-alone cmdlets. Add the content for your custom cmdlet Help to the Help file for your provider under the `CmdletHelpPaths` element. The following example shows the `command` element for a single provider cmdlet, and it shows how you specify the name of the provider cmdlet that your provider supports

XML

```
<CmdletHelpPaths>
  <command:command>
    <command:details>
      <command:name>ProviderCmdletName</command:name>
      <command:verb>Verb</command:verb>
      <command:noun>Noun</command:noun>
      <command:details>
    </command:command>
  <CmdletHelpPath>
```

[Windows PowerShell Provider Functionality](#)

[Provider Cmdlets](#)

[Writing a Windows PowerShell Provider](#)

Provider types

Article • 01/31/2024

Providers define their basic functionality by changing how the provider cmdlets, provided by PowerShell, perform their actions. For example, providers can use the default functionality of the `Get-Item` cmdlet, or they can change how that cmdlet operates when retrieving items from the data store. The provider functionality described in this document includes functionality defined by overwriting methods from specific provider base classes and interfaces.

ⓘ Note

For provider features that are pre-defined by PowerShell, see [Provider capabilities](#).

Drive-enabled providers

Drive-enabled providers specify the default drives available to the user and allow the user to add or remove drives. In most cases, providers are drive-enabled providers because they require some default drive to access the data store. However, when writing your own provider you might or might not want to allow the user to create and remove drives.

To create a drive-enabled provider, your provider class must derive from the [System.Management.Automation.Provider.DriveCmdletProvider](#) class or another class that derives from that class. The **DriveCmdletProvider** class defines the following methods for implementing the default drives of the provider and supporting the `New-PSDrive` and `Remove-PSDrive` cmdlets. In most cases, to support a provider cmdlet you must overwrite the method that the PowerShell engine calls to invoke the cmdlet, such as the `NewDrive` method for the `New-PSDrive` cmdlet, and optionally you can overwrite a second method, such as `NewDriveDynamicParameters`, for adding dynamic parameters to the cmdlet.

- The `InitializeDefaultDrives` method defines the default drives that are available to the user whenever the provider is used.
- The `NewDrive` and `NewDriveDynamicParameters` methods defines how your provider supports the `New-PSDrive` provider cmdlet. This cmdlet allows the user to create drives to access the data store.

- The [RemoveDrive](#) method defines how your provider supports the `Remove-PSDrive` provider cmdlet. This cmdlet allows the user to remove drives from the data store.

Item-enabled providers

Item-enabled providers allow the user to get, set, or clear the items in the data store. An "item" is an element of the data store that the user can access or manage independently. To create an item-enabled provider, your provider class must derive from the [System.Management.Automation.Provider.ItemCmdletProvider](#) class or another class that derives from that class.

The [ItemCmdletProvider](#) class defines the following methods for implementing specific provider cmdlets. In most cases, to support a provider cmdlet you must overwrite the method that the PowerShell engine calls to invoke the cmdlet, such as the `ClearItem` method for the `Clear-Item` cmdlet, and optionally you can overwrite a second method, such as `ClearItemDynamicParameters`, for adding dynamic parameters to the cmdlet.

- The [ClearItem](#) and [ClearItemDynamicParameters](#) methods define how your provider supports the `Clear-Item` provider cmdlet. This cmdlet allows the user to remove of the value of an item in the data store.
- The [GetItem](#) and [GetItemDynamicParameters](#) methods define how your provider supports the `Get-Item` provider cmdlet. This cmdlet allows the user to retrieve data from the data store.
- The [SetItem](#) and [SetItemDynamicParameters](#) methods define how your provider supports the `Set-Item` provider cmdlet. This cmdlet allows the user to update the values of items in the data store.
- The [InvokeDefaultAction](#) and [InvokeDefaultActionDynamicParameters](#) methods define how your provider supports the `Invoke-Item` provider cmdlet. This cmdlet allows the user to perform the default action specified by the item.
- The [ItemExists](#) and [ItemExistsDynamicParameters](#) methods define how your provider supports the `Test-Path` provider cmdlet. This cmdlet allows the user to determine if all the elements of a path exist.

In addition to the methods used to implement provider cmdlets, the [ItemCmdletProvider](#) class also defines the following methods:

- The [ExpandPath](#) method allows the user to use wildcards when specifying the provider path.

- The [IsValidPath](#) is used to determine if a path is syntactically and semantically valid for the provider.

Container-enabled providers

Container-enabled providers allow the user to manage items that are containers. A container is a group of child items under a common parent item. To create a container-enabled provider, your provider class must derive from the [System.Management.Automation.Provider.ContainerCmdletProvider](#) class or another class that derives from that class.

Important

Container-enabled providers can't access data stores that contain nested containers. If a child item of a container is another container, you must implement a navigation-enabled provider.

The [ContainerCmdletProvider](#) class defines the following methods for implementing specific provider cmdlets. In most cases, to support a provider cmdlet you must overwrite the method that the PowerShell engine calls to invoke the cmdlet, such as the `CopyItem` method for the `Copy-Item` cmdlet, and optionally you can overwrite a second method, such as `CopyItemDynamicParameters`, for adding dynamic parameters to the cmdlet.

- The [CopyItem](#) and [CopyItemDynamicParameters](#) methods define how your provider supports the `Copy-Item` provider cmdlet. This cmdlet allows the user to copy an item from one location to another.
- The [GetChildItems](#) and [GetChildItemsDynamicParameters](#) methods define how your provider supports the `Get-ChildItem` provider cmdlet. This cmdlet allows the user to retrieve the child items of the parent item.
- The [GetChildNames](#) and [GetChildNamesDynamicParameters](#) methods define how your provider supports the `Get-ChildItem` provider cmdlet if its `Name` parameter is specified.
- The [NewItem](#) and [NewItemDynamicParameters](#) methods define how your provider supports the `New-Item` provider cmdlet. This cmdlet allows the user to create new items in the data store.

- The [RemoveItem](#) and [RemoveItemDynamicParameters](#) methods define how your provider supports the `Remove-Item` provider cmdlet. This cmdlet allows the user to remove items from the data store.
- The [RenameItem](#) and [RenameItemDynamicParameters](#) methods define how your provider supports the `Rename-Item` provider cmdlet. This cmdlet allows the user to rename items in the data store.

In addition to the methods used to implement provider cmdlets, the [ContainerCmdletProvider](#) class also defines the following methods:

- The [HasChildItems](#) method can be used by the provider class to determine whether an item has child items.
- The [ConvertPath](#) method can be used by the provider class to create a new provider-specific path from a specified path.

Navigation-enabled providers

Navigation-enabled providers allow the user to move items in the data store. To create a navigation-enabled provider, your provider class must derive from the [System.Management.Automation.Provider.NavigationCmdletProvider](#) class.

The [NavigationCmdletProvider](#) class defines the following methods for implementing specific provider cmdlets. In most cases, to support a provider cmdlet you must overwrite the method that the PowerShell engine calls to invoke the cmdlet, such as the `MoveItem` method for the `Move-Item` cmdlet, and optionally you can overwrite a second method, such as `MoveItemDynamicParameters`, for adding dynamic parameters to the cmdlet.

- The [MoveItem](#) and [MoveItemDynamicParameters](#) methods define how your provider supports the `Move-Item` provider cmdlet. This cmdlet allows the user to move an item from one location in the store to another location.
- The [MakePath](#) method defines how your provider supports the `Join-Path` provider cmdlet. This cmdlet allows the user to combine a parent and child path segment to create a provider-internal path.

In addition to the methods used to implement provider cmdlets, the [NavigationCmdletProvider](#) class also defines the following methods:

- The [GetChildName](#) method extracts the name of the child node of a path.

- The [GetParentPath](#) method extracts the parent part of a path.
- The [IsItemContainer](#) method determines whether the item is a container item. In this context, a container is a group of child items under a common parent item.
- The [NormalizeRelativePath](#) method returns a path to an item that's relative to a specified base path.

Content-enabled providers

Content-enabled providers allow the user to clear, get, or set the content of items in a data store. For example, the [FileSystem provider](#) allows you to clear, get, and set the content of files in the file system. To create a content enabled provider, your provider class must implement the methods of the [System.Management.Automation.Provider.IContentCmdletProvider](#) interface.

The [IContentCmdletProvider](#) interface defines the following methods for implementing specific provider cmdlets. In most cases, to support a provider cmdlet you must overwrite the method that the PowerShell engine calls to invoke the cmdlet, such as the `ClearContent` method for the `Clear-Content` cmdlet, and optionally you can overwrite a second method, such as `ClearContentDynamicParameters`, for adding dynamic parameters to the cmdlet.

- The [ClearContent](#) and [ClearContentDynamicParameters](#) methods define how your provider supports the `Clear-Content` provider cmdlet. This cmdlet allows the user to delete the content of an item without deleting the item.
- The [GetContentReader](#) and [GetContentReaderDynamicParameters](#) methods define how your provider supports the `Get-Content` provider cmdlet. This cmdlet allows the user to retrieve the content of an item. The `GetContentReader` method returns an [System.Management.Automation.Provider.IContentReader](#) interface that defines the methods used to read the content.
- The [GetContentWriter](#) and [GetContentWriterDynamicParameters](#) methods define how your provider supports the `Set-Content` provider cmdlet. This cmdlet allows the user to update the content of an item. The `GetContentWriter` method returns an [System.Management.Automation.Provider.IContentWriter](#) interface that defines the methods used to write the content.

Property-enabled providers

Property-enabled providers allow the user to manage the properties of the items in the data store. To create a property-enabled provider, your provider class must implement the methods of the [System.Management.Automation.Provider.IPropertyCmdletProvider](#) and [System.Management.Automation.Provider.IDynamicPropertyCmdletProvider](#) interfaces. In most cases, to support a provider cmdlet you must overwrite the method that the PowerShell engine calls to invoke the cmdlet, such as the `ClearProperty` method for the Clear-Property cmdlet, and optionally you can overwrite a second method, such as `ClearPropertyDynamicParameters`, for adding dynamic parameters to the cmdlet.

The **IPropertyCmdletProvider** interface defines the following methods for implementing specific provider cmdlets:

- The [ClearProperty](#) and [ClearPropertyDynamicParameters](#) methods define how your provider supports the `Clear-ItemProperty` provider cmdlet. This cmdlet allows the user to delete the value of a property.
- The [GetProperty](#) and [GetPropertyDynamicParameters](#) methods define how your provider supports the `Get-ItemProperty` provider cmdlet. This cmdlet allows the user to retrieve the property of an item.
- The [SetProperty](#) and [SetPropertyDynamicParameters](#) methods define how your provider supports the `Set-ItemProperty` provider cmdlet. This cmdlet allows the user to update the properties of an item.

The **IDynamicPropertyCmdletProvider** interface defines the following methods for implementing specific provider cmdlets:

- The [CopyProperty](#) and [CopyPropertyDynamicParameters](#) methods define how your provider supports the `Copy-ItemProperty` provider cmdlet. This cmdlet allows the user to copy a property and its value from one location to another.
- The [MoveProperty](#) and [MovePropertyDynamicParameters](#) methods define how your provider supports the `Move-ItemProperty` provider cmdlet. This cmdlet allows the user to move a property and its value from one location to another.
- The [NewProperty](#) and [NewPropertyDynamicParameters](#) methods define how your provider supports the `New-ItemProperty` provider cmdlet. This cmdlet allows the user to create a new property and set its value.
- The [RemoveProperty](#) and [RemovePropertyDynamicParameters](#) methods define how your provider supports the `Remove-ItemProperty` cmdlet. This cmdlet allows the user to delete a property and its value.

- The [RenameProperty](#) and [RenamePropertyDynamicParameters](#) methods define how your provider supports the `Rename-ItemProperty` cmdlet. This cmdlet allows the user to change the name of a property.

Provider cmdlets

Article • 01/31/2024

The cmdlets that the user can run to manage a data store are referred to as provider cmdlets. To support these cmdlets, you need to overwrite some of the methods defined by the base provider classes and interfaces.

Here are the provider cmdlets that can be run by the user:

PSDrive cmdlets

Get-PSDrive

This cmdlet returns the PowerShell drives in the current session. You do not need to overwrite any methods to support this cmdlet.

New-PSDrive

This cmdlet allows the user to create PowerShell drives to access the data store. To support this cmdlet, overwrite the following methods of [System.Management.Automation.Provider.DriveCmdletProvider](#) class:

- [NewDrive](#)
- [NewDriveDynamicParameters](#)

Remove-PSDrive

This cmdlet allows the user to remove PowerShell drives that access the data store. To support this cmdlet, overwrite the [System.Management.Automation.Provider.DriveCmdletProvider.RemoveDrive](#) method.

Item cmdlets

Clear-Item

This cmdlet allows the user to remove the value of an item in the data store. To support this cmdlet, overwrite the following methods of [System.Management.Automation.Provider.ItemCmdletProvider](#) class:

- [ClearItem](#)
- [ClearItemDynamicParameters](#)

Copy-Item

This cmdlet allows the user to copy an item from one location to another. To support this cmdlet, overwrite the following methods of [System.Management.Automation.Provider.ContainerCmdletProvider](#) class:

- [CopyItem](#)
- [CopyItemDynamicParameters](#)

Get-Item

This cmdlet allows the user to retrieve data from the data store. To support this cmdlet, overwrite the following methods of [System.Management.Automation.Provider.ItemCmdletProvider](#) class:

- [GetItem](#)
- [GetItemDynamicParameters](#)

Get-ChildItem

This cmdlet allows the user to retrieve the child items of the parent item. To support this cmdlet, overwrite the following methods of [System.Management.Automation.Provider.ContainerCmdletProvider](#) class:

- [GetChildItems](#)
- [GetChildItemsDynamicParameters](#)
- [GetChildNames](#)
- [GetChildNamesDynamicParameters](#)

Invoke-Item

This cmdlet allows the user to perform the default action specified by the item. To support this cmdlet, overwrite the [System.Management.Automation.Provider.ItemCmdletProvider.InvokeDefaultAction](#) method.

Move-Item

This cmdlet allows the user to move an item from one location to another location. To support this cmdlet, overwrite the following methods of [System.Management.Automation.Provider.NavigationCmdletProvider](#) class:

- [MoveItem](#)
- [MoveItemDynamicParameters](#)

New-ItemProperty

This cmdlet allows the user to create a new item in the data store.

Remove-Item

This cmdlet allows the user to remove items from the data store. To support this cmdlet, overwrite the following methods of

[System.Management.Automation.Provider.ContainerCmdletProvider](#) class:

- [RemoveItem](#)
- [RemoveItemDynamicParameters](#)

Rename-Item

This cmdlet allows the user to rename items in the data store. To support this cmdlet, overwrite the following methods of

[System.Management.Automation.Provider.ContainerCmdletProvider](#) class:

- [RenameItem](#)
- [RenameItemDynamicParameters](#)

Set-Item

This cmdlet allows the user to update the values of items in the data store. To support this cmdlet, overwrite the following methods of

[System.Management.Automation.Provider.ItemCmdletProvider](#) class:

- [SetItem](#)
- [SetItemDynamicParameters](#)

Item content cmdlets

Add-Content

This cmdlet allows the user to add content to an item.

Clear-Content

This cmdlet allows the user to delete content from an item without deleting the item. To support this cmdlet, overwrite the following methods of [System.Management.Automation.Provider.IContentCmdletProvider](#) interface:

- [ClearContent](#)
- [ClearContentDynamicParameters](#)

Get-Content

This cmdlet allows the user to retrieve the content of an item. To support this cmdlet, overwrite the following methods of

[System.Management.Automation.Provider.IContentCmdletProvider](#) interface:

- [GetContentReader](#)
- [GetContentReaderDynamicParameters](#)

The [GetContentReader](#) method returns an

[System.Management.Automation.Provider.IContentReader](#) interface that defines the methods used to read the content.

Set-Content

This cmdlet allows the user to update the content of an item. To support this cmdlet, overwrite the following methods of

[System.Management.Automation.Provider.IContentCmdletProvider](#) interface:

- [GetContentWriter](#)
- [GetContentWriterDynamicParameters](#)

The [GetContentWriter](#) method returns an

[System.Management.Automation.Provider.IContentWriter](#) interface that defines the methods used to write the content.

Item property cmdlets

Clear-ItemProperty

This cmdlet allows the user to delete the value of a property. To support this cmdlet, overwrite the following methods of [System.Management.Automation.Provider.IPropertyCmdletProvider](#) interface:

- [ClearProperty](#)
- [ClearPropertyDynamicParameters](#)

Copy-ItemProperty

This cmdlet allows the user to copy a property and its value from one location to another. To support this cmdlet, overwrite the following methods of [System.Management.Automation.Provider.IDynamicPropertyCmdletProvider](#) interface:

- [CopyProperty](#)
- [CopyPropertyDynamicParameters](#)

Get-ItemProperty

This cmdlet retrieves the properties of an item. To support this cmdlet, overwrite the following methods of

[System.Management.Automation.Provider.IPropertyCmdletProvider](#) interface:

- [GetProperty](#)
- [GetPropertyDynamicParameters](#)

Move-ItemProperty

This cmdlet allows the user to move a property and its value from one location to another. To support this cmdlet, overwrite the following methods of [System.Management.Automation.Provider.IDynamicPropertyCmdletProvider](#) interface:

- [MoveProperty](#)
- [MovePropertyDynamicParameters](#)

New-ItemProperty

This cmdlet allows the user to create a new property and set its value. To support this cmdlet, overwrite the following methods of

[System.Management.Automation.Provider.IDynamicPropertyCmdletProvider](#) interface:

- [NewProperty](#)
- [NewPropertyDynamicParameters](#)

Remove-ItemProperty

This cmdlet allows the user to delete a property and its value. To support this cmdlet, overwrite the following methods of [System.Management.Automation.Provider.IDynamicPropertyCmdletProvider](#) interface:

- [RemoveProperty](#)
- [RemovePropertyDynamicParameters](#)

Rename-ItemProperty

This cmdlet allows the user to change the name of a property. To support this cmdlet, overwrite the following methods of

[System.Management.Automation.Provider.IDynamicPropertyCmdletProvider](#) interface:

- [RenameProperty](#)
- [RenamePropertyDynamicParameters](#)

Set-ItemProperty

This cmdlet allows the user to update the properties of an item. To support this cmdlet, overwrite the following methods of

[System.Management.Automation.Provider.IPropertyCmdletProvider](#) interface:

- [SetProperty](#)
- [SetPropertyDynamicParameters](#)

Location cmdlets

Get-Location

Retrieves information about the current working location. You do not need to overwrite any methods to support this cmdlet.

Pop-Location

This cmdlet changes the current location to the location most recently pushed onto the stack. You do not need to overwrite any methods to support this cmdlet.

Push-Location

This cmdlet adds the current location to the top of a list of locations (a "stack"). You do not need to overwrite any methods to support this cmdlet.

Set-Location

This cmdlet sets the current working location to a specified location. You do not need to overwrite any methods to support this cmdlet.

Path cmdlets

Join-Path

This cmdlet allows the user to combine a parent and child path segment to create a provider-internal path. To support this cmdlet, overwrite the [System.Management.Automation.Provider.NavigationCmdletProvider.MakePath](#) method.

Convert-Path

This cmdlet converts a path from a PowerShell path to a PowerShell provider path.

Split-Path

Returns the specified part of a path.

Resolve-Path

Resolves the wildcard characters in a path, and displays the path contents.

Test-Path

This cmdlet determines whether all elements of a path exist. To support this cmdlet, overwrite the following methods of [System.Management.Automation.Provider.ItemCmdletProvider](#) class:

- [ItemExists](#)
- [ItemExistsDynamicParameters](#)

PSProvider cmdlets

Get-PSProvider

This cmdlet returns information about the providers available in the session. You do not need to overwrite any methods to support this cmdlet.

Provider cmdlet parameters

Article • 03/24/2025

Provider cmdlets come with a set of static parameters that are available to all providers that support the cmdlet, as well as dynamic parameters that are added when the user specifies a certain value for certain static parameters of the provider cmdlet.

Provider Cmdlet Static Parameters

Static parameters are defined by Windows PowerShell. A large set of these parameters is implemented by Windows PowerShell to provide consistency across all the providers and to provide a simpler development experience. Examples of these parameters include the `LiteralPath`, `Exclude`, and `Include` parameters of the `Get-Item` cmdlet. A smaller set of these parameters can be overwritten to provide actions that are specific to your provider. Examples of these parameters include the `Path` and `Value` parameter of the `Set-Item` cmdlet. Here is a list of the parameters that can be overwritten for the provider cmdlets.

`Clear-Content` cmdlet You can define how your provider will use the values passed to the `Path` parameter of the `Clear-Content` cmdlet by implementing the [System.Management.Automation.Provider.IContentCmdletProvider.ClearContent*](#) method.

`Clear-Item` cmdlet You can define how your provider will use the values passed to the `Path` parameter of the `Clear-Item` cmdlet by implementing the [System.Management.Automation.Provider.ItemCmdletProvider.ClearItem*](#) method.

`Clear-ItemProperty` cmdlet You can define how your provider will use the values passed to the `Path` and `Name` parameters of the `Clear-ItemProperty` cmdlet by implementing the [System.Management.Automation.Provider.IPropertyCmdletProvider.ClearProperty*](#) method.

`Copy-Item` cmdlet You can define how your provider will use the values passed to the `Path`, `Destination`, and `Recurse` parameters of the `Copy-Item` cmdlet by implementing the [System.Management.Automation.Provider.ContainerCmdletProvider.CopyItem](#) method.

`Get-ChildItems` cmdlet You can define how your provider will use the values passed to the `Path` and `Recurse` parameters of the `Get-ChildItem` cmdlet by implementing the [System.Management.Automation.Provider.ContainerCmdletProvider.GetChildItems*](#) and

`System.Management.Automation.Provider.ContainerCmdletProvider.GetChildNames*` methods.

`Get-Content` cmdlet You can define how your provider will use the values passed to the `Path` parameter of the `Get-Content` cmdlet by implementing the `System.Management.Automation.Provider.IContentCmdletProvider.GetContentReader*` method.

`Get-Item` cmdlet You can define how your provider will use the values passed to the `Path` parameter of the `Get-Item` cmdlet by implementing the `System.Management.Automation.Provider.ItemCmdletProvider.GetItem*` method.

`Get-ItemProperty` cmdlet You can define how your provider will use the values passed to the `Path` and `Name` parameters of the `Get-ItemProperty` cmdlet by implementing the `System.Management.Automation.Provider.IPropertyCmdletProvider.GetProperty*` method.

`Invoke-Item` cmdlet You can define how your provider will use the values passed to the `Path` parameter of the `Invoke-Item` cmdlet by implementing the `System.Management.Automation.Provider.ItemCmdletProvider.InvokeDefaultAction*` method.

`Move-Item` cmdlet You can define how your provider will use the values passed to the `Path` and `Destination` parameters of the `Move-Item` cmdlet by implementing the `System.Management.Automation.Provider.NavigationCmdletProvider.MoveItem*` method.

`New-Item` cmdlet You can define how your provider will use the values passed to the `Path`, `ItemType`, and `Value` parameters of the `New-Item` cmdlet by implementing the `System.Management.Automation.Provider.ContainerCmdletProvider.NewItem*` method.

`New-ItemProperty` cmdlet You can define how your provider will use the values passed to the `Path`, `Name`, `.PropertyType`, and `Value` parameters of the `New-ItemProperty` cmdlet by implementing the `Microsoft.PowerShell.Commands.RegistryProvider.NewProperty*` method.

`Remove-Item` You can define how your provider will use the values passed to the `Path` and `Recurse` parameters of the `Remove-Item` cmdlet by implementing the `System.Management.Automation.Provider.ContainerCmdletProvider.RemoveItem*` method.

`Remove-ItemProperty` You can define how your provider will use the values passed to the `Path` and `Name` parameters of the `Remove-ItemProperty` cmdlet by implementing the [System.Management.Automation.Provider.IDynamicPropertyCmdletProvider.RemoveProperty*](#) method.

`Rename-Item` cmdlet You can define how your provider will use the values passed to the `Path` and `NewName` parameters of the `Rename-Item` cmdlet by implementing the [System.Management.Automation.Provider.ContainerCmdletProvider.RenameItem*](#) method.

`Rename-ItemProperty` You can define how your provider will use the values passed to the `Path`, `NewName`, and `Name` parameters of the `Rename-ItemProperty` cmdlet by implementing the [System.Management.Automation.Provider.IDynamicPropertyCmdletProvider.RenameProperty*](#) method.

`Set-Content` cmdlet You can define how your provider will use the values passed to the `Path` parameter of the `Set-Content` cmdlet by implementing the [System.Management.Automation.Provider.IContentCmdletProvider.GetContentWriter*](#) method.

`Set-Item` cmdlet You can define how your provider will use the values passed to the `Path` and `Value` parameters of the `Set-Item` cmdlet by implementing the [System.Management.Automation.Provider.ItemCmdletProvider.SetItem*](#) method.

`Set-ItemProperty` cmdlet You can define how your provider will use the values passed to the `Path` and `Value` parameters of the `Set-Item` cmdlet by implementing the [System.Management.Automation.Provider.IPropertyCmdletProvider SetProperty*](#) method.

`Test-Path` cmdlet You can define how your provider will use the values passed to the `Path` parameter of the `Test-Path` cmdlet by implementing the [System.Management.Automation.Provider.ItemCmdletProvider.InvokeDefaultAction*](#) method.

In addition, you cannot specify the characteristics of these parameters, such as whether they are optional or required, nor can you give these parameters an alias or specify any of the validation attributes. In contrast, you can specify parameter characteristics in stand-alone cmdlets by using attributes such as the `Parameters` attribute.

Provider Cmdlet Dynamic Parameters

Dynamic parameters for cmdlet providers are similar to dynamic providers for stand-alone cmdlets. In both cases, the parameters are added to the cmdlet when the user specifies a certain value for one of the default parameters, such as the `path` parameter. However, not all of the static parameters can be used to trigger the addition of dynamic parameters. For more information about dynamic parameters, see [Provider Cmdlet Dynamic Parameters](#).

Provider cmdlet dynamic parameters

Article • 01/31/2024

Providers can define dynamic parameters that are added to a provider cmdlet when the user specifies a certain value for one of the static parameters of the cmdlet. For example, a provider can add different dynamic parameters based on what path the user specifies when they call the `Get-Item` or `Set-Item` provider cmdlets.

Dynamic Parameter Methods

Dynamic parameters are defined by implementing one of the dynamic parameter methods, such as the

`System.Management.Automation.Provider.ItemCmdletProvider.GetItemDynamicParameters*` and

`System.Management.Automation.Provider.SetItemDynamicParameters.SetItemDynamicParameters*` methods. These methods return an object that has public properties that are decorated with attributes similar to those of stand-alone cmdlets. Here is an example of an implementation of the

`System.Management.Automation.Provider.ItemCmdletProvider.GetItemDynamicParameters*` method taken from the Certificate provider:

C#

```
protected override object GetItemDynamicParameters(string path)
{
    return new CertificateProviderDynamicParameters();
}
```

Unlike the static parameters of provider cmdlets, you can specify the characteristics of these parameters in the same way that parameters are defined in stand-alone cmdlets. Here is an example of a dynamic parameter class taken from the Certificate provider:

C#

```
internal sealed class CertificateProviderDynamicParameters
{
    /// <summary>
    /// Dynamic parameter the controls whether we only return
    /// code signing certs.
    /// </summary>
    [Parameter()]
    public SwitchParameter CodeSigningCert
    {
```

```

    get
    {
        {
            return codeSigningCert;
        }
    }

    set
    {
        {
            codeSigningCert = value;
        }
    }
}

private SwitchParameter codeSigningCert = new SwitchParameter();
}

```

Dynamic Parameters

Here is a list of the static parameters that can be used to add dynamic parameters.

- `Clear-Content` cmdlet - You can define dynamic parameters that are triggered by the `Path` parameter of the Clear-Clear cmdlet by implementing the `System.Management.Automation.Provider.IContentCmdletProvider.ClearContentDynamicParameters*` method.
- `Clear-Item` cmdlet - You can define dynamic parameters that are triggered by the `Path` parameter of the `Clear-Item` cmdlet by implementing the `System.Management.Automation.Provider.ItemCmdletProvider.ClearItemDynamicParameters*` method.
- `Clear-ItemProperty` cmdlet - You can define dynamic parameters that are triggered by the `Path` parameter of the `Clear-ItemProperty` cmdlet by implementing the `System.Management.Automation.Provider.IPropertyCmdletProvider.ClearPropertyDynamicParameters*` method.
- `Copy-Item` cmdlet - You can define dynamic parameters that are triggered by the `Path`, `Destination`, and `Recurse` parameters of the `Copy-Item` cmdlet by implementing the `System.Management.Automation.Provider.ContainerCmdletProvider.CopyItemDynamicParameters*` method.

- `Get-ChildItem` cmdlet - You can define dynamic parameters that are triggered by the `Path` and `Recurse` parameters of the `Get-ChildItem` cmdlet by implementing the `System.Management.Automation.Provider.ContainerCmdletProvider.GetChildItemsDynamicParameters*` and `System.Management.Automation.Provider.ContainerCmdletProvider.GetChildNamesDynamicParameters*` methods.
- `Get-Content` cmdlet - You can define dynamic parameters that are triggered by the `Path` parameter of the `Get-Content` cmdlet by implementing the `System.Management.Automation.Provider.IContentCmdletProvider.GetContentReaderDynamicParameters*` method.
- `Get-Item` cmdlet - You can define dynamic parameters that are triggered by the `Path` parameter of the `Get-Item` cmdlet by implementing the `System.Management.Automation.Provider.ItemCmdletProvider.GetItemDynamicParameters*` method.
- `Get-ItemProperty` cmdlet - You can define dynamic parameters that are triggered by the `Path` and `Name` parameters of the `Get-ItemProperty` cmdlet by implementing the `System.Management.Automation.Provider.IPropertyCmdletProvider.GetPropertyDynamicParameters*` method.
- `Invoke-Item` cmdlet - You can define dynamic parameters that are triggered by the `Path` parameter of the `Invoke-Item` cmdlet by implementing the `System.Management.Automation.Provider.ItemCmdletProvider.InvokeDefaultActionDynamicParameters*` method.
- `Move-Item` cmdlet - You can define dynamic parameters that are triggered by the `Path` and `Destination` parameters of the `Move-Item` cmdlet by implementing the `System.Management.Automation.Provider.NavigationCmdletProvider.MoveItemDynamicParameters*` method.
- `New-Item` cmdlet - You can define dynamic parameters that are triggered by the `Path`, `ItemType`, and `Value` parameters of the `New-Item` cmdlet by implementing the `System.Management.Automation.Provider.ContainerCmdletProvider.NewItemDynamicParameters*` method.
- `New-ItemProperty` cmdlet - You can define dynamic parameters that are triggered by the `Path`, `Name`, `.PropertyType`, and `Value` parameters of the `New-ItemProperty`

cmdlet by implementing the `System.Management.Automation.Provider.IDynamicPropertyCmdletProvider.NewPropertyDynamicParameters*` method.

- `New-PSDrive` cmdlet - You can define dynamic parameters that are triggered by the `System.Management.Automation.PSDriveInfo` object returned by the `New-PSDrive` cmdlet by implementing the `System.Management.Automation.Provider.DriveCmdletProvider.NewDriveDynamicParameters*` method.
- `Remove-Item` cmdlet - You can define dynamic parameters that are triggered by the `Path` and `Recurse` parameters of the `Remove-Item` cmdlet by implementing the `System.Management.Automation.Provider.ContainerCmdletProvider.RemoveItemDynamicParameters*` method.
- `Remove-ItemProperty` cmdlet - You can define dynamic parameters that are triggered by the `Path` and `Name` parameters of the `Remove-ItemProperty` cmdlet by implementing the `System.Management.Automation.Provider.IDynamicPropertyCmdletProvider.RemovePropertyDynamicParameters*` method.
- `Rename-Item` cmdlet - You can define dynamic parameters that are triggered by the `Path` and `NewName` parameters of the `Rename-Item` cmdlet by implementing the `System.Management.Automation.Provider.ContainerCmdletProvider.RenameItemDynamicParameters*` method.
- `Rename-ItemProperty` - You can define dynamic parameters that are triggered by the `Path`, `Name`, and `NewName` parameters of the `Rename-ItemProperty` cmdlet by implementing the `System.Management.Automation.Provider.IDynamicPropertyCmdletProvider.RenamePropertyDynamicParameters*` method.
- `Set-Content` cmdlet - You can define dynamic parameters that are triggered by the `Path` parameter of the `Set-Content` cmdlet by implementing the `System.Management.Automation.Provider.IContentCmdletProvider.GetContentWriterDynamicParameters*` method.
- `Set-Item` cmdlet - You can define dynamic parameters that are triggered by the `Path` and `Value` parameters of the `Set-Item` cmdlet by implementing the `System.Management.Automation.Provider.ItemCmdletProvider.SetItemDynamicParameters*` method.

- `Set-ItemProperty` cmdlet - You can define dynamic parameters that are triggered by the `Path` and `Value` parameters of the `Set-Item` cmdlet by implementing the `System.Management.Automation.Provider.IPropertyCmdletProvider SetPropertyDynamicParameters*` method.
- `Test-Path` cmdlet - You can define dynamic parameters that are triggered by the `Path` parameter of the `Test-Path` cmdlet by implementing the `System.Management.Automation.Provider.ItemCmdletProvider.InvokeDefaultActionDynamicParameters*` method.

Writing an item provider

Article • 03/24/2025

This topic describes how to implement the methods of a Windows PowerShell provider that access and manipulate items in the data store. To be able to access items, a provider must derive from the [System.Management.Automation.Provider.ItemCmdletProvider](#) class.

The provider in the examples in this topic uses an Access database as its data store. There are several helper methods and classes that are used to interact with the database. For the complete sample that includes the helper methods, see [AccessDBProviderSample03](#)

For more information about Windows PowerShell providers, see [Windows PowerShell Provider Overview](#).

Implementing item methods

The [System.Management.Automation.Provider.ItemCmdletProvider](#) class exposes several methods that can be used to access and manipulate the items in a data store. For a complete list of these methods, see [ItemCmdletProvider Methods](#). In this example, we will implement four of these methods.

[System.Management.Automation.Provider.ItemCmdletProvider.GetItem*](#) gets an item at a specified path.

[System.Management.Automation.Provider.ItemCmdletProvider.SetItem*](#) sets the value of the specified item.

[System.Management.Automation.Provider.ItemCmdletProvider.ItemExists*](#) checks whether an item exists at the specified path.

[System.Management.Automation.Provider.ItemCmdletProvider.IsValidPath*](#) checks a path to see if it maps to a location in the data store.

ⓘ Note

This topic builds on the information in [Windows PowerShell Provider QuickStart](#).

This topic does not cover the basics of how to set up a provider project, or how to implement the methods inherited from the

[System.Management.Automation.Provider.DriveCmdletProvider](#) class that create and remove drives.

Declaring the provider class

Declare the provider to derive from the [System.Management.Automation.Provider.ItemCmdletProvider](#) class, and decorate it with the [System.Management.Automation.Provider.CmdletProviderAttribute](#).

C#

```
[CmdletProvider("AccessDB", ProviderCapabilities.None)]  
  
public class AccessDBProvider : ItemCmdletProvider  
{  
  
}
```

Implementing GetItem

The [System.Management.Automation.Provider.ItemCmdletProvider.GetItem*](#) is called by the PowerShell engine when a user calls the [Microsoft.PowerShell.Commands.GetItemCommand](#) cmdlet on your provider. The method returns the item at the specified path. In the Access database example, the method checks whether the item is the drive itself, a table in the database, or a row in the database. The method sends the item to the PowerShell engine by calling the [System.Management.Automation.Provider.CmdletProvider.WriteItemObject*](#) method.

C#

```
protected override void GetItem(string path)  
{  
    // check if the path represented is a drive  
    if (PathIsDrive(path))  
    {  
        WriteItemObject(this.PSDriveInfo, path, true);  
        return;  
    } // if (PathIsDrive...  
  
    // Get table name and row information from the path and do  
    // necessary actions  
    string tableName;  
    int rowCount;  
  
    PathType type = GetNamesFromPath(path, out tableName, out  
    rowCount);  
  
    if (type == PathType.Table)  
    {  
        DatabaseTableInfo table = GetTable(tableName);  
    }  
}
```

```

        WriteItemObject(table, path, true);
    }
    else if (type == PathType.Row)
    {
        DatabaseRowInfo row = GetRow(tableName, lineNumber);
        WriteItemObject(row, path, false);
    }
    else
    {
        ThrowTerminatingInvalidOperationException(path);
    }

}

```

Implementing SetItem

The [System.Management.Automation.Provider.ItemCmdletProvider.SetItem*](#) method is called by the PowerShell engine calls when a user calls the [Microsoft.PowerShell.Commands.SetItemCommand](#) cmdlet. It sets the value of the item at the specified path.

In the Access database example, it makes sense to set the value of an item only if that item is a row, so the method throws [NotSupportedException](#) when the item is not a row.

C#

```

protected override void SetItem(string path, object values)
{
    // Get type, table name and row number from the path specified
    string tableName;
    int lineNumber;

    PathType type = GetNamesFromPath(path, out tableName, out
rowNumber);

    if (type != PathType.Row)
    {
        WriteError(new ErrorRecord(new NotSupportedException(
            "SetNotSupported"), "", 
        ErrorCategory.InvalidOperation, path));

        return;
    }

    // Get in-memory representation of table
    OdbcDataAdapter da = GetAdapterForTable(tableName);

    if (da == null)
    {
        return;
    }
}

```

```

        }

        DataSet ds = GetDataSetForTable(da, tableName);
        DataTable table = GetDataTable(ds, tableName);

        if (rowNumber >= table.Rows.Count)
        {
            // The specified row number has to be available. If not
            // NewItem has to be used to add a new row
            throw new ArgumentException("Row specified is not
available");
        } // if (rowNum...

        string[] colValues = (values as string).Split(',');
        // set the specified row
        DataRow row = table.Rows[rowNumber];

        for (int i = 0; i < colValues.Length; i++)
        {
            row[i] = colValues[i];
        }

        // Update the table
        if (ShouldProcess(path, "SetItem"))
        {
            da.Update(ds, tableName);
        }
    }
}

```

Implementing ItemExists

The [System.Management.Automation.Provider.ItemCmdletProvider.ItemExists*](#) method is called by the PowerShell engine when a user calls the [Microsoft.PowerShell.Commands.TestPathCommand](#) cmdlet. The method determines whether there is an item at the specified path. If the item does exist, the method passes it back to the PowerShell engine by calling [System.Management.Automation.Provider.CmdletProvider.WriteItemObject*](#).

C#

```

protected override bool ItemExists(string path)
{
    // check if the path represented is a drive
    if (PathIsDrive(path))
    {
        return true;
    }

    // Obtain type, table name and row number from path
}

```

```

        string tableName;
        int rowNumber;

        PathType type = GetNamesFromPath(path, out tableName, out
rowNumber);

        DatabaseTableInfo table = GetTable(tableName);

        if (type == PathType.Table)
        {
            // if specified path represents a table then
DatabaseTableInfo
            // object for the same should exist
            if (table != null)
            {
                return true;
            }
        }
        else if (type == PathType.Row)
        {
            // if specified path represents a row then DatabaseTableInfo
should
            // exist for the table and then specified row number must be
within
            // the maximum row count in the table
            if (table != null && rowNumber < table.RowCount)
            {
                return true;
            }
        }

        return false;

    }

```

Implementing IsValidPath

The [System.Management.Automation.Provider.ItemCmdletProvider.IsValidPath*](#) method checks whether the specified path is syntactically valid for the current provider. It does not check whether an item exists at the path.

C#

```

protected override bool IsValidPath(string path)
{
    bool result = true;

    // check if the path is null or empty
    if (String.IsNullOrEmpty(path))
    {
        result = false;
    }
}
```

```
}

// convert all separators in the path to a uniform one
path = NormalizePath(path);

// split the path into individual chunks
string[] pathChunks = path.Split(pathSeparator.ToCharArray());

foreach (string pathChunk in pathChunks)
{
    if (pathChunk.Length == 0)
    {
        result = false;
    }
}
return result;
}
```

Next steps

A typical real-world provider is capable of supporting items that contain other items, and of moving items from one path to another within the drive. For an example of a provider that supports containers, see [Writing a container provider](#). For an example of a provider that supports moving items, see [Writing a navigation provider](#).

Writing a container provider

Article • 03/24/2025

This topic describes how to implement the methods of a Windows PowerShell provider that support items that contain other items, such as folders in the FileSystem provider.

To be able to support containers, a provider must derive from the

[System.Management.Automation.Provider.ContainerCmdletProvider](#) class.

The provider in the examples in this topic uses an Access database as its data store.

There are several helper methods and classes that are used to interact with the

database. For the complete sample that includes the helper methods, see

[AccessDBProviderSample04](#).

For more information about Windows PowerShell providers, see [Windows PowerShell Provider Overview](#).

Implementing container methods

The [System.Management.Automation.Provider.ContainerCmdletProvider](#) class implements methods that support containers, and create, copy, and remove items. For a complete list of these methods, see [System.Management.Automation.Provider.ContainerCmdletProvider](#).

ⓘ Note

This topic builds on the information in [Windows PowerShell Provider QuickStart](#).

This topic does not cover the basics of how to set up a provider project, or how to implement the methods inherited from the

[System.Management.Automation.Provider.DriveCmdletProvider](#) class that create and remove drives. This topic also does not cover how to implement methods exposed by the [System.Management.Automation.Provider.ItemCmdletProvider](#) class. For an example that shows how to implement item cmdlets, see [Writing an item provider](#).

Declaring the provider class

Declare the provider to derive from the

[System.Management.Automation.Provider.ContainerCmdletProvider](#) class, and decorate it with the [System.Management.Automation.Provider.CmdletProviderAttribute](#).

C#

```
[CmdletProvider("AccessDB", ProviderCapabilities.None)]
public class AccessDBProvider : ContainerCmdletProvider
{
}
```

Implementing GetChildItems

The PowerShell engine calls the

[System.Management.Automation.Provider.ContainerCmdletProvider.GetChildItems*](#) method when a user calls the [Microsoft.PowerShell.Commands.GetChildItemCommand](#) cmdlet. This method gets the items that are the children of the item at the specified path.

In the Access database example, the behavior of the

[System.Management.Automation.Provider.ContainerCmdletProvider.GetChildItems*](#) method depends on the type of the specified item. If the item is the drive, then the children are tables, and the method returns the set of tables from the database. If the specified item is a table, then the children are the rows of that table. If the item is a row, then it has no children, and the method returns that row only. All child items are sent back to the PowerShell engine by the

[System.Management.Automation.Provider.CmdletProvider.WriteItemObject*](#) method.

C#

```
protected override void GetChildItems(string path, bool recurse)
{
    // If path represented is a drive then the children in the path
    // are
    // tables. Hence all tables in the drive represented will have to
    // be
    // returned
    if (PathIsDrive(path))
    {
        foreach (DatabaseTableInfo table in GetTables())
        {
            WriteItemObject(table, path, true);

            // if the specified item exists and recurse has been set
            // then
            // all child items within it have to be obtained as well
            if (ItemExists(path) && recurse)
            {
                GetChildItems(path + pathSeparator + table.Name,
                recurse);
            }
        }
    }
}
```

```

        } // foreach (DatabaseTableInfo...
    } // if (PathIsDrive...
    else
    {
        // Get the table name, row number and type of path from the
        // path specified
        string tableName;
        int rowNumber;

        PathType type = GetNamesFromPath(path, out tableName, out
rowNumber);

        if (type == PathType.Table)
        {
            // Obtain all the rows within the table
            foreach (DatabaseRowInfo row in GetRows(tableName))
            {
                WriteItemObject(row, path + pathSeparator +
row.RowNumber,
                                false);
            } // foreach (DatabaseRowInfo...
        }
        else if (type == PathType.Row)
        {
            // In this case the user has directly specified a row,
hence
            // just give that particular row
            DatabaseRowInfo row = GetRow(tableName, rowNumber);
            WriteItemObject(row, path + pathSeparator +
row.RowNumber,
                                false);
        }
        else
        {
            // In this case, the path specified is not valid
            ThrowTerminatingInvalidOperationException(path);
        }
    } // else
}

```

Implementing GetChildNames

The

[System.Management.Automation.Provider.ContainerCmdletProvider.GetChildNames*](#)
method is similar to the

[System.Management.Automation.Provider.ContainerCmdletProvider.GetChildItems*](#)
method, except that it returns only the name property of the items, and not the items
themselves.

```

protected override void GetChildNames(string path,
                                     ReturnContainers returnContainers)
{
    // If the path represented is a drive, then the child items are
    // tables. get the names of all the tables in the drive.
    if (PathIsDrive(path))
    {
        foreach (DatabaseTableInfo table in GetTables())
        {
            WriteItemObject(table.Name, path, true);
        } // foreach (DatabaseTableInfo...
    } // if (PathIsDrive...
    else
    {
        // Get type, table name and row number from path specified
        string tableName;
        int rowNumber;

        PathType type = GetNamesFromPath(path, out tableName, out
rowNumber);

        if (type == PathType.Table)
        {
            // Get all the rows in the table and then write out the
            // row numbers.
            foreach (DatabaseRowInfo row in GetRows(tableName))
            {
                WriteItemObject(row.RowNumber, path, false);
            } // foreach (DatabaseRowInfo...
        }
        else if (type == PathType.Row)
        {
            // In this case the user has directly specified a row,
            hence
            // just give that particular row
            DatabaseRowInfo row = GetRow(tableName, rowNumber);

            WriteItemObject(row.RowNumber, path, false);
        }
        else
        {
            ThrowTerminatingInvalidOperationException(path);
        }
    } // else
}

```

Implementing NewItem

The [System.Management.Automation.Provider.ContainerCmdletProvider.NewItem](#)* method creates a new item of the specified type at the specified path. The PowerShell

engine calls this method when a user calls the [Microsoft.PowerShell.Commands.NewItemCommand](#) cmdlet.

In this example, the method implements logic to determine that the path and type match. That is, only a table can be created directly under the drive (the database), and only a row can be created under a table. If the specified path and item type don't match in this way, the method throws an exception.

C#

```
protected override void NewItem(string path, string type,
                               object newItemValue)
{
    string tableName;
    int rowNumber;

    PathType pt = GetNamesFromPath(path, out tableName, out
rowNumber);

    if (pt == PathType.Invalid)
    {
        ThrowTerminatingInvalidPathException(path);
    }

    // Check if type is either "table" or "row", if not throw an
    // exception
    if (!String.Equals(type, "table",
 StringComparison.OrdinalIgnoreCase)
        && !String.Equals(type, "row",
 StringComparison.OrdinalIgnoreCase))
    {
        WriteError(new ErrorRecord
            (new ArgumentException("Type must be either
a table or row"),
             "CannotCreateSpecifiedObject",
             ErrorCategory.InvalidArgument,
             path
            )
        );
    }

    throw new ArgumentException("This provider can only create
items of type \"table\" or \"row\"");
}

// Path type is the type of path of the container. So if a drive
// is specified, then a table can be created under it and if a
table
// is specified, then a row can be created under it. For the sake
of
// completeness, if a row is specified, then if the row specified
by
// the path does not exist, a new row is created. However, the
```

```

row
    // number may not match as the row numbers only get incremented
based
    // on the number of rows

    if (PathIsDrive(path))
    {
        if (String.Equals(type, "table",
StringComparison.OrdinalIgnoreCase))
        {
            // Execute command using ODBC connection to create a
table
            try
            {
                // create the table using an sql statement
                string newTableName = newItemValue.ToString();

                if (!TableNameIsValid(newTableName))
                {
                    return;
                }
                string sql = "create table " + newTableName
                            + " (ID INT)";

                // Create the table using the Odbc connection from
the
                // drive.
                AccessDBPSDriveInfo di = this.PSDriveInfo as
AccessDBPSDriveInfo;

                if (di == null)
                {
                    return;
                }
                OdbcConnection connection = di.Connection;

                if (ShouldProcess(newTableName, "create"))
                {
                    OdbcCommand cmd = new OdbcCommand(sql,
connection);
                    cmd.ExecuteScalar();
                }
            }
            catch (Exception ex)
            {
                WriteError(new ErrorRecord(ex,
"CannotCreateSpecifiedTable",
ErrorCategory.InvalidOperation, path)
);
            }
        } // if (String...
        else if (String.Equals(type, "row",
StringComparison.OrdinalIgnoreCase))
        {
            throw new

```

```

                    ArgumentException("A row cannot be created under a
database, specify a path that represents a Table");
                }
            } // if (PathIsDrive...
        else
        {
            if (String.Equals(type, "table",
StringComparison.OrdinalIgnoreCase))
            {
                if (rowNumber < 0)
                {
                    throw new
                        ArgumentException("A table cannot be created
within another table, specify a path that represents a database");
                }
                else
                {
                    throw new
                        ArgumentException("A table cannot be created
inside a row, specify a path that represents a database");
                }
            } //if (String.Equals....
            // if path specified is a row, create a new row
            else if (String.Equals(type, "row",
StringComparison.OrdinalIgnoreCase))
            {
                // The user is required to specify the values to be
inserted
                // into the table in a single string separated by commas
                string value = newItemValue as string;

                if (String.IsNullOrEmpty(value))
                {
                    throw new
                        ArgumentException("Value argument must have comma
separated values of each column in a row");
                }
                string[] rowValues = value.Split(',');
            }

            OdbcDataAdapter da = GetAdapterForTable(tableName);

            if (da == null)
            {
                return;
            }

            DataSet ds = GetDataSetForTable(da, tableName);
            DataTable table = GetDataTable(ds, tableName);

            if (rowValues.Length != table.Columns.Count)
            {
                string message =
                    String.Format(CultureInfo.CurrentCulture,
                    "The table has {0} columns and
the value specified must have so many comma separated values",

```

```

                table.Columns.Count);

            throw new ArgumentException(message);
        }

        if (!Force && (rowNumber >=0 && rowNumber <
table.Rows.Count))
        {
            string message =
String.Format(CultureInfo.CurrentCulture,
                                         "The row {0} already
exists. To create a new row specify row number as {1}, or specify path to a
table, or use the -Force parameter",
                                         rowNumber,
table.Rows.Count);

            throw new ArgumentException(message);
        }

        if (rowNumber > table.Rows.Count)
        {
            string message =
String.Format(CultureInfo.CurrentCulture,
                                         "To create a new row specify row
number as {0}, or specify path to a table",
                                         table.Rows.Count);

            throw new ArgumentException(message);
        }

        // Create a new row and update the row with the input
        // provided by the user
        DataRow row = table.NewRow();
        for (int i = 0; i < rowValues.Length; i++)
        {
            row[i] = rowValues[i];
        }
        table.Rows.Add(row);

        if (ShouldProcess(tableName, "update rows"))
        {
            // Update the table from memory back to the data
source
            da.Update(ds, tableName);
        }

    }// else if (String...
}// else ...

}

```

Implementing CopyItem

The [System.Management.Automation.Provider.ContainerCmdletProvider.CopyItem](#) copies the specified item to the specified path. The PowerShell engine calls this method when a user calls the [Microsoft.PowerShell.Commands.CopyItemCommand](#) cmdlet. This method can also be recursive, copying all of the items children in addition to the item itself.

Similarly to the

[System.Management.Automation.Provider.ContainerCmdletProvider.NewItem*](#) method, this method performs logic to make sure that the specified item is of the correct type for the path to which it is being copied. For example, if the destination path is a table, the item to be copied must be a row.

C#

```
protected override void CopyItem(string path, string copyPath, bool recurse)
{
    string tableName, copyTableName;
    int rowCount, copyRowCount;

    PathType type = GetNamesFromPath(path, out tableName, out
rowCount);
    PathType copyType = GetNamesFromPath(copyPath, out copyTableName,
out copyRowCount);

    if (type == PathType.Invalid)
    {
        ThrowTerminatingInvalidOperationException(path);
    }

    if (copyType == PathType.Invalid)
    {
        ThrowTerminatingInvalidOperationException(copyPath);
    }

    // Get the table and the table to copy to
    OdbcDataAdapter da = GetAdapterForTable(tableName);
    if (da == null)
    {
        return;
    }

    DataSet ds = GetDataSetForTable(da, tableName);
    DataTable table = GetDataTable(ds, tableName);

    OdbcDataAdapter cda = GetAdapterForTable(copyTableName);
    if (cda == null)
    {
        return;
    }

    DataSet cds = GetDataSetForTable(cda, copyTableName);
```

```

DataTable copyTable = GetDataTable(cds, copyTableName);

// if source represents a table
if (type == PathType.Table)
{
    // if copyPath does not represent a table
    if (copyType != PathType.Table)
    {
        ArgumentException e = new ArgumentException("Table can
only be copied on to another table location");

        WriteError(new ErrorRecord(e, "PathNotValid",
            ErrorCategory.InvalidArgument, copyPath));

        throw e;
    }

    // if table already exists then Force parameter should be set
    // to force a copy
    if (!Force && GetTable(copyTableName) != null)
    {
        throw new ArgumentException("Specified path already
exists");
    }

    for (int i = 0; i < table.Rows.Count; i++)
    {
        DataRow row = table.Rows[i];
        DataRow copyRow = copyTable.NewRow();

        copyRow.ItemArray = row.ItemArray;
        copyTable.Rows.Add(copyRow);
    }
} // if (type == ...
// if source represents a row
else
{
    if (copyType == PathType.Row)
    {
        if (!Force && (copyRowNumber < copyTable.Rows.Count))
        {
            throw new ArgumentException("Specified path already
exists.");
        }

        DataRow row = table.Rows[rowNumber];
        DataRow copyRow = null;

        if (copyRowNumber < copyTable.Rows.Count)
        {
            // copy to an existing row
            copyRow = copyTable.Rows[copyRowNumber];
            copyRow.ItemArray = row.ItemArray;
            copyRow[0] = GetNextID(copyTable);
        }
    }
}

```

```

        else if (copyRowNumber == copyTable.Rows.Count)
    {
        // copy to the next row in the table that will
        // be created
        copyRow = copyTable.NewRow();
        copyRow.ItemArray = row.ItemArray;
        copyRow[0] = GetNextID(copyTable);
        copyTable.Rows.Add(copyRow);
    }
    else
    {
        // attempting to copy to a nonexistent row or a row
        // that cannot be created now - throw an exception
        string message =
String.Format(CultureInfo.CurrentCulture,
                           "The item cannot be specified
to the copied row. Specify row number as {0}, or specify a path to the
table.",

                           table.Rows.Count);

        throw new ArgumentException(message);
    }
}
else
{
    // destination path specified represents a table,
    // create a new row and copy the item
    DataRow copyRow = copyTable.NewRow();
    copyRow.ItemArray = table.Rows[rowNumber].ItemArray;
    copyRow[0] = GetNextID(copyTable);
    copyTable.Rows.Add(copyRow);
}
}

if (ShouldProcess(copyTableName, "CopyItems"))
{
    cda.Update(cds, copyTableName);
}

} //CopyItem

```

Implementing RemoveItem

The [System.Management.Automation.Provider.ContainerCmdletProvider.RemoveItem*](#) method removes the item at the specified path. The PowerShell engine calls this method when a user calls the [Microsoft.PowerShell.Commands.RemoveItemCommand](#) cmdlet.

C#

```

protected override void RemoveItem(string path, bool recurse)
{

```

```

    string tableName;
    int rowNumber = 0;

    PathType type = GetNamesFromPath(path, out tableName, out
rowNumber);

    if (type == PathType.Table)
    {
        // if recurse flag has been specified, delete all the rows as
well
        if (recurse)
        {
            OdbcDataAdapter da = GetAdapterForTable(tableName);
            if (da == null)
            {
                return;
            }

            DataSet ds = GetDataSetForTable(da, tableName);
            DataTable table = GetDataTable(ds, tableName);

            for (int i = 0; i < table.Rows.Count; i++)
            {
                table.Rows[i].Delete();
            }

            if (ShouldProcess(path, "RemoveItem"))
            {
                da.Update(ds, tableName);
                RemoveTable(tableName);
            }
        }//if (recurse...
        else
        {
            // Remove the table
            if (ShouldProcess(path, "RemoveItem"))
            {
                RemoveTable(tableName);
            }
        }
    }
    else if (type == PathType.Row)
    {
        OdbcDataAdapter da = GetAdapterForTable(tableName);
        if (da == null)

        }
    }
else
{
    ThrowTerminatingInvalidOperationException(path);
}

Next steps

A typical real-world provider is capable of moving items from one path to another within the drive. For an example of a provider that supports moving items, see [Writing a navigation provider](#).

[Windows PowerShell Provider Overview](#)

Writing a navigation provider

Article • 03/24/2025

This topic describes how to implement the methods of a Windows PowerShell provider that support nested containers (multi-level data stores), moving items, and relative paths. A navigation provider must derive from the [System.Management.Automation.Provider.NavigationCmdletProvider](#) class.

The provider in the examples in this topic uses an Access database as its data store. There are several helper methods and classes that are used to interact with the database. For the complete sample that includes the helper methods, see [AccessDBProviderSample05](#).

For more information about Windows PowerShell providers, see [Windows PowerShell Provider Overview](#).

Implementing navigation methods

The [System.Management.Automation.Provider.NavigationCmdletProvider](#) class implements methods that support nested containers, relative paths, and moving items. For a complete list of these methods, see [NavigationCmdletProvider Methods](#).

Note

This topic builds on the information in [Windows PowerShell Provider QuickStart](#). This topic does not cover the basics of how to set up a provider project, or how to implement the methods inherited from the [System.Management.Automation.Provider.DriveCmdletProvider](#) class that create and remove drives. This topic also does not cover how to implement methods exposed by the [System.Management.Automation.Provider.ItemCmdletProvider](#) or [System.Management.Automation.Provider.ContainerCmdletProvider](#) classes. For an example that shows how to implement item cmdlets, see [Writing an item provider](#). For an example that shows how to implement container cmdlets, see [Writing a container provider](#).

Declaring the provider class

Declare the provider to derive from the [System.Management.Automation.Provider.NavigationCmdletProvider](#) class, and

decorate it with the [System.Management.Automation.Provider.CmdletProviderAttribute](#).

```
[CmdletProvider("AccessDB", ProviderCapabilities.None)]
public class AccessDBProvider : NavigationCmdletProvider
{
}
```

Implementing IsItemContainer

The [System.Management.Automation.Provider.NavigationCmdletProvider.IsItemContainer*](#) method checks whether the item at the specified path is a container.

C#

```
protected override bool IsItemContainer(string path)
{
    if (PathIsDrive(path))
    {
        return true;
    }

    string[] pathChunks = ChunkPath(path);
    string tableName;
    int rowCount;

    PathType type = GetNamesFromPath(path, out tableName, out
rowCount);

    if (type == PathType.Table)
    {
        foreach (DatabaseTableInfo ti in GetTables())
        {
            if (string.Equals(ti.Name, tableName,
StringComparison.OrdinalIgnoreCase))
            {
                return true;
            }
        } // foreach (DatabaseTableInfo...
    } // if (pathChunks...

    return false;
}
```

Implementing GetChildName

The

[System.Management.Automation.Provider.NavigationCmdletProvider.GetChildNames*](#) method gets the name property of the child item at the specified path. If the item at the specified path is not a child of a container, then this method should return the path.

C#

```
protected override string GetChildName(string path)
{
    if (PathIsDrive(path))
    {
        return path;
    }

    string tableName;
    int rowNumber;

    PathType type = GetNamesFromPath(path, out tableName, out
rowNumber);

    if (type == PathType.Table)
    {
        return tableName;
    }
    else if (type == PathType.Row)
    {
        return rowNumber.ToString(CultureInfo.CurrentCulture);
    }
    else
    {
        ThrowTerminatingInvalidOperationException(path);
    }

    return null;
}
```

Implementing GetParentPath

The

[System.Management.Automation.Provider.NavigationCmdletProvider.GetParentPath*](#) method gets the path of the parent of the item at the specified path. If the item at the specified path is the root of the data store (so it has no parent), then this method should return the root path.

C#

```
protected override string GetParentPath(string path, string root)
{
    // If root is specified then the path has to contain
```

```

// the root. If not nothing should be returned
if (!String.IsNullOrEmpty(root))
{
    if (!path.Contains(root))
    {
        return null;
    }
}

return path.Substring(0, path.LastIndexOf(pathSeparator,
 StringComparison.OrdinalIgnoreCase));
}

```

Implementing MakePath

The [System.Management.Automation.Provider.NavigationCmdletProvider.MakePath*](#) method joins a specified parent path and a specified child path to create a provider-internal path (for information about path types that providers can support, see [Windows PowerShell Provider Overview](#)). The PowerShell engine calls this method when a user calls the [Microsoft.PowerShell.Commands.JoinPathCommand](#) cmdlet.

C#

```

protected override string MakePath(string parent, string child)
{
    string result;

    string normalParent = NormalizePath(parent);
    normalParent = RemoveDriveFromPath(normalParent);
    string normalChild = NormalizePath(child);
    normalChild = RemoveDriveFromPath(normalChild);

    if (String.IsNullOrEmpty(normalParent) &&
String.IsNullOrEmpty(normalChild))
    {
        result = String.Empty;
    }
    else if (String.IsNullOrEmpty(normalParent) &&
!String.IsNullOrEmpty(normalChild))
    {
        result = normalChild;
    }
    else if (!String.IsNullOrEmpty(normalParent) &&
String.IsNullOrEmpty(normalChild))
    {
        if (normalParent.EndsWith(pathSeparator,
StringComparison.OrdinalIgnoreCase))
        {
            result = normalParent;
        }
        else
    }
}

```

```

        {
            result = normalParent + pathSeparator;
        }
    } // else if (!String...
else
{
    if (!normalParent.Equals(String.Empty) &&
        !normalParent.EndsWith(pathSeparator,
StringComparison.OrdinalIgnoreCase))
    {
        result = normalParent + pathSeparator;
    }
    else
    {
        result = normalParent;
    }

    if (normalChild.StartsWith(pathSeparator,
StringComparison.OrdinalIgnoreCase))
    {
        result += normalChild.Substring(1);
    }
    else
    {
        result += normalChild;
    }
} // else

return result;
}

```

Implementing NormalizeRelativePath

The

[System.Management.Automation.Provider.NavigationCmdletProvider.NormalizeRelativePath](#)* method takes `path` and `basepath` parameters, and returns a normalized path that is equivalent to the `path` parameter and relative to the `basepath` parameter.

C#

```

protected override string NormalizeRelativePath(string path,
                                                string basepath)
{
    // Normalize the paths first
    string normalPath = NormalizePath(path);
    normalPath = RemoveDriveFromPath(normalPath);
    string normalBasePath = NormalizePath(basepath);
    normalBasePath = RemoveDriveFromPath(normalBasePath);

    if (String.IsNullOrEmpty(normalBasePath))
    {

```

```

        return normalPath;
    }
    else
    {
        if (!normalPath.Contains(normalBasePath))
        {
            return null;
        }

        return normalPath.Substring(normalBasePath.Length +
pathSeparator.Length);
    }
}

```

Implementing MoveItem

The [System.Management.Automation.Provider.NavigationCmdletProvider.MoveItem*](#) method moves an item from the specified path to the specified destination path. The PowerShell engine calls this method when a user calls the [Microsoft.PowerShell.Commands.MoveItemCommand](#) cmdlet.

C#

```

protected override void MoveItem(string path, string destination)
{
    // Get type, table name and rowNumber from the path
    string tableName, destTableName;
    int rowNumber, destRowNumber;

    PathType type = GetNamesFromPath(path, out tableName, out
rowNumber);

    PathType destType = GetNamesFromPath(destination, out
destTableName,
                                         out destRowNumber);

    if (type == PathType.Invalid)
    {
        ThrowTerminatingInvalidOperationException(path);
    }

    if (destType == PathType.Invalid)
    {
        ThrowTerminatingInvalidOperationException(destination);
    }

    if (type == PathType.Table)
    {
        ArgumentException e = new ArgumentException("Move not
supported for tables");

```

```

        WriteError(new ErrorRecord(e, "MoveNotSupported",
            ErrorCategory.InvalidArgument, path));

    throw e;
}
else
{
    OdbcDataAdapter da = GetAdapterForTable(tableName);
    if (da == null)
    {
        return;
    }

    DataSet ds = GetDataSetForTable(da, tableName);
    DataTable table = GetDataTable(ds, tableName);

    OdbcDataAdapter dda = GetAdapterForTable(destTableName);
    if (dda == null)
    {
        return;
    }

    DataSet dds = GetDataSetForTable(dda, destTableName);
    DataTable destTable = GetDataTable(dds, destTableName);
    DataRow row = table.Rows[rowNumber];

    if (destType == PathType.Table)
    {
        DataRow destRow = destTable.NewRow();

        destRow.ItemArray = row.ItemArray;
    }
    else
    {
        DataRow destRow = destTable.Rows[destRowNumber];

        destRow.ItemArray = row.ItemArray;
    }

    // Update the changes
    if (ShouldProcess(path, "MoveItem"))
    {
        WriteItemObject(row, path, false);
        dda.Update(dds, destTableName);
    }
}
}

```

Windows PowerShell Provider Overview

Provider Samples

Article • 03/24/2025

This section includes samples of providers that access a Microsoft Access database. These samples include provider classes that derive from all the base provider classes.

In This Section

This section includes the following topics:

[AccessDBProviderSample01 Sample](#) This sample shows how to declare the provider class that derives directly from the [System.Management.Automation.Provider.CmdletProvider](#) class. It is included here only for completeness.

[AccessDBProviderSample02](#) This sample shows how to overwrite the [System.Management.Automation.Provider.DriveCmdletProvider.NewDrive*](#) and [System.Management.Automation.Provider.DriveCmdletProvider.RemoveDrive*](#) methods to support calls to the `New-PSDrive` and `Remove-PSDrive` cmdlets. The provider class in this sample derives from the [System.Management.Automation.Provider.DriveCmdletProvider](#) class.

[AccessDBProviderSample03](#) This sample shows how to overwrite the [System.Management.Automation.Provider.ItemCmdletProvider.GetItem*](#) and [System.Management.Automation.Provider.ItemCmdletProvider.SetItem*](#) methods to support calls to the `Get-Item` and `Set-Item` cmdlets. The provider class in this sample derives from the [System.Management.Automation.Provider.ItemCmdletProvider](#) class.

[AccessDBProviderSample04](#) This sample shows how to overwrite container methods to support calls to the `Copy-Item`, `Get-ChildItem`, `New-Item`, and `Remove-Item` cmdlets. These methods should be implemented when the data store contains items that are containers. A container is a group of child items under a common parent item. The provider class in this sample derives from the [System.Management.Automation.Provider.ContainerCmdletProvider](#) class.

[AccessDBProviderSample05](#) This sample shows how to overwrite container methods to support calls to the `Move-Item` and `Join-Path` cmdlets. These methods should be implemented when the user needs to move items within a container and if the data store contains nested containers. The provider class in this sample derives from the [System.Management.Automation.Provider.NavigationCmdletProvider](#) class.

[AccessDBProviderSample06](#) This sample shows how to overwrite content methods to support calls to the `Clear-Content`, `Get-Content`, and `Set-Content` cmdlets. These methods should be implemented when the user needs to manage the content of the items in the data store. The provider class in this sample derives from the `System.Management.Automation.Provider.NavigationCmdletProvider` class, and it implements the `System.Management.Automation.Provider.IContentCmdletProvider` interface.

[Writing a Windows PowerShell Provider](#)

AccessDBProviderSample01

Article • 03/24/2025

This sample shows how to declare a provider class that derives directly from the [System.Management.Automation.Provider.CmdletProvider](#) class. It is included here only for completeness.

Demonstrates

Important

Your provider class will most likely derive from one of the following classes and possibly implement other provider interfaces:

- [System.Management.Automation.Provider.ItemCmdletProvider](#) class. See [AccessDBProviderSample03](#).
- [System.Management.Automation.Provider.ContainerCmdletProvider](#) class. See [AccessDBProviderSample04](#).
- [System.Management.Automation.Provider.NavigationCmdletProvider](#) class. See [AccessDBProviderSample05](#).

For more information about choosing which provider class to derive from based on provider features, see [Designing Your Windows PowerShell Provider](#).

This sample demonstrates the following:

- Declaring the `CmdletProvider` attribute.
- Defining a provider class that derives directly from the [System.Management.Automation.Provider.CmdletProvider](#) class.

Example

This sample shows how to define a provider class and how to declare the `CmdletProvider` attribute.

C#

```
using System.Management.Automation;
using System.Management.Automation.Provider;
```

```
using System.ComponentModel;

namespace Microsoft.Samples.PowerShell.Providers
{
    #region AccessDBProvider

    /// <summary>
    /// Simple provider.
    /// </summary>
    [CmdletProvider("AccessDB", ProviderCapabilities.None)]
    public class AccessDBProvider : CmdletProvider
    {

    }

    #endregion AccessDBProvider
}
```

[Designing Your Windows PowerShell Provider](#)

AccessDBProviderSample02

Article • 03/24/2025

This sample shows how to overwrite the `System.Management.Automation.Provider.DriveCmdletProvider.NewDrive*` and `System.Management.Automation.Provider.DriveCmdletProvider.RemoveDrive*` methods to support calls to the `New-PSDrive` and `Remove-PSDrive` cmdlets. The provider class in this sample derives from the `System.Management.Automation.Provider.DriveCmdletProvider` class.

Demonstrates

Important

Your provider class will most likely derive from one of the following classes and possibly implement other provider interfaces:

- [System.Management.Automation.Provider.ItemCmdletProvider](#) class. See [AccessDBProviderSample03](#).
- [System.Management.Automation.Provider.ContainerCmdletProvider](#) class. See [AccessDBProviderSample04](#).
- [System.Management.Automation.Provider.NavigationCmdletProvider](#) class. See [AccessDBProviderSample05](#).

For more information about choosing which provider class to derive from based on provider features, see [Designing Your Windows PowerShell Provider](#).

This sample demonstrates the following:

- Declaring the `CmdletProvider` attribute.
- Defining a provider class that derives from the `System.Management.Automation.Provider.DriveCmdletProvider` class.
- Overwriting the `System.Management.Automation.Provider.DriveCmdletProvider.NewDrive*` method to support creating new drives. (This sample does not show how to add dynamic parameters to the `New-PSDrive` cmdlet.)

- Overwriting the [System.Management.Automation.Provider.DriveCmdletProvider.RemoveDrive*](#) method to support removing existing drives.

Example

This sample shows how to overwrite the [System.Management.Automation.Provider.DriveCmdletProvider.NewDrive*](#) and [System.Management.Automation.Provider.DriveCmdletProvider.RemoveDrive*](#) methods. For this sample provider, when a drive is created its connection information is stored in an `AccessDBPsDriveInfo` object.

C#

```

[Designing Your Windows PowerShell Provider](#)

AccessDBProviderSample03

Article • 03/24/2025

This sample shows how to overwrite the `System.Management.Automation.Provider.ItemCmdletProvider.GetItem*` and `System.Management.Automation.Provider.ItemCmdletProvider.SetItem*` methods to support calls to the `Get-Item` and `Set-Item` cmdlets. The provider class in this sample derives from the `System.Management.Automation.Provider.ItemCmdletProvider` class.

Demonstrates

ⓘ Important

Your provider class will most likely derive from one of the following classes and possibly implement other provider interfaces:

- [System.Management.Automation.Provider.ItemCmdletProvider](#) class.
- [System.Management.Automation.Provider.ContainerCmdletProvider](#) class.
See [AccessDBProviderSample04](#).
- [System.Management.Automation.Provider.NavigationCmdletProvider](#) class.
See [AccessDBProviderSample05](#).

For more information about choosing which provider class to derive from based on provider features, see [Designing Your Windows PowerShell Provider](#).

This sample demonstrates the following:

- Declaring the `CmdletProvider` attribute.
- Defining a provider class that derives from the `System.Management.Automation.Provider.ItemCmdletProvider` class.
- Overwriting the `System.Management.Automation.Provider.DriveCmdletProvider.NewDrive*` method to change the behavior of the `New-PSDrive` cmdlet, allowing the user to create new drives. (This sample does not show how to add dynamic parameters to the `New-PSDrive` cmdlet.)
- Overwriting the `System.Management.Automation.Provider.DriveCmdletProvider.RemoveDrive*` method to support removing existing drives.

- Overwriting the [System.Management.Automation.Provider.ItemCmdletProvider.GetItem*](#) method to change the behavior of the `Get-Item` cmdlet, allowing the user to retrieve items from the data store. (This sample does not show how to add dynamic parameters to the `Get-Item` cmdlet.)
- Overwriting the [System.Management.Automation.Provider.ItemCmdletProvider.SetItem*](#) method to change the behavior of the `Set-Item` cmdlet, allowing the user to update the items in the data store. (This sample does not show how to add dynamic parameters to the `Get-Item` cmdlet.)
- Overwriting the [System.Management.Automation.Provider.ItemCmdletProvider.ItemExists*](#) method to change the behavior of the `Test-Path` cmdlet. (This sample does not show how to add dynamic parameters to the `Test-Path` cmdlet.)
- Overwriting the [System.Management.Automation.Provider.ItemCmdletProvider.IsValidPath*](#) method to determine if the provided path is valid.

Example

This sample shows how to overwrite the methods needed to get and set items in a Microsoft Access data base.

C#

```
using System;
using System.IO;
using System.Data;
using System.Data.Odbc;
using System.Collections.ObjectModel;
using System.Text;
using System.Diagnostics;
using System.Text.RegularExpressions;
using System.Management.Automation;
using System.Management.Automation.Provider;
using System.ComponentModel;
using System.Globalization;

Designing Your Windows PowerShell Provider

AccessDBProviderSample04

Article • 03/24/2025

This sample shows how to overwrite container methods to support calls to the `Copy-Item`, `Get-ChildItem`, `New-Item`, and `Remove-Item` cmdlets. These methods should be implemented when the data store contains items that are containers. A container is a group of child items under a common parent item. The provider class in this sample derives from the [System.Management.Automation.Provider.ContainerCmdletProvider](#) class.

Demonstrates

Important

Your provider class will most likely derive from the
[System.Management.Automation.Provider.NavigationCmdletProvider](#)

This sample demonstrates the following:

- Declaring the `CmdletProvider` attribute.
- Defining a provider class that derives from the [System.Management.Automation.Provider.ContainerCmdletProvider](#) class.
- Overwriting the [System.Management.Automation.Provider.ContainerCmdletProvider.CopyItem](#) method to change the behavior of the `Copy-Item` cmdlet which allows the user to copy items from one location to another. (This sample does not show how to add dynamic parameters to the `Copy-Item` cmdlet.)
- Overwriting the [System.Management.Automation.Provider.ContainerCmdletProvider.GetChildItems](#) * method to change the behavior of the `Get-ChildItems` cmdlet, which allows the user to retrieve the child items of the parent item. (This sample does not show how to add dynamic parameters to the `Get-ChildItems` cmdlet.)
- Overwriting the [System.Management.Automation.Provider.ContainerCmdletProvider.GetChildNames](#) \$* method to change the behavior of the `Get-ChildItems` cmdlet when the `Name` parameter of the cmdlet is specified.
- Overwriting the [System.Management.Automation.Provider.ContainerCmdletProvider.NewItem](#)*

method to change the behavior of the `New-Item` cmdlet, which allows the user to add items to the data store. (This sample does not show how to add dynamic parameters to the `New-Item` cmdlet.)

- Overwriting the `System.Management.Automation.Provider.ContainerCmdletProvider.RemoveItem*` method to change the behavior of the `Remove-Item` cmdlet. (This sample does not show how to add dynamic parameters to the `Remove-Item` cmdlet.)

Example

This sample shows how to overwrite the methods needed to copy, create, and remove items, as well as methods for getting the child items of a parent item.

[Designing Your Windows PowerShell Provider](#)

AccessDBProviderSample05

Article • 03/24/2025

This sample shows how to overwrite container methods to support calls to the `Move-Item` and `Join-Path` cmdlets. These methods should be implemented when the user needs to move items within a container and if the data store contains nested containers. The provider class in this sample derives from the [System.Management.Automation.Provider.NavigationCmdletProvider](#) class.

Demonstrates

Important

Your provider class will most likely derive from one of the following classes and possibly implement other provider interfaces:

- [System.Management.Automation.Provider.ItemCmdletProvider](#) class. See [AccessDBProviderSample03](#).
- [System.Management.Automation.Provider.ContainerCmdletProvider](#) class. See [AccessDBProviderSample04](#).
- [System.Management.Automation.Provider.NavigationCmdletProvider](#) class.

For more information about choosing which provider class to derive from based on provider features, see [Designing Your Windows PowerShell Provider](#).

This sample demonstrates the following:

- Declaring the `CmdletProvider` attribute.
- Defining a provider class that derives from the [System.Management.Automation.Provider.NavigationCmdletProvider](#) class.
- Overwriting the [System.Management.Automation.Provider.NavigationCmdletProvider.MoveItem*](#) method to change the behavior of the `Move-Item` cmdlet, allowing the user to move items from one location to another. (This sample does not show how to add dynamic parameters to the `Move-Item` cmdlet.)
- Overwriting the [System.Management.Automation.Provider.NavigationCmdletProvider.MakePath*](#)

method to change the behavior of the `Join-Path` cmdlet.

- Overwriting the `System.Management.Automation.Provider.NavigationCmdletProvider.I.setItemContainer*` method.
- Overwriting the `System.Management.Automation.Provider.NavigationCmdletProvider.GetChildName*` method.
- Overwriting the `System.Management.Automation.Provider.NavigationCmdletProvider.GetParentPath*` method.
- Overwriting the `System.Management.Automation.Provider.NavigationCmdletProvider.NormalizeRelativePath*` method.

Example

This sample shows how to overwrite the methods needed to move items in a Microsoft Access data base.

AccessDBProviderSample06

Article • 03/24/2025

This sample shows how to overwrite content methods to support calls to the `Clear-Content`, `Get-Content`, and `Set-Content` cmdlets. These methods should be implemented when the user needs to manage the content of the items in the data store. The provider class in this sample derives from the `System.Management.Automation.Provider.NavigationCmdletProvider` class, and it implements the `System.Management.Automation.Provider.IContentCmdletProvider` interface.

Demonstrates

ⓘ Important

Your provider class will most likely derive from one of the following classes and possibly implement other provider interfaces:

- [System.Management.Automation.Provider.ItemCmdletProvider](#) class. See [AccessDBProviderSample03](#).
- [System.Management.Automation.Provider.ContainerCmdletProvider](#) class. See [AccessDBProviderSample04](#).
- [System.Management.Automation.Provider.NavigationCmdletProvider](#) class.

For more information about choosing which provider class to derive from based on provider features, see [Designing Your Windows PowerShell Provider](#).

This sample demonstrates the following:

- Declaring the `CmdletProvider` attribute.
- Defining a provider class that derives from the `System.Management.Automation.Provider.NavigationCmdletProvider` class and that declares the `System.Management.Automation.Provider.IContentCmdletProvider` interface.
- Overwriting the `System.Management.Automation.Provider.IContentCmdletProvider.ClearContent*` method to change the behavior of the `Clear-Content` cmdlet, allowing the user to remove the content from an item. (This sample does not show how to add dynamic parameters to the `Clear-Content` cmdlet.)

- Overwriting the `System.Management.Automation.Provider.IContentCmdletProvider.GetContentReader*` method to change the behavior of the `Get-Content` cmdlet, allowing the user to retrieve the content of an item. (This sample does not show how to add dynamic parameters to the `Get-Content` cmdlet.).
- Overwriting the `Microsoft.PowerShell.Commands.FileSystemProvider.GetContentWriter*` method to change the behavior of the `Set-Content` cmdlet, allowing the user to update the content of an item. (This sample does not show how to add dynamic parameters to the `Set-Content` cmdlet.)

Example

This sample shows how to overwrite the methods needed to clear, get, and set the content of items in a Microsoft Access data base.

Windows PowerShell Host Quickstart

Article • 12/18/2023

To host Windows PowerShell in your application, you use the [System.Management.Automation.PowerShell](#) class. This class provides methods that create a pipeline of commands and then execute those commands in a runspace. The simplest way to create a host application is to use the default runspace. The default runspace contains all of the core Windows PowerShell commands. If you want your application to expose only a subset of the Windows PowerShell commands, you must create a custom runspace.

Using the default runspace

To start, we'll use the default runspace, and use the methods of the [System.Management.Automation.PowerShell](#) class to add commands, parameters, statements, and scripts to a pipeline.

AddCommand

You use the [System.Management.Automation.PowerShell.AddCommand](#) method to add commands to the pipeline. For example, suppose you want to get the list of running processes on the machine. The way to run this command is as follows.

1. Create a [System.Management.Automation.PowerShell](#) object.

```
C#  
  
PowerShell ps = PowerShell.Create();
```

2. Add the command that you want to execute.

```
C#  
  
ps.AddCommand("Get-Process");
```

3. Invoke the command.

```
C#  
  
ps.Invoke();
```

If you call the `AddCommand` method more than once before you call the `System.Management.Automation.PowerShell.Invoke` method, the result of the first command is piped to the second, and so on. If you do not want to pipe the result of a previous command to a command, add it by calling the `System.Management.Automation.PowerShell.AddStatement` instead.

AddParameter

The previous example executes a single command without any parameters. You can add parameters to the command by using the `System.Management.Automation.PSCmdlet.AddParameter` method. For example, the following code gets a list of all of the processes that are named `powershell` running on the machine.

C#

```
PowerShell.Create().AddCommand("Get-Process")
    .AddParameter("Name", "powershell")
    .Invoke();
```

You can add additional parameters by calling the `AddParameter` method repeatedly.

C#

```
PowerShell.Create().AddCommand("Get-ChildItem")
    .AddParameter("Path", @"C:\Windows")
    .AddParameter("Filter", "*.*")
    .Invoke();
```

You can also add a dictionary of parameter names and values by calling the `System.Management.Automation.PowerShell.AddParameters` method.

C#

```
IDictionary parameters = new Dictionary<String, String>();
parameters.Add("Path", @"C:\Windows");
parameters.Add("Filter", "*.*");

PowerShell.Create().AddCommand("Get-Process")
    .AddParameters(parameters)
    .Invoke()
```

AddStatement

You can simulate batching by using the [System.Management.Automation.PowerShell.AddStatement](#) method, which adds an additional statement to the end of the pipeline. The following code gets a list of running processes with the name `powershell`, and then gets the list of running services.

C#

```
PowerShell ps = PowerShell.Create();
ps.AddCommand("Get-Process").AddParameter("Name", "powershell");
ps.AddStatement().AddCommand("Get-Service");
ps.Invoke();
```

AddScript

You can run an existing script by calling the [System.Management.Automation.PowerShell.AddScript](#) method. The following example adds a script to the pipeline and runs it. This example assumes there is already a script named `MyScript.ps1` in a folder named `D:\PSScripts`.

C#

```
PowerShell ps = PowerShell.Create();
ps.AddScript("D:\PSScripts\MyScript.ps1").Invoke();
```

There is also a version of the `AddScript` method that takes a boolean parameter named `useLocalScope`. If this parameter is set to `true`, then the script is run in the local scope. The following code will run the script in the local scope.

C#

```
PowerShell ps = PowerShell.Create();
ps.AddScript(@"D:\PSScripts\MyScript.ps1", true).Invoke();
```

Creating a custom runspace

While the default runspace used in the previous examples loads all of the core Windows PowerShell commands, you can create a custom runspace that loads only a specified subset of all commands. You might want to do this to improve performance (loading a larger number of commands is a performance hit), or to restrict the capability of the user to perform operations. A runspace that exposes only a limited number of commands is called a constrained runspace. To create a constrained runspace, you use

the [System.Management.Automation.Runspaces.Runspace](#) and [System.Management.Automation.Runspaces.InitialSessionState](#) classes.

Creating an InitialSessionState object

To create a custom runspace, you must first create a [System.Management.Automation.Runspaces.InitialSessionState](#) object. In the following example, we use the [System.Management.Automation.Runspaces.RunspaceFactory](#) to create a runspace after creating a default InitialSessionState object.

C#

```
InitialSessionState iss = InitialSessionState.CreateDefault();
Runspace rs = RunspaceFactory.CreateRunspace(iss);
rs.Open();
PowerShell ps = PowerShell.Create();
ps.Runspace = rs;
ps.AddCommand("Get-Command");
ps.Invoke();
rs.Close();
```

Constraining the runspace

In the previous example, we created a default [System.Management.Automation.Runspaces.InitialSessionState](#) object that loads all of the built-in core Windows PowerShell. We could also have called the [System.Management.Automation.Runspaces.InitialSessionState.CreateDefault2](#) method to create an InitialSessionState object that would load only the commands in the Microsoft.PowerShell.Core snapin. To create a more constrained runspace, you must create an empty InitialSessionState object by calling the [System.Management.Automation.Runspaces.InitialSessionState.Create](#) method, and then add commands to the InitialSessionState.

Using a runspace that loads only the commands that you specify provides significantly improved performance.

You use the methods of the [System.Management.Automation.Runspaces.SessionStateCmdletEntry](#) class to define cmdlets for the initial session state. The following example creates an empty initial session state, then defines and adds the `Get-Command` and `Import-Module` commands to the initial session state. We then create a runspace constrained by that initial session state, and execute the commands in that runspace.

Create the initial session state.

```
C#
```

```
InitialSessionState iss = InitialSessionState.Create();
```

Define and add commands to the initial session state.

```
C#
```

```
SessionStateCmdletEntry getCommand = new SessionStateCmdletEntry(
    "Get-Command", typeof(Microsoft.PowerShell.Commands.GetCommandCommand),
    "");
SessionStateCmdletEntry importModule = new SessionStateCmdletEntry(
    "Import-Module",
    typeof(Microsoft.PowerShell.Commands.ImportModuleCommand), "");
iss.Commands.Add(getCommand);
iss.Commands.Add(importModule);
```

Create and open the runspace.

```
C#
```

```
Runspace rs = RunspaceFactory.CreateRunspace(iss);
rs.Open();
```

Execute a command and show the result.

```
C#
```

```
PowerShell ps = PowerShell.Create();
ps.Runspace = rs;
ps.AddCommand("Get-Command");
Collection<CommandInfo> result = ps.Invoke<CommandInfo>();
foreach (var entry in result)
{
    Console.WriteLine(entry.Name);
}
```

Close the runspace.

```
C#
```

```
rs.Close();
```

When run, the output of this code will look as follows.

PowerShell

```
Get-Command  
Import-Module
```

Creating Runspaces

Article • 03/24/2025

A runspace is the operating environment for the commands that are invoked by a host application. This environment includes the commands and data that are currently present, and any language restrictions that currently apply.

Host applications can use the default runspace that is provided by Windows PowerShell, which includes all available core commands, or create a custom runspace that includes only a subset of the available commands. To create a customized runspace, you create a [System.Management.Automation.Runspaces.InitialSessionState](#) object and assign it to your runspace.

Runspace tasks

1. [Creating an InitialSessionState](#)
2. [Creating a constrained runspace](#)
3. [Creating multiple runspaces](#)

Creating an InitialSessionState

Article • 12/18/2023

PowerShell commands run in a runspace. To host PowerShell in your application, you must create a `System.Management.Automation.Runspaces.Runspace` object. Every runspace has a `System.Management.Automation.Runspaces.InitialSessionState` object associated with it. The `InitialSessionState` specifies characteristics of the runspace, such as which commands, variables, and modules are available for that runspace.

Create a default InitialSessionState

The `CreateDefault` and `CreateDefault2` methods of the `InitialSessionState` class can be used to create an `InitialSessionState` object. The `CreateDefault` method creates an `InitialSessionState` with all of the built-in commands loaded, while the `CreateDefault2` method loads only the commands required to host PowerShell (the commands from the `Microsoft.PowerShell.Core` module).

If you want to further limit the commands available in your host application you need to create a constrained runspace. For information, see [Creating a constrained runspace](#).

The following code shows how to create an `InitialSessionState`, assign it to a runspace, add commands to the pipeline in that runspace, and invoke the commands. For more information about adding and invoking commands, see [Adding and invoking commands](#).

C#

```
namespace SampleHost
{
    using System;
    using System.Management.Automation;
    using System.Management.Automation.Runspaces;

    class HostP4b
    {
        static void Main(string[] args)
        {
            // Call InitialSessionState.CreateDefault() to create an empty
            // InitialSessionState object, then add the variables that will be
            // available when the runspace is opened.
            InitialSessionState iss = InitialSessionState.CreateDefault();
            SessionStateVariableEntry var1 =
                new SessionStateVariableEntry("test1",
                                              "MyVar1",
                                              "Initial session state MyVar1 test");
        }
    }
}
```

```
iss.Variables.Add(var1);

SessionStateVariableEntry var2 =
    new SessionStateVariableEntry("test2",
        "MyVar2",
        "Initial session state MyVar2 test");
iss.Variables.Add(var2);

// Call RunspaceFactory.CreateRunspace(InitialSessionState) to
// create the runspace where the pipeline is run.
Runspace rs = RunspaceFactory.CreateRunspace(iss);
rs.Open();

// Call PowerShell.Create() to create the PowerShell object, then
// specify the runspace and pipeline commands.
PowerShell ps = PowerShell.Create();
ps.Runspace = rs;
ps.AddCommand("Get-Variable");
ps.AddArgument("test*");

Console.WriteLine("Variable          Value");
Console.WriteLine("-----");

// Call ps.Invoke() to run the pipeline synchronously.
foreach (PSObject result in ps.Invoke())
{
    Console.WriteLine("{0,-20}{1}",
        result.Members["Name"].Value,
        result.Members["Value"].Value);
} // End foreach.

// Close the runspace to free resources.
rs.Close();

} // End Main.
} // End SampleHost.
}
```

Creating a constrained runspace

Article • 03/24/2025

For performance or security reasons, you might want to restrict the Windows PowerShell commands available to your host application. To do this you create an empty [System.Management.Automation.Runspaces.InitialSessionState](#) by calling the [System.Management.Automation.Runspaces.InitialSessionState.Create*](#) method, and then add only the commands you want available.

Using a runspace that loads only the commands that you specify provides significantly improved performance.

You use the methods of the [System.Management.Automation.Runspaces.SessionStateCmdletEntry](#) class to define cmdlets for the initial session state.

You can also make commands private. Private commands can be used by the host application, but not by users of the application.

Adding commands to an empty runspace

The following example demonstrates how to create an empty InitialSessionState and add commands to it.

C#

```
namespace Microsoft.Samples.PowerShell.Runspace
{
    using System;
    using System.Collections.ObjectModel;
    using System.Management.Automation;
    using System.Management.Automation.Runspace;
    using Microsoft.PowerShell.Commands;
    using PowerShell = System.Management.Automation.PowerShell;

    /// <summary>
    /// This class contains the Main entry point for the application.
    /// </summary>
    internal class Runspace10b
    {
        /// <summary>
        /// This sample shows how to create an empty initial session state,
        /// how to add commands to the session state, and then how to create a
        /// runspace that has only those two commands. A PowerShell object
        /// is used to run the Get-Command cmdlet to show that only two commands
        /// are available.
    }
}
```

```
/// </summary>
/// <param name="args">Parameter not used.</param>
private static void Main(string[] args)
{
    // Create an empty InitialSessionState and then add two commands.
    InitialSessionState iss = InitialSessionState.Create();

    // Add the Get-Process and Get-Command cmdlets to the session state.
    SessionStateCmdletEntry ssce1 = new SessionStateCmdletEntry(
        "Get-Process",

        typeof(GetProcessCommand),
        null);
    iss.Commands.Add(ssce1);

    SessionStateCmdletEntry ssce2 = new SessionStateCmdletEntry(
        "Get-Command",
        typeof(GetCommandCommand),
        null);
    iss.Commands.Add(ssce2);

    // Create a runspace.
    using (Runspace myRunSpace = RunspaceFactory.CreateRunspace(iss))
    {
        myRunSpace.Open();
        using (PowerShell powershell = PowerShell.Create())
        {
            powershell.Runspace = myRunSpace;

            // Create a pipeline with the Get-Command command.
            powershell.AddCommand("Get-Command");

            Collection<PSObject> results = powershell.Invoke();

            Console.WriteLine("Verb           Noun");
            Console.WriteLine("-----");

            // Display each result object.
            foreach (PSObject result in results)
            {
                Console.WriteLine(
                    "{0,-20} {1}",
                    result.Members["verb"].Value,
                    result.Members["Noun"].Value);
            }
        }

        // Close the runspace and release any resources.
        myRunSpace.Close();
    }

    System.Console.WriteLine("Hit any key to exit...");
    System.Console.ReadKey();
}
```

```
}
```

Making commands private

You can also make a command private, by setting it's [System.Management.Automation.CommandInfo.Visibility](#) property to [System.Management.Automation.SessionStateEntryVisibility](#) **Private**. The host application and other commands can call that command, but the user of the application cannot. In the following example, the [Get-ChildItem](#) command is private.

C#

```
defaultSessionState = InitialSessionState.CreateDefault();
commandIndex = GetIndexOfEntry(defaultSessionState.Commands, "Get-
ChildItem");
defaultSessionState.Commands[commandIndex].Visibility =
SessionStateEntryVisibility.Private;

this.runspace = RunspaceFactory.CreateRunspace(defaultSessionState);
this.runspace.Open();
```

Creating multiple runspaces

Article • 09/17/2021

If you create a large number of runspaces, you might consider creating a runspace pool. Using a [System.Management.Automation.Runspaces.RunspacePool](#) object, rather than creating a large number of individual runspaces with the same characteristics, can improve performance.

Creating and using a runspace pool.

The following example shows how to create a runspace pool and how to run a command asynchronously in a runspace of the pool.

C#

```
namespace HostRunspacePool
{
    using System;
    using System.Collections.ObjectModel;
    using System.Management.Automation;
    using System.Management.Automation.Runspaces;

    /// <summary>
    /// This class provides the Main entry point for the Host application.
    /// </summary>
    internal class HostRunspacePool
    {
        /// <summary>
        /// This sample demonstrates the following.
        /// 1. Creating and opening a runspace pool.
        /// 2. Creating a PowerShell object.
        /// 3. Adding commands and arguments to the PowerShell object.
        /// 4. Running the commands asynchronously using the runspace
        ///     of the runspace pool.
        /// </summary>
        /// <param name="args">Parameter is not used.</param>
        private static void Main(string[] args)
        {
            // Create a pool of runspaces.
            using (RunspacePool rsp = RunspaceFactory.CreateRunspacePool())
            {
                rsp.Open();

                // Create a PowerShell object to run the following command.
                // Get-Process wmi*
                PowerShell gpc = PowerShell.Create();
                // Specify the runspace to use and add commands.
                gpc.RunspacePool = rsp;
```

```
gpc.AddCommand("Get-Process").AddArgument("wmi*");

    // Invoke the command asynchronously.
    IAsyncResult gpcAsyncResult = gpc.BeginInvoke();
    // Get the results of running the command.
    PSDataCollection<PSObject> gpcOutput =
gpc.EndInvoke(gpcAsyncResult);

    // Process the output.
    Console.WriteLine("The output from running the command: Get-Process
wmi*");
    for (int i= 0; i < gpcOutput.Count; i++)
{
    Console.WriteLine(
        "Process Name: {0} Process Id: {1}",
        gpcOutput[i].Properties["ProcessName"].Value,
        gpcOutput[i].Properties["Id"].Value);
}
} // End using.
} // End Main entry point.
} // End HostPs5 class.
}
```

[Creating an InitialSessionState](#)

Adding and invoking commands

Article • 03/24/2025

After creating a runspace, you can add Windows PowerShell commands and scripts to a pipeline, and then invoke the pipeline synchronously or asynchronously.

Creating a pipeline

The [System.Management.Automation.PowerShell](#) class provides several methods to add commands, parameters, and scripts to the pipeline. You can invoke the pipeline synchronously by calling an overload of the [System.Management.Automation.PowerShell.Invoke*](#) method, or asynchronously by calling an overload of the [System.Management.Automation.PowerShell.BeginInvoke*](#) and then the [System.Management.Automation.PowerShell.EndInvoke*](#) method.

AddCommand

1. Create a [System.Management.Automation.PowerShell](#) object.

```
C#  
  
PowerShell ps = PowerShell.Create();
```

2. Add the command that you want to execute.

```
C#  
  
ps.AddCommand("Get-Process");
```

3. Invoke the command.

```
C#  
  
ps.Invoke();
```

If you call the [System.Management.Automation.PowerShell.AddCommand*](#) method more than once before you call the [System.Management.Automation.PowerShell.Invoke*](#) method, the result of the first command is piped to the second, and so on. If you do not want to pipe the result of a

previous command to a command, add it by calling the [System.Management.Automation.PowerShell.AddStatement*](#) instead.

AddParameter

The previous example executes a single command without any parameters. You can add parameters to the command by using the [System.Management.Automation.PSCmdlet.AddParameter*](#) method. For example, the following code gets a list of all of the processes that are named `powershell` running on the machine.

C#

```
PowerShell.Create().AddCommand("Get-Process")
    .AddParameter("Name", "powershell")
    .Invoke();
```

You can add additional parameters by calling

[System.Management.Automation.PSCmdlet.AddParameter*](#) repeatedly.

C#

```
PowerShell.Create().AddCommand("Get-Command")
    .AddParameter("Name", "Get-VM")
    .AddParameter("Module", "Hyper-V")
    .Invoke();
```

You can also add a dictionary of parameter names and values by calling the

[System.Management.Automation.PowerShell.AddParameters*](#) method.

C#

```
IDictionary parameters = new Dictionary<String, String>();
parameters.Add("Name", "Get-VM");

parameters.Add("Module", "Hyper-V");
PowerShell.Create().AddCommand("Get-Command")
    .AddParameters(parameters)
    .Invoke()
```

AddStatement

You can simulate batching by using the [System.Management.Automation.PowerShell.AddStatement](#)* method, which adds an additional statement to the end of the pipeline. The following code gets a list of running processes with the name `powershell`, and then gets the list of running services.

C#

```
PowerShell ps = PowerShell.Create();
ps.AddCommand("Get-Process").AddParameter("Name", "powershell");
ps.AddStatement().AddCommand("Get-Service");
ps.Invoke();
```

AddScript

You can run an existing script by calling the [System.Management.Automation.PowerShell.AddScript](#)* method. The following example adds a script to the pipeline and runs it. This example assumes there is already a script named `MyScript.ps1` in a folder named `D:\PSScripts`.

C#

```
PowerShell ps = PowerShell.Create();
ps.AddScript(File.ReadAllText(@"D:\PSScripts\MyScript.ps1")).Invoke();
```

There is also a version of the [System.Management.Automation.PowerShell.AddScript](#)* method that takes a boolean parameter named `useLocalScope`. If this parameter is set to `true`, then the script is run in the local scope. The following code will run the script in the local scope.

C#

```
PowerShell ps = PowerShell.Create();
ps.AddScript(File.ReadAllText(@"D:\PSScripts\MyScript.ps1"), true).Invoke();
```

Invoking a pipeline synchronously

After you add elements to the pipeline, you invoke it. To invoke the pipeline synchronously, you call an overload of the [System.Management.Automation.PowerShell.Invoke](#)* method. The following example shows how to synchronously invoke a pipeline.

C#

```

using System;
using System.Collections.Generic;
using System.Linq;
using System.Text;
using System.Management.Automation;

namespace HostPS1e
{
    class HostPS1e
    {
        static void Main(string[] args)
        {
            // Using the PowerShell.Create and AddCommand
            // methods, create a command pipeline.
            PowerShell ps = PowerShell.Create().AddCommand ("Sort-Object");

            // Using the PowerShell.Invoke method, run the command
            // pipeline using the supplied input.
            foreach (PSObject result in ps.Invoke(new int[] { 3, 1, 6, 2, 5, 4 }))
            {
                Console.WriteLine("{0}", result);
            } // End foreach.
        } // End Main.
    } // End HostPS1e.
}

```

Invoking a pipeline asynchronously

You invoke a pipeline asynchronously by calling an overload of the [System.Management.Automation.PowerShell.BeginInvoke*](#) to create an [IAsyncResult](#) object, and then calling the [System.Management.Automation.PowerShell.EndInvoke*](#) method.

The following example shows how to invoke a pipeline asynchronously.

C#

```

using System;
using System.Collections.Generic;
using System.Linq;
using System.Text;
using System.Management.Automation;

namespace HostPS3
{
    class HostPS3
    {
        static void Main(string[] args)
        {
            // Use the PowerShell.Create and PowerShell.AddCommand

```

```
// methods to create a command pipeline that includes
// Get-Process cmdlet. Do not include spaces immediately
// before or after the cmdlet name as that will cause
// the command to fail.
PowerShell ps = PowerShell.Create().AddCommand("Get-Process");

// Create an IAsyncResult object and call the
// BeginInvoke method to start running the
// command pipeline asynchronously.
IAsyncResult asyncpl = ps.BeginInvoke();

// Using the PowerShell.Invoke method, run the command
// pipeline using the default runspace.
foreach (PSObject result in ps.EndInvoke(asyncpl))
{
    Console.WriteLine("{0,-20}{1}",
        result.Members["ProcessName"].Value,
        result.Members["Id"].Value);
} // End foreach.
System.Console.WriteLine("Hit any key to exit.");
System.Console.ReadKey();
} // End Main.
} // End HostPS3.
}
```

[Creating a constrained runspace](#)

Creating remote runspaces

Article • 09/17/2021

PowerShell commands that take a `ComputerName` parameter can be run on any computer that runs PowerShell. To run commands that don't take a `ComputerName` parameter, you can use WS-Management to configure a runspace that connects to a specified computer, and run commands on that computer.

Using a `WSManConnection` to create a remote runspace

To create a runspace that connects to a remote computer, you create a `System.Management.Automation.Runspaces.WSManConnectionInfo` object. You specify the target endpoint for the connection by setting the `System.Management.Automation.Runspaces.WSManConnectionInfo.ConnectionUri` property of the object. You then create a runspace by calling the `System.Management.Automation.Runspaces.RunspaceFactory.CreateRunspace` method, specifying the `System.Management.Automation.Runspaces.WSManConnectionInfo` object as the `connectionInfo` parameter.

The following example shows how to create a runspace that connects to a remote computer. In the example, `RemoteComputerUri` is used as a placeholder for the actual URI of a remote computer.

C#

```
namespace Samples
{
    using System;
    using System.Collections.ObjectModel;
    using System.Management.Automation; // PowerShell namespace.
    using System.Management.Automation.Runspaces; // PowerShell namespace.

    /// <summary>
    /// This class contains the Main entry point for this host application.
    /// </summary>
    internal class RemoteRunspace02
    {
        /// <summary>
        /// This sample shows how to create a remote runspace that
        /// runs commands on the local computer.
        /// </summary>
        /// <param name="args">Parameter not used.</param>
        private static void Main(string[] args)
```

```

{
    // Create a WSMANConnectionInfo object using the default constructor
    // to connect to the "localHost". The WSMANConnectionInfo object can
    // also be used to specify connections to remote computers.
    Uri RemoteComputerUri = new Uri("http://Server01:5985/WSMAN");
    WSMANConnectionInfo connectionInfo = new
    WSMANConnectionInfo(RemoteComputerUri);

        // Set the OperationTimeout property and OpenTimeout properties.
        // The OperationTimeout property is used to tell PowerShell
        // how long to wait (in milliseconds) before timing out for an
        // operation. The OpenTimeout property is used to tell Windows
        // PowerShell how long to wait (in milliseconds) before timing out
        // while establishing a remote connection.
    connectionInfo.OperationTimeout = 4 * 60 * 1000; // 4 minutes.
    connectionInfo.OpenTimeout = 1 * 60 * 1000; // 1 minute.

        // Create a remote runspace using the connection information.
        //using (Runspace remoteRunspace = RunspaceFactory.CreateRunspace())
        using (Runspace remoteRunspace =
    RunspaceFactory.CreateRunspace(connectionInfo))
    {
        // Establish the connection by calling the Open() method to open the
        runspace.
        // The OpenTimeout value set previously will be applied while
        establishing
        // the connection. Establishing a remote connection involves sending
        and
        // receiving some data, so the OperationTimeout will also play a
        role in this process.
        remoteRunspace.Open();

        // Create a PowerShell object to run commands in the remote
        runspace.
        using (PowerShell powershell = PowerShell.Create())
        {
            powershell.Runspace = remoteRunspace;
            powershell.AddCommand("Get-Process");
            powershell.Invoke();

            Collection<PSObject> results = powershell.Invoke();

            Console.WriteLine("Process                  HandleCount");
            Console.WriteLine("-----");

            // Display the results.
            foreach (PSObject result in results)
            {
                Console.WriteLine(
                    "{0,-20} {1}",
                    result.Members["ProcessName"].Value,
                    result.Members["HandleCount"].Value);
            }
        }
    }
}

```

```
// Close the connection. Call the Close() method to close the remote
// runspace. The Dispose() method (called by using primitive) will
call
    // the Close() method if it is not already called.
    remoteRunspace.Close();
}
}
}
}
```

Creating a custom user interface

Article • 03/24/2025

Windows PowerShell provides abstract classes and interfaces that allow you to create a custom interactive UI that hosts the Windows PowerShell engine. To create a custom UI, you must implement the [System.Management.Automation.Host.PSHost](#) class.

Optionally, you can also implement the

[System.Management.Automation.Host.PSHostRawUserInterface](#) and

[System.Management.Automation.Host.PSHostUserInterface](#) classes, and the

[System.Management.Automation.Host.IHostSupportsInteractiveSession](#) and

[System.Management.Automation.Host.IHostUISupportsMultipleChoiceSelection](#)

interfaces.

Host Application Samples

Article • 09/17/2021

This section includes sample code that is provided in the Windows PowerShell 2.0 SDK.

In This Section

[PowerShell API Samples](#) This section includes sample code that shows how to create runspaces that restrict functionality, and how to asynchronously run commands using a runspace pool to supply the runspaces.

[Custom Host Samples](#) Includes sample code for writing a custom host. The host is the component of Windows PowerShell that provides communications between the user and the Windows PowerShell engine. For more information about custom hosts, see [Custom Host](#).

[Runspace Samples](#) Includes sample code for creating runspaces. For more information about how runspaces are used, see [Host Application Runspaces](#).

[Remote Runspace Samples](#) This section includes sample code that shows how to create runspaces that can be used to connect to a computer by using WS-Management-based Windows PowerShell remoting.

Windows PowerShell API Samples

Article • 12/18/2023

This section includes sample code that shows how to create runspaces that restrict functionality, and how to asynchronously run commands by using a runspace pool to supply the runspaces. You can use Microsoft Visual Studio to create a console application and then copy the code from the topics in this section into your host application.

In This Section

[PowerShell01 Sample](#) This sample shows how to use a `System.Management.Automation.Runspaces.InitialSessionState` object to limit the functionality of a runspace. The output of this sample demonstrates how to restrict the language mode of the runspace, how to mark a cmdlet as private, how to add and remove cmdlets and providers, how to add a proxy command, and more.

[PowerShell02 Sample](#) This sample shows how to run commands asynchronously by using the runspaces of a runspace pool. The sample generates a list of commands, and then runs those commands while the Windows PowerShell engine opens a runspace from the pool when it is needed.

Windows PowerShell01 Sample

Article • 03/24/2025

This sample shows how to use a [System.Management.Automation.Runspaces.InitialSessionState](#) object to limit the functionality of a runspace. The output of this sample demonstrates how to restrict the language mode of the runspace, how to mark a cmdlet as private, how to add and remove cmdlets and providers, how to add a proxy command, and more. This sample concentrates on how to restrict the runspace programmatically. Scripting alternatives to restricting the runspace include the `$ExecutionContext.SessionState.LanguageMode` and `PSSessionConfiguration` commands.

Requirements

This sample requires Windows PowerShell 2.0.

Demonstrates

This sample demonstrates the following:

- Restricting the language by setting the [System.Management.Automation.Runspaces.InitialSessionState.LanguageMode](#) property.
- Adding aliases to the initial session state by using a [System.Management.Automation.Runspaces.SessionStateAliasEntry](#) object.
- Marking commands as private.
- Removing providers from the initial session state by using the [System.Management.Automation.Runspaces.InitialSessionState.Providers](#) property.
- Removing commands from the initial session state by using the [System.Management.Automation.Runspaces.InitialSessionState.Commands](#) property.
- Adding commands and providers to the [System.Management.Automation.Runspaces.InitialSessionState](#) object.

Example

This sample shows several ways to limit the functionality of a runspace.

C#

```
namespace Sample
{
    using System;
    using System.Collections.ObjectModel;
    using System.Management.Automation;
    using System.Management.Automation.Runspaces;

    /// <summary>
    /// This class contains the Main entry point for the application.
    /// </summary>
    internal class PowerShell01
    {
        /// <summary>
        /// The runspace used to run commands.
        /// </summary>
        private Runspace runspace;

        /// <summary>
        /// Return the first index of the entry in <paramref name="entries"/>
        /// with the name <paramref name="name"/>. Return -1 if it is not found.
        /// </summary>
        /// <typeparam name="T">Type of ConstrainedSessionStateEntry</typeparam>
        /// <param name="entries">Collection of entries to search for <paramref
        name="name"/> in.</param>
        /// <param name="name">Named of the entry we are looking for</param>
        /// <returns>
        /// The first index of the entry in <paramref name="entries"/> with the
        /// name <paramref name="name"/>, or return -1 if it is not found.
        /// </returns>
        private static int GetIndexOfEntry<T>(
            InitialSessionStateEntryCollection<T> entries,
            string name) where T : ConstrainedSessionStateEntry
        {
            int foundIndex = 0;
            foreach (T entry in entries)
            {
                if (entry.Name.Equals(name, StringComparison.OrdinalIgnoreCase))
                {
                    return foundIndex;
                }

                foundIndex++;
            }

            return -1;
        }

        /// <summary>
        /// Run commands to demonstrate the ways to constrain the runspace.
        /// </summary>
    }
}
```

```
/// <param name="args">This parameter is unused.</param>
private static void Main(string[] args)
{
    new PowerShell01().RunCommands();
}

/// <summary>
/// Run a script to display the results and errors.
/// </summary>
/// <param name="script">Script to be run.</param>
/// <param name="scriptComment">Comment to be printed about
/// the script.</param>
private void RunScript(string script, string scriptComment)
{

Windows PowerShell02 Sample

Article • 09/17/2021

This sample shows how to run commands asynchronously using the runspaces of a runspace pool. The sample generates a list of commands, and then runs those commands while the Windows PowerShell engine opens a runspace from the pool when it is needed.

Requirements

- This sample requires Windows PowerShell 2.0.

Demonstrates

This sample demonstrates the following:

- Creating a RunspacePool object with a minimum and maximum number of runspaces allowed to be open at the same time.
- Creating a list of commands.
- Running the commands asynchronously.
- Calling the [System.Management.Automation.Runspaces.RunspacePool.GetAvailableRunspaces](#) * method to see how many runspaces are free.
- Capturing the command output with the [System.Management.Automation.PowerShell.EndInvoke](#)* method.

Example

This sample shows how to open the runspaces of a runspace pool, and how to asynchronously run commands in those runspaces.

C#

```
namespace Sample
{
    using System;
    using System.Collections;
    using System.Collections.Generic;
    using System.Management.Automation;
    using System.Management.Automation.Runspaces;

    /// <summary>
```

```

/// This class contains the Main entry point for the application.
/// </summary>
internal class PowerShell02
{
    /// <summary>
    /// Runs many commands with the help of a RunspacePool.
    /// </summary>
    /// <param name="args">This parameter is unused.</param>
    private static void Main(string[] args)
    {
        // Creating and opening runspace pool. Use a minimum of 1 runspace and
        // a maximum of
        // 5 runspaces can be opened at the same time.
        RunspacePool runspacePool = RunspaceFactory.CreateRunspacePool(1, 5);
        runspacePool.Open();

        using (runspacePool)
        {
            // Define the commands to be run.
            List<PowerShell> powerShellCommands = new List<PowerShell>();

            // The command results.
            List<IAsyncResult> powerShellCommandResults = new List<IAsyncResult>();
        }

        // The maximum number of runspaces that can be opened at one time is
        // 5, but we can queue up many more commands that will use the
        // runspace pool.
        for (int i = 0; i < 100; i++)
        {
            // Using a PowerShell object, run the commands.
            PowerShell powershell = PowerShell.Create();

            // Instead of setting the Runspace property of powershell,
            // the RunspacePool property is used. That is the only difference
            // between running commands with a runspace and running commands
            // with a runspace pool.
            powershell.RunspacePool = runspacePool;

            // The script to be run outputs a sequence number and the number
            // of available runspaces
            // in the pool.
            string script = String.Format(
                "write-output ' Command: {0}, Available Runspaces:
{1}'",
                i,
                runspacePool.GetAvailableRunspaces());

            // The three lines below look the same running with a runspace or
            // with a runspace pool.
            powershell.AddScript(script);
            powerShellCommands.Add(powershell);
            powerShellCommandResults.Add(powershell.BeginInvoke());
        }
    }
}

```

```

    // Collect the results.
    for (int i = 0; i < 100; i++)
    {
        // EndInvoke will wait for each command to finish, so we will be
        getting the commands
        // in the same 0 to 99 order that they have been invoked with
        BeginInvoke.

        PSDataCollection<PSObject> results =
powerShellCommands[i].EndInvoke(powerShellCommandResults[i]);

        // Print all the results. One PSObject with a plain string is the
        expected result.
        PowerShell02.PrintCollection(results);
    }
}

/// <summary>
/// Iterates through a collection printing all items.
/// </summary>
/// <param name="collection">collection to be printed</param>
private static void PrintCollection(IList collection)
{
    foreach (object obj in collection)
    {
        Console.WriteLine("PowerShell Result: {0}", obj);
    }
}
}

Custom Host Samples

Article • 09/17/2021

This section includes sample code for writing a custom host. You can use Microsoft Visual Studio to create a console application and then copy the code from the topics in this section into your host application.

In This Section

[Host01 Sample](#) This sample shows how to implement a host application that uses a basic custom host.

[Host02 Sample](#) This sample shows how to write a host application that uses the Windows PowerShell runtime along with a custom host implementation. The host application sets the host culture to German, runs the [Get-Process](#) cmdlet and displays the results as you would see them using pwrsh.exe, and then prints out the current date and time in German.

[Host03 Sample](#) This sample shows how to build an interactive console-based host application that reads commands from the command line, executes the commands, and then displays the results to the console.

[Host04 Sample](#) This sample shows how to build an interactive console-based host application that reads commands from the command line, executes the commands, and then displays the results to the console. This host application also supports displaying prompts that allow the user to specify multiple choices.

[Host05 Sample](#) This sample shows how to build an interactive console-based host application that reads commands from the command line, executes the commands, and then displays the results to the console. This host application also supports calls to remote computers by using the [Enter-PSSession](#) and [Exit-PSSession](#) cmdlets

[Host06 Sample](#) This sample shows how to build an interactive console-based host application that reads commands from the command line, executes the commands, and then displays the results to the console. In addition, this sample uses the Tokenizer APIs to specify the color of the text that is entered by the user.

Host01 Sample

Article • 04/10/2024

This sample shows how to implement a host application that uses a custom host. In this sample a runspace is created that uses the custom host, and then the [System.Management.Automation.PowerShell](#) API is used to run a script that calls "exit." The host application then looks at the output of the script and prints out the results.

This sample uses the default UI features provided by Windows PowerShell. For more information about implementing the UI features of a custom host, see [Host02 Sample](#).

Requirements

This sample requires Windows PowerShell 2.0.

Demonstrates

- Creating a custom host class that derives from the [System.Management.Automation.Host.PSHost](#) class.
- Creating a runspace that uses the custom host class.
- Creating a [System.Management.Automation.PowerShell](#) object that runs a script that calls exit.
- Verifying that the correct exit code was used in the exit process.

Example 1

The following code shows an implementation of a host application that uses a simple custom host interface.

C#

```
namespace Microsoft.Samples.PowerShell.Host
{
    using System;
    using System.Management.Automation;
    using System.Management.Automation.Runspaces;
    using PowerShell = System.Management.Automation.PowerShell;

    /// <summary>
```

```
/// This class contains the Main entry point for this host application.  
/// </summary>  
internal class Host01  
{  
  
    /// <summary>  
    /// Indicator to tell the host application that it should exit.  
    /// </summary>  
    private bool shouldExit;  
  
    /// <summary>  
    /// The exit code that the host application will use to exit.  
    /// </summary>  
    private int exitCode;  
  
    /// <summary>  
    /// Gets or sets a value indicating whether the  
    /// host application should exit.  
    /// </summary>  
    public bool ShouldExit  
    {  
        get { return this.shouldExit; }  
        set { this.shouldExit = value; }  
    }  
  
    /// <summary>  
    /// Gets or sets the PSHost implementation that is  
    /// used to tell the host application what code to use  
    /// when exiting.  
    /// </summary>  
    public int ExitCode  
    {  
        get { return this.exitCode; }  
        set { this.exitCode = value; }  
    }  
  
    /// <summary>  
    /// This sample uses a PowerShell object to run  
    /// a script that calls exit. The host application looks at  
    /// this and prints out the result.  
    /// </summary>  
    /// <param name="args">Parameter not used.</param>  
    private static void Main(string[] args)  
    {  
        // Create an instance of this host application class so that  
        // the Windows PowerShell engine will have access to the  
        // ShouldExit and ExitCode parameters.  
        Host01 me = new Host01();  
  
        // Create the host instance to use.  
        MyHost myHost = new MyHost(me);  
  
        // Create a runspace that uses the host object and run the  
        // script using a PowerShell object.  
        using (Runspace myRunSpace =
```

```

RunspaceFactory.CreateRunspace(myHost))
{
    // Open the runspace.
    myRunSpace.Open();

    // Create a PowerShell object to run the script.
    using (PowerShell powershell = PowerShell.Create())
    {
        powershell.Runspace = myRunSpace;

        // Create the pipeline and run the script
        // "exit (2+2)".
        string script = "exit (2+2)";
        powershell.AddScript(script);
        powershell.Invoke(script);
    }

    // Check the flags and see if they were set properly.
    Console.WriteLine(
        "ShouldExit={0} (should be True); ExitCode={1} (should
be 4)",
        me.ShouldExit,
        me.ExitCode);

    // close the runspace to free resources.
    myRunSpace.Close();
}

Console.WriteLine("Hit any key to exit...");
Console.ReadKey();
}
}

```

Example 2

The following code is the implementation of the [System.Management.Automation.Host.PSHost](#) class that is used by this host application. Those elements that are not implemented throw an exception or return nothing.

C#

```

namespace Microsoft.Samples.PowerShell.Host
{
    using System;
    using System.Globalization;
    using System.Management.Automation.Host;

    /// <summary>
    /// This is a sample implementation of the PSHost abstract class for
    /// console applications. Not all members are implemented. Those that

```

```
/// are not implemented throw a NotImplementedException exception or
/// return nothing.
/// </summary>
internal class MyHost : PSHost
{
    /// <summary>
    /// A reference to the PSHost implementation.
    /// </summary>
    private Host01 program;

    /// <summary>
    /// The culture information of the thread that created
    /// this object.
    /// </summary>
    private CultureInfo originalCultureInfo =
        System.Threading.Thread.CurrentThread.CurrentCulture;

    /// <summary>
    /// The UI culture information of the thread that created
    /// this object.
    /// </summary>
    private CultureInfo originalUICultureInfo =
        System.Threading.Thread.CurrentThread.CurrentCulture;

    /// <summary>
    /// The identifier of this PSHost implementation.
    /// </summary>
    private Guid myId = Guid.NewGuid();

    /// <summary>
    /// Initializes a new instance of the MyHost class. Keep
    /// a reference to the host application object so that it
    /// can be informed of when to exit.
    /// </summary>
    /// <param name="program">
    /// A reference to the host application object.
    /// </param>
    public MyHost(Host01 program)
    {
        this.program = program;
    }

    /// <summary>
    /// Return the culture information to use. This implementation
    /// returns a snapshot of the culture information of the thread
    /// that created this object.

Host02 Sample

Article • 03/24/2025

This sample shows how to write a host application that uses the Windows PowerShell runtime along with a custom host implementation. The host application sets the host culture to German, runs the [Get-Process](#) cmdlet and displays the results as you would see them by using pwrsh.exe, and then prints out the current date and time in German.

Requirements

This sample requires Windows PowerShell 2.0.

Demonstrates

- Creating a custom host whose classes derive from the [System.Management.Automation.Host.PSHost](#) class, the [System.Management.Automation.Host.PSHostUserInterface](#) class, and the [System.Management.Automation.Host.PSHostRawUserInterface](#) class.
- Creating a runspace that uses the custom host.
- Setting the host culture to German.
- Creating a [System.Management.Automation.PowerShell](#) object that runs a script to retrieve and sort the processes, then retrieves the current date which is displayed in German.

Example 1

The following code shows an implementation of a host application that uses the custom host.

C#

```
// Copyright (c) 2006 Microsoft Corporation. All rights reserved.  
//  
// THIS CODE AND INFORMATION IS PROVIDED "AS IS" WITHOUT WARRANTY OF  
// ANY KIND, EITHER EXPRESSED OR IMPLIED, INCLUDING BUT NOT LIMITED TO  
// THE IMPLIED WARRANTIES OF MERCHANTABILITY AND/OR FITNESS FOR A  
// PARTICULAR PURPOSE.  
  
using System;
```

```
using System.Collections.Generic;
using System.Text;
using System.Management.Automation;
using System.Management.Automation.Host;
using System.Management.Automation.Runspaces;
using System.Globalization;

namespace Microsoft.Samples.PowerShell.Host
{
    class Host02
    {
        /// <summary>
        /// Define the property that the PSHost implementation will
        /// use to tell the host application that it should exit.
        /// </summary>
        public bool ShouldExit
        {
            get { return shouldExit; }
            set { shouldExit = value; }
        }
        private bool shouldExit;

        /// <summary>
        /// Define the property that the PSHost implementation will
        /// use to tell the host application what exit code to use
        /// when exiting.
        /// </summary>
        public int ExitCode
        {
            get { return exitCode; }
            set { exitCode = value; }
        }
        private int exitCode;

        /// <summary>
        /// This sample uses the PowerShell runtime along with a host
        /// implementation to call Get-Process and display the results
        /// as you would see them in powershell.exe.
        /// </summary>
        /// <param name="args">Ignored</param>
        static void Main(string[] args)
        {
            // Set the current culture to German. We want this to be picked up
            when the MyHost
            // instance is created...
            System.Threading.Thread.CurrentThread.CurrentCulture =
            CultureInfo.GetCultureInfo("de-de");

            // Create the runspace so that you can access the pipeline.
            MyHost myHost = new MyHost(new Host02());

            Runspace myRunSpace = RunspaceFactory.CreateRunspace(myHost);
            myRunSpace.Open();

            // Create the pipeline.
```

```

Pipeline pipe = myRunSpace.CreatePipeline();

// Add the script we want to run. This script does two things.
// First, it runs the Get-Process cmdlet with the cmdlet output
// sorted by handle count. Second, the GetDate cmdlet is piped
// to the Out-String cmdlet so that we can see the
// date displayed in German.

pipe.Commands.AddScript(@"
    Get-Process | sort HandleCount
    # This should display the date in German...
    Get-Date | Out-String
");

// Add the default outputer to the end of the pipe and indicate
// that it should handle both output and errors from the previous
// commands. This will result in the output being written using the
PSHost
// and PSHostUserInterface classes instead of returning objects to the
hosting
// application.
pipe.Commands.Add("Out-Default");

pipe.Commands[0].MergeMyResults(PipelineResultTypes.Error,PipelineResultType
s.Output);

// Invoke the pipeline. There will not be any objects
// returned. The Out-Default cmdlet consumes the objects.
pipe.Invoke();

System.Console.WriteLine("Hit any key to exit...");
System.Console.ReadKey();
}

}
}

```

Example 2

The following code is the implementation of the [System.Management.Automation.Host.PSHost](#) class that is used by this host application. Those elements that are not implemented throw an exception or return nothing.

C#

```

namespace Microsoft.Samples.PowerShell.Host
{
    using System;
    using System.Globalization;
    using System.Management.Automation.Host;

    /// <summary>

```

```
/// This is a sample implementation of the PSHost abstract class for
/// console applications. Not all members are implemented. Those that
/// are not implemented throw a NotImplementedException exception or
/// return nothing.
/// </summary>
internal class MyHost : PSHost
{
    /// <summary>
    /// A reference to the PSHost implementation.
    /// </summary>
    private Host02 program;

    /// <summary>
    /// The culture information of the thread that created
    /// this object.
    /// </summary>
    private CultureInfo originalCultureInfo =
        System.Threading.Thread.CurrentThread.CurrentCulture;

    /// <summary>
    /// The UI culture information of the thread that created
    /// this object.
    /// </summary>
    private CultureInfo originalUICultureInfo =
        System.Threading.Thread.CurrentThread.CurrentUICulture;

Host03 Sample

Article • 09/17/2021

This sample shows how to build an interactive console-based host application that reads commands from the command line, executes the commands, and then displays the results to the console.

Requirements

This sample requires Windows PowerShell 2.0.

Demonstrates

- Creating a custom host whose classes derive from the [System.Management.Automation.Host.PSHost](#) class, the [System.Management.Automation.Host.PSHostUserInterface](#) class, and the [System.Management.Automation.Host.PSHostRawUserInterface](#) class.
- Building a console application that uses these host classes to build an interactive Windows PowerShell shell.

Example 1

This example allows the user to enter commands at a command line, processes those commands, and then prints out the results.

Host04 Sample

Article • 03/24/2025

This sample shows how to build an interactive console-based host application that reads commands from the command line, executes the commands, and then displays the results to the console. This host application also supports displaying prompts that allow the user to specify multiple choices.

Requirements

This sample requires Windows PowerShell 2.0.

Demonstrates

- Creating a custom host whose classes derive from the [System.Management.Automation.Host.PSHost](#) class, the [System.Management.Automation.Host.PSHostUserInterface](#) class, and the [System.Management.Automation.Host.PSHostRawUserInterface](#) class.
- Building a console application that uses these host classes to build an interactive Windows PowerShell shell.
- Creating a `$PROFILE` variable and loading the following profiles.
 - current user, current host
 - current user, all hosts
 - all users, current host
 - all users, all hosts
- Implement the [System.Management.Automation.Host.IHostUISupportsMultipleChoiceSelection](#) interface.

Example 1

This example allows the user to enter commands at a command line, processes those commands, and then prints out the results.

```
C#
```

```
namespace Microsoft.Samples.PowerShell.Host
{
```

```
using System;
using System.Collections.ObjectModel;
using System.Management.Automation;
using System.Management.Automation.Runspaces;
using PowerShell = System.Management.Automation.PowerShell;

/// <summary>
/// This class contains the Main entry point for this host application.
/// </summary>
internal class PSListenerConsoleSample
{
    /// <summary>
    /// Indicator to tell the host application that it should exit.
    /// </summary>
    private bool shouldExit;

    /// <summary>
    /// The exit code that the host application will use to exit.
    /// </summary>
    private int exitCode;

    /// <summary>
    /// Holds a reference to the PSHost object for this interpreter.

Host05 Sample

Article • 03/24/2025

This sample shows how to build an interactive console-based host application that reads commands from the command line, executes the commands, and then displays the results to the console. This host application also supports calls to remote computers by using the [Enter-PSSession](#) and [Exit-PSSession](#) cmdlets.

Requirements

- This sample requires Windows PowerShell 2.0.
- This application must be run in elevated mode (Run as administrator).

Demonstrates

- Creating a custom host whose classes derive from the [System.Management.Automation.Host.PSHost](#) class, the [System.Management.Automation.Host.PSHostUserInterface](#) class, and the [System.Management.Automation.Host.PSHostRawUserInterface](#) class.
- Building a console application that uses these host classes to build an interactive Windows PowerShell shell.
- Creating a `$PROFILE` variable and loading the following profiles.
 - current user, current host
 - current user, all hosts
 - all users, current host
 - all users, all hosts
- Implement the [System.Management.Automation.Host.IHostUISupportsMultipleChoiceSelection](#) interface.
- Implement the [System.Management.Automation.Host.IHostSupportsInteractiveSession](#) interface to support interactive remoting by using the [Enter-PSSession](#) and [Exit-PSSession](#) cmdlets.

Example 1

This example allows the user to enter commands at a command line, processes those commands, and then prints out the results.

C#

```
namespace Microsoft.Samples.PowerShell.Host
{
    using System;
    using System.Collections.Generic;
    using System.Collections.ObjectModel;
    using System.Management.Automation;
    using System.Management.Automation.Host;
    using System.Management.Automation.Runspaces;
    using System.Text;
    using PowerShell = System.Management.Automation.PowerShell;

    /// <summary>
    /// Simple PowerShell interactive console host listener implementation.
    This class
        /// implements a basic read-evaluate-print loop or 'listener' allowing you
        to
            /// interactively work with the PowerShell engine.
        /// </summary>
    internal class PSListenerConsoleSample

    return hotkeysAndPlainLabels;
}
}
}

```

Example 4

The following code is the implementation of the

[System.Management.Automation.Host.PSHostRawUserInterface](#) class that is used by this host application. Those elements that are not implemented throw an exception or return nothing.

C#

```

namespace Microsoft.Samples.PowerShell.Host
{
    using System;
    using System.Management.Automation.Host;

    /// <summary>
    /// A sample implementation of the PSHostRawUserInterface for console
    /// applications. Members of this class that easily map to the .NET
    /// console class are implemented. More complex methods are not
    /// implemented and throw a NotImplementedException exception.
    /// </summary>
    internal class MyRawUserInterface : PSHostRawUserInterface
    {
        /// <summary>
        /// Gets or sets the background color of text to be written.
        /// This maps to the corresponding Console.BackgroundColor property.
        /// </summary>
        public override ConsoleColor BackgroundColor
        {
            get { return Console.BackgroundColor; }
            set { Console.BackgroundColor = value; }
        }

        /// <summary>

```

```
/// Gets or sets the host buffer size adapted from the Console buffer
/// size members.
/// </summary>

Host06 Sample

Article • 03/24/2025

This sample shows how to build an interactive console-based host application that reads commands from the command line, executes the commands, and then displays the results to the console. In addition, this sample uses the Tokenizer APIs to specify the color of the text that is entered by the user.

Requirements

- This sample requires Windows PowerShell 2.0.
- This application must be run in elevated mode (Run as administrator).

Demonstrates

- Creating a custom host whose classes derive from the [System.Management.Automation.Host.PSHost](#) class, the [System.Management.Automation.Host.PSHostUserInterface](#) class, and the [System.Management.Automation.Host.PSHostRawUserInterface](#) class.
- Building a console application that uses these host classes to build an interactive Windows PowerShell shell.
- Creating a `$PROFILE` variable and loading the following profiles.
 - current user, current host
 - current user, all hosts
 - all users, current host
 - all users, all hosts
- Implement the [System.Management.Automation.Host.IHostUISupportsMultipleChoiceSelection](#) interface.
- Implement the [System.Management.Automation.Host.IHostSupportsInteractiveSession](#) interface to support interactive remoting by using the [Enter-PSSession](#) and [Exit-PSSession](#) cmdlets.
- Use the Tokenize API to colorize the command line as it is typed.

Example 1

This example allows the user to enter commands at a command line, processes those commands, and then prints out the results.

C#

```
namespace Microsoft.Samples.PowerShell.Host
{
    using System;
    using System.Collections.Generic;
    using System.Collections.ObjectModel;
    using System.Management.Automation;
    using System.Management.Automation.Host;
    using System.Management.Automation.Runspaces;
    using System.Text;
    using PowerShell = System.Management.Automation.PowerShell;

    /// <summary>
    /// This sample shows how to implement a basic read-evaluate-print
    /// loop (or 'listener') that allowing you to interactively work
    /// with the Windows PowerShell engine.
    /// </summary>
    internal class PSListenerConsoleSample
    {
        /// <summary>
        /// Used to read user input.
        /// </summary>

Example 5

The following code reads the command line and colors the text as it is entered. Tokens are determined by using the [System.Management.Automation.PSParser.Tokenize*](#) method.

C#

```

namespace Microsoft.Samples.PowerShell.Host
{
    using System;
    using System.Collections.ObjectModel;
    using System.Management.Automation;
    using System.Text;

    /// <summary>
    /// This class is used to read the command line and color the text as
    /// it is entered. Tokens are determined using the PSParser.Tokenize
    /// method.
    /// </summary>
    internal class ConsoleReadLine
    {

```

```
/// <summary>
/// The buffer used to edit.
/// </summary>
private StringBuilder buffer = new StringBuilder();

/// <summary>
/// The position of the cursor within the buffer.
/// </summary>
private int current;

/// <summary>
/// The count of characters in buffer rendered.
/// </summary>
private int rendered;

/// <summary>
/// Store the anchor and handle cursor movement
/// </summary>
private Cursor cursor;

/// <summary>
/// The array of colors for tokens, indexed by PSTokenType
/// </summary>

Runspace Samples

Article • 03/24/2025

This section includes sample code that shows how to use different types of runspaces to run commands synchronously and asynchronously. You can use Microsoft Visual Studio to create a console application and then copy the code from the topics in this section into your host application.

In This Section

Note

For samples of host applications that create custom host interfaces, see [Custom Host Samples](#).

[Runspace01 Sample](#) This sample shows how to use the `System.Management.Automation.PowerShell` class to run the `Get-Process` cmdlet synchronously and display its output in a console window.

[Runspace02 Sample](#) This sample shows how to use the `System.Management.Automation.PowerShell` class to run the `Get-Process` and `Sort-Object` cmdlets synchronously. The results of these commands is displayed by using a `System.Windows.Forms.DataGridView` control.

[Runspace03 Sample](#) This sample shows how to use the `System.Management.Automation.PowerShell` class to run a script synchronously, and how to handle non-terminating errors. The script receives a list of process names and then retrieves those processes. The results of the script, including any non-terminating errors that were generated when running the script, are displayed in a console window.

[Runspace04 Sample](#) This sample shows how to use the `System.Management.Automation.PowerShell` class to run commands, and how to catch terminating errors that are thrown when running the commands. Two commands are run, and the last command is passed a parameter argument that is not valid. As a result no objects are returned and a terminating error is thrown.

[Runspace05 Sample](#) This sample shows how to add a snap-in to a `System.Management.Automation.Runspaces.InitialSessionState` object so that the cmdlet of the snap-in is available when the runspace is opened. The snap-in provides a

Get-Proc cmdlet (defined by the [GetProcessSample01 Sample](#)) that is run synchronously using a [System.Management.Automation.PowerShell](#) object.

Runspace06 Sample This sample shows how to add a module to a [System.Management.Automation.Runspaces.InitialSessionState](#) object so that the module is loaded when the runspace is opened. The module provides a Get-Proc cmdlet (defined by the [GetProcessSample02 Sample](#)) that is run synchronously using a [System.Management.Automation.PowerShell](#) object.

Runspace07 Sample This sample shows how to create a runspace, and then use that runspace to run two cmdlets synchronously by using a [System.Management.Automation.PowerShell](#) object.

Runspace08 Sample This sample shows how to add commands and arguments to the pipeline of a [System.Management.Automation.PowerShell](#) object and how to run the commands synchronously.

Runspace09 Sample This sample shows how to add a script to the pipeline of a [System.Management.Automation.PowerShell](#) object and how to run the script asynchronously. Events are used to handle the output of the script.

Runspace10 Sample This sample shows how to create a default initial session state, how to add a cmdlet to the [System.Management.Automation.Runspaces.InitialSessionState](#), how to create a runspace that uses the initial session state, and how to run the command by using a [System.Management.Automation.PowerShell](#) object.

Runspace11 Sample This shows how to use the [System.Management.Automation.ProxyCommand](#) class to create a proxy command that calls an existing cmdlet, but restricts the set of available parameters. The proxy command is then added to an initial session state that is used to create a constrained runspace. This means that the user can access the functionality of the cmdlet only through the proxy command.

Runspace01 Sample

Article • 09/17/2021

This sample shows how to use the [System.Management.Automation.PowerShell](#) class to run the [Get-Process](#) cmdlet synchronously. The [Get-Process](#) cmdlet returns [System.Diagnostics.Process](#) objects for each process running on the local computer. The values of the [System.Diagnostics.Process.ProcessName*](#) and [System.Diagnostics.Process.HandleCount*](#) properties are then extracted from the returned objects and displayed in a console window.

Requirements

This sample requires Windows PowerShell 2.0.

Demonstrates

- Creating a [System.Management.Automation.PowerShell](#) object to run a command.
- Adding a command to the pipeline of the [System.Management.Automation.PowerShell](#) object.
- Running the command synchronously.
- Using [System.Management.Automation.PSObject](#) objects to extract properties from the objects returned by the command.

Example

This sample runs the [Get-Process](#) cmdlet synchronously in the default runspace provided by Windows PowerShell.

C#

```
namespace Microsoft.Samples.PowerShell.Runspaces
{
    using System;
    using System.Management.Automation;
    using PowerShell = System.Management.Automation.PowerShell;

    /// <summary>
    /// This class contains the Main entry point for this host application.

Runspace02 Sample

Article • 03/24/2025

This sample shows how to use the [System.Management.Automation.PowerShell](#) class to run the [Get-Process](#) and [Sort-Object](#) cmdlets synchronously. The [Get-Process](#) cmdlet returns [System.Diagnostics.Process](#) objects for each process running on the local computer, and the [Sort-Object](#) sorts the objects based on their [System.Diagnostics.Process.Id*](#) property. The results of these commands is displayed by using a [System.Windows.Forms.DataGridView](#) control.

Requirements

This sample requires Windows PowerShell 2.0.

Demonstrates

This sample demonstrates the following.

- Creating a [System.Management.Automation.PowerShell](#) object to run commands.
- Adding commands to the pipeline of [System.Management.Automation.PowerShell](#) object.
- Running the commands synchronously.
- Using a [System.Windows.Forms.DataGridView](#) control to display the output of the commands in a Windows Forms application.

Example

This sample runs the [Get-Process](#) and [Sort-Object](#) cmdlets synchronously in the default runspace provided by Windows PowerShell. The output is displayed in a form using a [System.Windows.Forms.DataGridView](#) control.

C#

```
namespace Microsoft.Samples.PowerShell.Runspaces
{
    using System;
    using System.Collections;
    using System.Collections.ObjectModel;
    using System.Management.Automation;
```

```
using System.Management.Automation.Runspaces;
using System.Windows.Forms;
using PowerShell = System.Management.Automation.PowerShell;

/// <summary>
/// This class contains the Main entry point for this host application.
/// </summary>
internal class Runspace02
{
    /// <summary>
    /// This method creates the form where the output is displayed.
    /// </summary>
    private static void CreateForm()
    {
        Form form = new Form();
        DataGridView grid = new DataGridView();
        form.Controls.Add(grid);
        grid.Dock = DockStyle.Fill;

        // Create a PowerShell object. Creating this object takes care of
        // building all of the other data structures needed to run the
        command.

        using (PowerShell powershell = PowerShell.Create())
        {
            powershell.AddCommand("Get-Process").AddCommand("Sort-
Object").AddArgument("ID");
            if (Runspace.DefaultRunspace == null)
            {
                Runspace.DefaultRunspace = powershell.Runspace;
            }

            Collection<PSObject> results = powershell.Invoke();

            // The generic collection needs to be re-wrapped in an ArrayList
            // for data-binding to work.
            ArrayList objects = new ArrayList();
            objects.AddRange(results);

            // The DataGridView will use the PSObjectTypeDescriptor type
            // to retrieve the properties.
            grid.DataSource = objects;
        }

        form.ShowDialog();
    }

    /// <summary>
    /// This sample uses a PowerShell object to run the Get-Process
    /// and Sort-Object cmdlets synchronously. Windows Forms and
    /// data binding are then used to display the results in a
    /// DataGridView control.
    /// </summary>
    /// <param name="args">The parameter is not used.</param>
    /// <remarks>

Runspace03 Sample

Article • 09/17/2021

This sample shows how to use the [System.Management.Automation.PowerShell](#) class to run a script synchronously, and how to handle non-terminating errors. The script receives a list of process names and then retrieves those processes. The results of the script, including any non-terminating errors that were generated when running the script, are displayed in a console window.

Requirements

This sample requires Windows PowerShell 2.0.

Demonstrates

This sample demonstrates the following.

- Creating a [System.Management.Automation.PowerShell](#) object to run a script.
- Adding a script to the pipeline of the [System.Management.Automation.PowerShell](#) object.
- Passing input objects to the script from the calling program.
- Running the script synchronously.
- Using [System.Management.Automation.PSObject](#) objects to extract and display properties from the objects returned by the script.
- Retrieving and displaying error records that were generated when the script was run.

Example

This sample runs a script synchronously in the default runspace provided by Windows PowerShell. The output of the script and any non-terminating errors that were generated are displayed in a console window.

```
C#
```

```
namespace Microsoft.Samples.PowerShell.Runspaces
{
```

```
using System;
using System.Collections;
using System.Management.Automation;
using System.Management.Automation.Runspaces;
using PowerShell = System.Management.Automation.PowerShell;

/// <summary>
/// This class contains the Main entry point for this host application.
/// </summary>
internal class Runspace03
{
    /// <summary>
    /// This sample shows how to use the PowerShell class to run a
    /// script that retrieves process information for the list of
    /// process names passed to the script. It shows how to pass input
    /// objects to a script and how to retrieve error objects as well
    /// as the output objects.
    /// </summary>
    /// <param name="args">Parameter not used.</param>
    /// <remarks>
    /// This sample demonstrates the following:
    /// 1. Creating a PowerShell object to run a script.
    /// 2. Adding a script to the pipeline of the PowerShell object.
    /// 3. Passing input objects to the script from the calling program.
    /// 4. Running the script synchronously.
    /// 5. Using PSObject objects to extract and display properties from
    ///     the objects returned by the script.
    /// 6. Retrieving and displaying error records that were generated
    ///     when the script was run.
    /// </remarks>
    private static void Main(string[] args)
    {
        // Define a list of processes to look for.
        string[] processNames = new string[]
        {
            "lsass", "nosuchprocess", "services", "nosuchprocess2"
        };

        // The script to run to get these processes. Input passed
        // to the script will be available in the $input variable.
        string script = "$input | Get-Process -Name ${_}";

        // Create a PowerShell object. Creating this object takes care of
        // building all of the other data structures needed to run the script.
        using (PowerShell powershell = PowerShell.Create())
        {
            powershell.AddScript(script);

            Console.WriteLine("Process                  HandleCount");
            Console.WriteLine("-----");

            // Invoke the script synchronously and display the
            // ProcessName and HandleCount properties of the
            // objects that are returned.
            foreach (PSObject result in powershell.Invoke(processNames))

```

```
        {
            Console.WriteLine(
                "{0,-20} {1}",
                result.Members["ProcessName"].Value,
                result.Members["HandleCount"].Value);
        }

        // Process any error records that were generated while running
        // the script.
        Console.WriteLine("\nThe following non-terminating errors
occurred:\n");
        PSDataCollection<ErrorRecord> errors = powershell.Streams.Error;
        if (errors != null && errors.Count > 0)
        {
            foreach (ErrorRecord err in errors)
            {
                System.Console.WriteLine("    error: {0}", err.ToString());
            }
        }
    }

    System.Console.WriteLine("\nHit any key to exit...");
    System.Console.ReadKey();
}
}
```

Runspace04 Sample

Article • 09/17/2021

This sample shows how to use the [System.Management.Automation.PowerShell](#) class to run commands, and how to catch terminating errors that are thrown when running the commands. Two commands are run, and the last command is passed a parameter argument that is not valid. As a result, no objects are returned and a terminating error is thrown.

Requirements

This sample requires Windows PowerShell 2.0.

Demonstrates

This sample demonstrates the following.

- Creating a [System.Management.Automation.PowerShell](#) object.
- Adding commands to the pipeline of the [System.Management.Automation.PowerShell](#) object.
- Adding parameter arguments to the pipeline.
- Invoking the commands synchronously.
- Using [System.Management.Automation.PSObject](#) objects to extract and display properties from the objects returned by the commands.
- Retrieving and displaying error records that were generated during the running of the commands.
- Catching and displaying terminating exceptions thrown by the commands.

Example

This sample runs commands synchronously in the default runspace provided by Windows PowerShell. The last command throws a terminating error because a parameter argument that is not valid is passed to the command. The terminating error is trapped and displayed.

C#

```
namespace Microsoft.Samples.PowerShell.Runspaces
{
    using System;
    using System.Management.Automation;
    using System.Management.Automation.Runspaces;
    using PowerShell = System.Management.Automation.PowerShell;

    /// <summary>
    /// This class contains the Main entry point for this host application.
    /// </summary>
    internal class Runspace04
    {
        /// <summary>
        /// This sample shows how to use a PowerShell object to run commands.
        /// The commands generate a terminating exception that the caller
        /// should catch and process.
        /// </summary>
        /// <param name="args">The parameter is not used.</param>
        /// <remarks>
        /// This sample demonstrates the following:
        /// 1. Creating a PowerShell object to run commands.
        /// 2. Adding commands to the pipeline of the PowerShell object.
        /// 3. Passing input objects to the commands from the calling program.
        /// 4. Using PSObject objects to extract and display properties from the
        ///     objects returned by the commands.
        /// 5. Retrieving and displaying error records that were generated
        ///     while running the commands.
        /// 6. Catching and displaying terminating exceptions generated
        ///     while running the commands.
        /// </remarks>
        private static void Main(string[] args)
        {
            // Create a PowerShell object.
            using (PowerShell powershell = PowerShell.Create())
            {
                // Add the commands to the PowerShell object.
                powershell.AddCommand("Get-ChildItem").AddCommand("Select-
String").AddArgument("*");

                // Run the commands synchronously. Because of the bad regular
                expression,
                // no objects will be returned. Instead, an exception will be
                thrown.
                try
                {
                    foreach (PSObject result in powershell.Invoke())
                    {
                        Console.WriteLine('{0}', result.ToString());
                    }
                }

                // Process any error records that were generated while running the
                commands.
            }
        }
    }
}
```

```
Console.WriteLine("\nThe following non-terminating errors
occurred:\n");
PSDataCollection<ErrorRecord> errors = powershell.Streams.Error;
if (errors != null && errors.Count > 0)
{
    foreach (ErrorRecord err in errors)
    {
        System.Console.WriteLine("    error: {0}", err.ToString());
    }
}
catch (RuntimeException runtimeException)
{
    // Trap any exception generated by the commands. These exceptions
    // will all be derived from the RuntimeException exception.
    System.Console.WriteLine(
        "Runtime exception: {0}: {1}\n{2}",
        runtimeException.ErrorRecord.InvocationInfo.InvocationName,
        runtimeException.Message,
        runtimeException.ErrorRecord.InvocationInfo.PositionMessage);
}
}

System.Console.WriteLine("\nHit any key to exit...");
System.Console.ReadKey();
}
}
}
```

Runspace05 Sample

Article • 03/24/2025

This sample shows how to add a snap-in to a [System.Management.Automation.Runspaces.InitialSessionState](#) object so that the cmdlet of the snap-in is available when the runspace is opened. The snap-in provides a Get-Proc cmdlet (defined by the [GetProcessSample01 Sample](#)) that is run synchronously by using a [System.Management.Automation.PowerShell](#) object.

Requirements

This sample requires Windows PowerShell 2.0.

Demonstrates

This sample demonstrates the following.

- Creating a [System.Management.Automation.Runspaces.InitialSessionState](#) object.
- Adding the snap-in to the [System.Management.Automation.Runspaces.InitialSessionState](#) object.
- Creating a [System.Management.Automation.Runspaces.Runspace](#) object that uses the [System.Management.Automation.Runspaces.InitialSessionState](#) object.
- Creating a [System.Management.Automation.PowerShell](#) object that uses the runspace.
- Adding the snap-in's Get-Proc cmdlet to the pipeline of the [System.Management.Automation.PowerShell](#) object.
- Running the command synchronously.
- Extracting properties from the [System.Management.Automation.PSObject](#) objects returned by the command.

Example

This sample creates a runspace that uses a [System.Management.Automation.Runspaces.InitialSessionState](#) object to define the

elements that are available when the runspace is opened. In this sample, a snap-in that defines a Get-Proc cmdlet is added to the initial session state.

C#

```
namespace Microsoft.Samples.PowerShell.Runspaces
{
    using System;
    using System.Collections.ObjectModel;
    using System.Management.Automation;
    using System.Management.Automation.Runspaces;
    using PowerShell = System.Management.Automation.PowerShell;

    /// <summary>
    /// This class contains the Main entry point for this host application.
    /// </summary>
    internal class Runspace05
    {
        /// <summary>
        /// This sample shows how to define an initial session state that is
        /// used when creating a runspace. The sample invokes a command from
        /// a Windows PowerShell snap-in that is present in the console file.
        /// </summary>
        /// <param name="args">The parameter is not used.</param>
        /// <remarks>
        /// This sample assumes that user has copied the GetProcessSample01.dll
        /// that is produced by the GetProcessSample01 sample to the current
        /// directory.
        /// This sample demonstrates the following:
        /// 1. Creating a default initial session state.
        /// 2. Adding a snap-in to the initial session state.
        /// 3. Creating a runspace that uses the initial session state.
        /// 4. Creating a PowerShell object that uses the runspace.
        /// 5. Adding the snap-in's Get-Proc cmdlet to the PowerShell object.
        /// 6. Using PSObject objects to extract and display properties from
        ///     the objects returned by the cmdlet.
        /// </remarks>
        private static void Main(string[] args)
        {
            // Create the default initial session state. The default initial
            // session state contains all the elements provided by Windows
            // PowerShell.
            InitialSessionState iss = InitialSessionState.CreateDefault();
            PSSnapInException warning;
            iss.ImportPSSnapIn("GetProcPSSnapIn01", out warning);

            // Create a runspace. Notice that no PSHost object is supplied to the
            // CreateRunspace method so the default host is used. See the Host
            // samples for more information on creating your own custom host.
            using (Runspace myRunSpace = RunspaceFactory.CreateRunspace(iss))
            {
                myRunSpace.Open();

                // Create a PowerShell object.
```

```
using (PowerShell powershell = PowerShell.Create())
{
    // Add the snap-in cmdlet and specify the runspace.
    powershell.AddCommand("GetProcPSSnapIn01\Get-Proc");
    powershell.Runspace = myRunSpace;

    // Run the cmdlet synchronously.
    Collection<PSObject> results = powershell.Invoke();

    Console.WriteLine("Process           HandleCount");
    Console.WriteLine("-----");

    // Display the results.
    foreach (PSObject result in results)
    {
        Console.WriteLine(
            "{0,-20} {1}",
            result.Members["ProcessName"].Value,
            result.Members["HandleCount"].Value);
    }
}

// Close the runspace to release any resources.
myRunSpace.Close();
}
System.Console.WriteLine("Hit any key to exit...");
System.Console.ReadKey();
}
}
```

Runspace06 Sample

Article • 03/24/2025

This sample shows how to add a module to a [System.Management.Automation.Runspaces.InitialSessionState](#) object so that the module is loaded when the runspace is opened. The module provides a Get-Proc cmdlet (defined by the [GetProcessSample02 Sample](#)) that is run synchronously by using a [System.Management.Automation.PowerShell](#) object.

Requirements

This sample requires Windows PowerShell 2.0.

Demonstrates

This sample demonstrates the following.

- Creating a [System.Management.Automation.Runspaces.InitialSessionState](#) object.
- Adding the module to the [System.Management.Automation.Runspaces.InitialSessionState](#) object.
- Creating a [System.Management.Automation.Runspaces.Runspace](#) object that uses the [System.Management.Automation.Runspaces.InitialSessionState](#) object.
- Creating a [System.Management.Automation.PowerShell](#) object that uses the runspace.
- Adding the module's Get-Proc cmdlet to the pipeline of the [System.Management.Automation.PowerShell](#) object.
- Running the command synchronously.
- Extracting properties from the [System.Management.Automation.PSObject](#) objects returned by the command.

Example

This sample creates a runspace that uses a [System.Management.Automation.Runspaces.InitialSessionState](#) object to define the

elements that are available when the runspace is opened. In this sample, a module that defines a Get-Proc cmdlet is added to the initial session state.

C#

```
namespace Microsoft.Samples.PowerShell.Runspaces
{
    using System;
    using System.Collections.ObjectModel;
    using System.Management.Automation;
    using System.Management.Automation.Runspaces;
    using PowerShell = System.Management.Automation.PowerShell;

    /// <summary>
    /// This class contains the Main entry point for this host application.
    /// </summary>
    internal class Runspace06
    {
        /// <summary>
        /// This sample shows how to define an initial session state that is
        /// used when creating a runspace. The sample invokes a command from
        /// a binary module that is loaded by the initial session state.
        /// </summary>
        /// <param name="args">Parameter not used.</param>

Runspace07 Sample

Article • 03/24/2025

This sample shows how to create a runspace, and then use that runspace to run two cmdlets synchronously by using a [System.Management.Automation.PowerShell](#) object.

Requirements

This sample requires Windows PowerShell 2.0.

Demonstrates

This sample demonstrates the following.

- Creating a [System.Management.Automation.Runspaces.Runspace](#) object by using the [System.Management.Automation.Runspaces.RunspaceFactory](#) class.
- Creating a [System.Management.Automation.PowerShell](#) object that uses the runspace.
- Adding cmdlets to the pipeline of the [System.Management.Automation.PowerShell](#) object.
- Running the cmdlets synchronously.
- Extracting properties from the [System.Management.Automation.PSObject](#) objects returned by the command.

Example

This sample creates a runspace that used by a [System.Management.Automation.PSObject](#) object to run the [Get-Process](#) and [Measure-Object](#) cmdlets.

C#

```
namespace Microsoft.Samples.PowerShell.Runspaces
{
    using System;
    using System.Collections.ObjectModel;
    using System.Management.Automation;
    using System.Management.Automation.Runspaces;
    using PowerShell = System.Management.Automation.PowerShell;
```

```
/// <summary>
/// This class contains the Main entry point for this host application.
/// </summary>
internal class Runspace07
{
    /// <summary>
    /// This sample shows how to create a runspace and how to run commands
    /// using a PowerShell object. It builds a pipeline that runs the
    /// Get-Process cmdlet, which is piped to the Measure-Object
    /// cmdlet to count the number of processes running on the system.
    /// </summary>
    /// <param name="args">The parameter is not used.</param>
    /// <remarks>
    /// This sample demonstrates the following:
    /// 1. Creating a runspace using the RunspaceFactory class.
    /// 2. Creating a PowerShell object that uses the runspace.
    /// 3. Adding cmdlets to the pipeline of the PowerShell object.
    /// 4. Running the cmdlets synchronously.
    /// 5. Working with PSObject objects to extract properties
    ///     from the objects returned by the cmdlets.
    /// </remarks>
    private static void Main(string[] args)
    {
        Collection<PSObject> result;      // Will hold the result
                                         // of running the cmdlets.

        // Create a runspace. We can't use the RunspaceInvoke class
        // because we need to get at the underlying runspace to
        // explicitly add the commands. Notice that no PSHost object is
        // supplied to the CreateRunspace method so the default host is
        // used. See the Host samples for more information on creating
        // your own custom host.
        using (Runspace myRunSpace = RunspaceFactory.CreateRunspace())
        {
            myRunSpace.Open();

            // Create a PowerShell object and specify the runspace.
            PowerShell powershell = PowerShell.Create();
            powershell.Runspace = myRunSpace;

            // Use the using statement so we dispose of the PowerShell object
            // when we're done.
            using (powershell)
            {
                // Add the Get-Process cmdlet to the PowerShell object. Notice
                // we are specify the name of the cmdlet, not a script.
                powershell.AddCommand("Get-Process");

                // Add the Measure-Object cmdlet to count the number
                // of objects being returned. Commands are always added to the end
                // of the pipeline.
                powershell.AddCommand("Measure-Object");

                // Run the cmdlets synchronously and save the objects returned.
            }
        }
    }
}
```

```

        result = powershell.Invoke();
    }

    // Even after disposing of the pipeLine, we still need to set
    // the powershell variable to null so that the garbage collector
    // can clean it up.
    powershell = null;

    // Display the results of running the commands (checking that
    // everything is ok first.
    if (result == null || result.Count != 1)
    {
        throw new InvalidOperationException(
            "pipeline.Invoke() returned the wrong number of
objects");
    }

    PSMemberInfo count = result[0].Properties["Count"];
    if (count == null)
    {
        throw new InvalidOperationException(
            "The object returned doesn't have a 'count' property");
    }

    Console.WriteLine(
        "Runspace07: The Get-Process cmdlet returned {0}
objects",
        count.Value);

    // Close the runspace to release any resources.
    myRunSpace.Close();
}

System.Console.WriteLine("Hit any key to exit...");
System.Console.ReadKey();
}
}
}

Runspace08 Sample

Article • 03/24/2025

This sample shows how to add commands and arguments to the pipeline of a [System.Management.Automation.PowerShell](#) object and how to run the commands synchronously.

Requirements

This sample requires Windows PowerShell 2.0.

Demonstrates

This sample demonstrates the following.

- Creating a [System.Management.Automation.Runspaces.Runspace](#) object by using the [System.Management.Automation.Runspaces.RunspaceFactory](#) class.
- Creating a [System.Management.Automation.PowerShell](#) object that uses the runspace.
- Adding cmdlets to the pipeline of the [System.Management.Automation.PowerShell](#) object.
- Running the cmdlets synchronously.
- Extracting properties from the [System.Management.Automation.PSObject](#) objects returned by the command.

Example

This sample runs the [Get-Process](#) and [Sort-Object](#) cmdlets by using a [System.Management.Automation.PowerShell](#) object.

```
C#
```

```
namespace Microsoft.Samples.PowerShell.Runspaces
{
    using System;
    using System.Collections.Generic;
    using System.Collections.ObjectModel;
    using System.Management.Automation;
    using System.Management.Automation.Runspaces;
```

```

using PowerShell = System.Management.Automation.PowerShell;

/// <summary>
/// This class contains the Main entry point for this host application.
/// </summary>
internal class Runspace08
{
    /// <summary>
    /// This sample shows how to use a PowerShell object to run commands.
    The
        /// PowerShell object builds a pipeline that include the Get-Process
        cmdlet,
        /// which is then piped to the Sort-Object cmdlet. Parameters are added
        to the
            /// Sort-Object cmdlet to sort the HandleCount property in descending
            order.
        /// </summary>
        /// <param name="args">Parameter is not used.</param>
        /// <remarks>
        /// This sample demonstrates:
        /// 1. Creating a PowerShell object
        /// 2. Adding individual commands to the PowerShell object.
        /// 3. Adding parameters to the commands.
        /// 4. Running the pipeline of the PowerShell object synchronously.
        /// 5. Working with PSObject objects to extract properties
        ///     from the objects returned by the commands.
        /// </remarks>
    private static void Main(string[] args)
    {
        Collection<PSObject> results; // Holds the result of the pipeline
        execution.

            // Create the PowerShell object. Notice that no runspace is specified
            so a
            // new default runspace is used.
            PowerShell powershell = PowerShell.Create();

            // Use the using statement so that we can dispose of the PowerShell
            object
            // when we are done.
            using (powershell)
            {
                // Add the Get-Process cmdlet to the pipeline of the PowerShell
                object.
                powershell.AddCommand("Get-Process");

                // Add the Sort-Object cmdlet and its parameters to the pipeline of
                // the PowerShell object so that we can sort the HandleCount
                property
                    // in descending order.
                    powershell.AddCommand("Sort-
                Object").AddParameter("Descending").AddParameter("Property", "HandleCount");

                    // Run the commands of the pipeline synchronously.
                    results = powershell.Invoke();
    }
}

```

```
}

// Even after disposing of the PowerShell object, we still
// need to set the powershell variable to null so that the
// garbage collector can clean it up.
powershell = null;

Console.WriteLine("Process           HandleCount");
Console.WriteLine("-----");

// Display the results returned by the commands.
foreach (PSObject result in results)
{
    Console.WriteLine(
        "{0,-20} {1}",
        result.Members["ProcessName"].Value,
        result.Members["HandleCount"].Value);
}

System.Console.WriteLine("Hit any key to exit...");
System.Console.ReadKey();
}
}
```

Runspace09 Sample

Article • 03/24/2025

This sample shows how to add a script to the pipeline of a [System.Management.Automation.PowerShell](#) object and how to run the script asynchronously. Events are used to handle the output of the script.

Requirements

This sample requires Windows PowerShell 2.0.

Demonstrates

This sample demonstrates the following.

- Creating a [System.Management.Automation.PowerShell](#) object that uses the runspace.
- Adding a script the pipeline of the [System.Management.Automation.PowerShell](#) object.
- Using the [System.Management.Automation.PowerShell.BeginInvoke*](#) method to run the pipeline asynchronously.
- Using the events of the [System.Management.Automation.PowerShell](#) object to process the output of the script.
- Using the [System.Management.Automation.PowerShell.Stop*](#) method to interrupt the invocation of the pipeline.

Example

This sample runs to run a script that generates the numbers from 1 to 10 with delays between each number. The script is run asynchronously and events are used to handle the output.

C#

```
namespace Microsoft.Samples.PowerShell.Runspaces
{
    using System;
    using System.Collections.Generic;
```

```

using System.Collections.ObjectModel;
using System.Diagnostics;
using System.Management.Automation;
using System.Management.Automation.Runspaces;
using PowerShell = System.Management.Automation.PowerShell;

/// <summary>
/// This class contains the Main entry point for this host application.
/// </summary>
internal class Runspace09

Runspace10 Sample

Article • 03/24/2025

This sample shows how to create a default initial session state, how to add a cmdlet to the [System.Management.Automation.Runspaces.InitialSessionState](#), how to create a runspace that uses the initial session state, and how to run the command by using a [System.Management.Automation.PowerShell](#) object.

Requirements

This sample requires Windows PowerShell 2.0.

Demonstrates

This sample demonstrates the following.

- Creating a [System.Management.Automation.Runspaces.InitialSessionState](#) object.
- Adding a cmdlet (defined by the Host application) to the [System.Management.Automation.Runspaces.InitialSessionState](#) object.
- Creating a [System.Management.Automation.Runspaces.Runspace](#) object that uses the object.
- Creating a [System.Management.Automation.PowerShell](#) object that uses the [System.Management.Automation.Runspaces.Runspace](#) object.
- Adding the command to the pipeline of the [System.Management.Automation.PowerShell](#) object.
- Extracting properties from the [System.Management.Automation.PSObject](#) objects returned by the command.

Example

This sample creates a runspace that uses a [System.Management.Automation.Runspaces.InitialSessionState](#) object to define the elements that are available when the runspace is opened. In this sample, the Get-Proc cmdlet (defined by the Host application) is added to the initial session state, and the cmdlet is run synchronously by using a [System.Management.Automation.PowerShell](#) object.

C#

```
namespace Microsoft.Samples.PowerShell.Runspaces
{
    using System;
    using System.Collections.Generic;
    using System.Collections.ObjectModel;
    using System.Diagnostics;
    using System.Management.Automation;
    using System.Management.Automation.Runspaces;
    using PowerShell = System.Management.Automation.PowerShell;

    #region GetProcCommand

    /// <summary>
    /// Class that implements the GetProcCommand.
    /// </summary>
    [Cmdlet(VerbsCommon.Get, "Proc")]
    public class GetProcCommand : Cmdlet

Runspace11 Sample

Article • 03/24/2025

This sample shows how to use the [System.Management.Automation.ProxyCommand](#) class to create a proxy command that calls an existing cmdlet, but restricts the set of available parameters. The proxy command is then added to an initial session state that is used to create a constrained runspace. This means that the user can access the functionality of the cmdlet only through the proxy command.

Requirements

This sample requires Windows PowerShell 2.0.

Demonstrates

This sample demonstrates the following.

- Creating a [System.Management.Automation.CommandMetadata](#) object that describes the metadata of an existing cmdlet.
- Creating a [System.Management.Automation.Runspaces.InitialSessionState](#) object.
- Modifying the cmdlet metadata to remove a parameter of the cmdlet.
- Adding the cmdlet to the [System.Management.Automation.Runspaces.InitialSessionState](#) object and making the cmdlet private.
- Creating a proxy function that calls the existing cmdlet, but exposes only a restricted set of parameters.
- Adding the proxy function to the initial session state.
- Creating a [System.Management.Automation.PowerShell](#) object that uses the [System.Management.Automation.Runspaces.Runspace](#) object.
- Calling the private cmdlet and the proxy function using a [System.Management.Automation.PowerShell](#) object to demonstrate the constrained runspace.

Example

This creates a proxy command for a private cmdlet to demonstrate a constrained runspace.

```
C#  
  
namespace Microsoft.Samples.PowerShell.Runspaces  
{  
    using System;  
    using System.Collections.Generic;  
    using System.Diagnostics;  
    using System.Management.Automation;  
    using System.Management.Automation.Runspaces;  
    using PowerShell = System.Management.Automation.PowerShell;  
  
    #region GetProcCommand  
  
    /// <summary>  
    /// This class implements the Get-Proc cmdlet. It has been copied  
    /// verbatim from the GetProcessSample02.cs sample.  
    /// </summary>  
    [Cmdlet(VerbsCommon.Get, "Proc")]  
    public class GetProcCommand : Cmdlet  
    {  
        #region Parameters  
  
        /// <summary>  
        /// The names of the processes to act on.  
        /// </summary>  
        private string[] processNames;  
  
        /// <summary>  
        /// Gets or sets the list of process names on which  
        /// the Get-Proc cmdlet will work.  
        /// </summary>  
        [Parameter(Position = 0)]  
        [ValidateNotNullOrEmpty]  
        public string[] Name  
        {  
            get { return this.processNames; }  
            set { this.processNames = value; }  
        }  
  
        #endregion Parameters  
  
        #region Cmdlet Overrides  
  
        /// <summary>  
        /// The ProcessRecord method calls the Process.GetProcesses  
        /// method to retrieve the processes specified by the Name  
        /// parameter. Then, the WriteObject method writes the  
        /// associated processes to the pipeline.  
        /// </summary>  
        protected override void ProcessRecord()  
        {
```

```

        // If no process names are passed to the cmdlet, get all
        // processes.
        if (this.processNames == null)
        {
            WriteObject(Process.GetProcesses(), true);
        }

Remote Runspace Samples

Article • 09/17/2021

This section includes sample code that shows how to create runspaces that can be used to connect to a computer by using WS-Management-based Windows PowerShell remoting. You can use Microsoft Visual Studio to create a console application and then copy the code from the topics in this section into your host application.

In This Section

Note

For more information about running commands on a remote computer, see [Windows PowerShell Remoting](#).

[RemoteRunspace01 Sample](#) This sample shows how to create a remote runspace that is used to establish a remote connection.

[RemoteRunspacePool01 Sample](#) This sample shows how to construct a remote runspace pool and how to run multiple commands concurrently by using this pool.

RemoteRunspace01 Sample

Article • 03/24/2025

This sample shows how to create a remote runspace that is used to establish a remote connection.

Requirements

This sample requires Windows PowerShell 2.0.

Demonstrates

- Creating a [System.Management.Automation.Runspaces.WSManConnectionInfo](#) object.
- Setting the [System.Management.Automation.Runspaces.RunspaceConnectionInfo.OperationTimeout*](#) and [System.Management.Automation.Runspaces.RunspaceConnectionInfo.OpenTimeout*](#) properties of the [System.Management.Automation.Runspaces.WSManConnectionInfo](#) object.
- Creating a remote runspace that uses the [System.Management.Automation.Runspaces.WSManConnectionInfo](#) object to establish the remote connection.
- Closing the remote runspace to release the remote connection.

Example

This sample defines a remote connection and then uses that connection information to establish a remote connection.

C#

```
namespace Microsoft.Samples.PowerShell.Runspaces
{
    using System;
    using System.Management.Automation; // Windows PowerShell
    namespace
    {
        using System.Management.Automation.Runspaces; // Windows PowerShell
        namespace.
```

```

/// <summary>
/// This class contains the Main entry point for the application.
/// </summary>
internal class RemoteRunspace01
{
    /// <summary>
    /// This sample shows how to use a WSMANConnectionInfo object to set
    /// various timeouts and how to establish a remote connection.
    /// </summary>
    /// <param name="args">This parameter is not used.</param>
    public static void Main(string[] args)
    {
        // Create a WSMANConnectionInfo object using the default constructor
        // to connect to the "localhost". The WSMANConnectionInfo object can
        // also specify connections to remote computers.
        WSMANConnectionInfo connectionInfo = new WSMANConnectionInfo();

        // Set the OperationTimeout property. The OperationTimeout is used to
        tell
        // Windows PowerShell how long to wait (in milliseconds) before timing
        out
        // for any operation. This includes sending input data to the remote
        computer,
        // receiving output data from the remote computer, and more. The user
        can
        // change this timeout depending on whether the connection is to a
        computer
        // in the data center or across a slow WAN.
        connectionInfo.OperationTimeout = 4 * 60 * 1000; // 4 minutes.

        // Set the OpenTimeout property. OpenTimeout is used to tell Windows
        PowerShell
        // how long to wait (in milliseconds) before timing out while
        establishing a
        // remote connection. The user can change this timeout depending on
        whether the
        // connection is to a computer in the data center or across a slow
        WAN.
        connectionInfo.OpenTimeout = 1 * 60 * 1000; // 1 minute.

        // Create a remote runspace using the connection information.
        using (Runspace remoteRunspace =
RunspaceFactory.CreateRunspace(connectionInfo))
        {
            // Establish the connection by calling the Open() method to open the
            runspace.
            // The OpenTimeout value set previously will be applied while
            establishing
            // the connection. Establishing a remote connection involves sending
            and
            // receiving some data, so the OperationTimeout will also play a
            role in this process.
            remoteRunspace.Open();

```

```
// Add the code to run commands in the remote runspace here. The
// OperationTimeout value set previously will play a role here
because
    // running commands involves sending and receiving data.

    // Close the connection. Call the Close() method to close the remote
    // runspace. The Dispose() method (called by using primitive) will
call
    // the Close() method if it is not already called.
    remoteRunspace.Close();
}
}
}
}
```

RemoteRunspacePool01 Sample

Article • 03/24/2025

This sample shows how to construct a remote runspace pool and how to run multiple commands concurrently by using this pool.

Requirements

This sample requires Windows PowerShell 2.0.

Demonstrates

- Creating a [System.Management.Automation.Runspaces.WSManConnectionInfo](#) object.
- Setting the [System.Management.Automation.Runspaces.RunspaceConnectionInfo.OperationTimeout*](#) and [System.Management.Automation.Runspaces.RunspaceConnectionInfo.OpenTimeout*](#) properties of the [System.Management.Automation.Runspaces.WSManConnectionInfo](#) object.
- Creating a remote runspace that uses the [System.Management.Automation.Runspaces.WSManConnectionInfo](#) object to establish the remote connection.
- Running the [Get-Process](#) and [Get-Service](#) cmdlets concurrently by using the remote runspace pool.
- Closing the remote runspace pool to release the remote connection.

Example

This sample shows how to construct a remote runspace pool and how to run multiple commands concurrently by using this pool.

C#

```
namespace Samples
{
    using System;
    using System.Management.Automation;           // Windows PowerShell
```

```
namespace.
using System.Management.Automation.Runspaces; // Windows PowerShell
namespace.

/// <summary>
/// This class contains the Main entry point for the application.
/// </summary>
internal class RemoteRunspacePool01
{
    /// <summary>
    /// This sample shows how to construct a remote RunspacePool and how to
    /// concurrently run the Get-Process and Get-Service commands using the
    /// runspaces of the pool.
    /// </summary>
    /// <param name="args">Parameter is not used.</param>
    public static void Main(string[] args)
    {
        // Create a WSMANConnectionInfo object using the default constructor
        to
        // connect to the "localhost". The WSMANConnectionInfo object can also
        // specify connections to remote computers.
        WSMANConnectionInfo connectionInfo = new WSMANConnectionInfo();

        // Create a remote runspace pool that uses the WSMANConnectionInfo
        object.
        // The minimum runspaces value of 1 specifies that Windows PowerShell
        will
        // keep at least 1 runspace open. The maximum runspaces value of 2
        specifies
        // that Windows PowerShell will allow 2 runspaces to be opened at the
        // same time so that two commands can be run concurrently.
        using (RunspacePool remoteRunspacePool =
            RunspaceFactory.CreateRunspacePool(1, 2, connectionInfo))
        {
            // Call the Open() method to open the runspace pool and establish
            // the connection.
            remoteRunspacePool.Open();

            // Call the Create() method to create a pipeline, call the
            AddCommand(string)
                // method to add the "Get-Process" command, and then call the
            BeginInvoke()
                // method to run the command asynchronously using a runspace of the
            pool.
            PowerShell gpsCommand = PowerShell.Create().AddCommand("Get-
            Process");
            gpsCommand.RunspacePool = remoteRunspacePool;
            IAsyncResult gpsCommandAsyncResult = gpsCommand.BeginInvoke();

            // The previous call does not block the current thread because it is
            // running asynchronously. Because the remote runspace pool can open
            two
            // runspace, the second command can be run.
            PowerShell getServiceCommand = PowerShell.Create().AddCommand("Get-
            Service");
        }
    }
}
```

```

getServiceCommand.RunspacePool = remoteRunspacePool;
IAsyncResult getServiceCommandAsyncResult =
getServiceCommand.BeginInvoke();

    // When you are ready to handle the output, wait for the command to
    // complete
    // before extracting results. A call to the EndInvoke() method will
    // block and return
    // the output.
    PSDataCollection<PSObject> gpsCommandOutput =
gpsCommand.EndInvoke(gpsCommandAsyncResult);

    // Process the output from the first command.
    if ((gpsCommandOutput != null) && (gpsCommandOutput.Count > 0))
{
    Console.WriteLine("The first output from running Get-Process
command: ");
    Console.WriteLine(
        "Process Name: {0} Process Id: {1}",
        gpsCommandOutput[0].Properties["ProcessName"].Value,
        gpsCommandOutput[0].Properties["Id"].Value);
    Console.WriteLine();
}

    // Now process the output from the second command. As discussed
previously, wait
    // for the command to complete before extracting the results.
    PSDataCollection<PSObject> getServiceCommandOutput =
getServiceCommand.EndInvoke(
    getServiceCommandAsyncResult);

    // Process the output of the second command as needed.
    if ((getServiceCommandOutput != null) &&
(getServiceCommandOutput.Count > 0))
{
    Console.WriteLine("The first output from running Get-Service
command: ");
    Console.WriteLine(
        "Service Name: {0} Description: {1} State: {2}",
        getServiceCommandOutput[0].Properties["ServiceName"].Value,
        getServiceCommandOutput[0].Properties["DisplayName"].Value,
        getServiceCommandOutput[0].Properties["Status"].Value);
}

    // Once done with running all the commands, close the remote
runspace pool.
    // The Dispose() method (called by using primitive) will call
Close(), if it
    // is not already called.
    remoteRunspacePool.Close();
} // End Using.

```

```
    } // End Main.  
} // End RemoteRunspacePool01 class  
}
```

Formatting File Overview

Article • 03/13/2023

The display format for the objects that are returned by commands (cmdlets, functions, and scripts) are defined by using formatting files (`format.ps1xml`). Several of these files are provided by PowerShell to define the display format for those objects returned by PowerShell-provided commands, such as the `System.Diagnostics.Process` object returned by the `Get-Process` cmdlet. However, you can also create your own custom formatting files to overwrite the default display formats or you can write a custom formatting file to define the display of objects returned by your own commands.

Important

Formatting files do not determine the elements of an object that are returned to the pipeline. When an object is returned to the pipeline, all members of that object are available even if some are not displayed.

PowerShell uses the data in these formatting files to determine what is displayed and how the displayed data is formatted. The displayed data can include the properties of an object or the value of a script. Scripts are used if you want to display some value that is not available directly from the properties of an object, such as adding the value of two properties of an object and then displaying the sum as a piece of data. Formatting of the displayed data is done by defining views for the objects that you want to display. You can define a single view for each object, you can define a single view for multiple objects, or you can define multiple views for the same object. There is no limit to the number of views that you can define.

Common Features of Formatting Files

Each formatting file can define the following components that can be shared across all the views defined by the file:

- Default configuration setting, such as whether the data displayed in the rows of tables will be displayed on the next line if the data is longer than the width of the column. For more information about these settings, see [Wrap Element for TableRowEntry](#).
- Sets of objects that can be displayed by any of the views of the formatting file. For more information about these sets (referred to as **selection sets**), see [Defining Sets of Objects](#).

- Common controls that can be used by all the views of the formatting file. Controls give you finer control on how data is displayed. For more information about controls, see [Defining Custom Controls](#).

Formatting Views

Formatting views can display objects in a table format, list format, wide format, and custom format. For the most part, each formatting definition is described by a set of XML tags that describe the view. Each view contains the name of the view, the objects that use the view, and the elements of the view, such as the column and row information for a table view.

Table View

Lists the properties of an object or a script block value in one or more columns. Each column represents a single property of the object or a script value. You can define a table view that displays all the properties of an object, a subset of the properties of an object, or a combination of properties and script values. Each row of the table represents a returned object. Creating a table view is very similar to when you pipe an object to the `Format-Table` cmdlet. For more information about this view, see [Table View](#).

List View

Lists the properties of an object or a script value in a single column. Each row of the list displays an optional label or the property name followed by the value of the property or script. Creating a list view is very similar to piping an object to the `Format-List` cmdlet. For more information about this view, see [List View](#).

Wide View

Lists a single property of an object or a script value in one or more columns. There is no label or header for this view. Creating a wide view is very similar to piping an object to the `Format-Wide` cmdlet. For more information about this view, see [Wide View](#).

Custom View

Displays a customizable view of object properties or script values that does not adhere to the rigid structure of table views, list views, or wide views. You can define a stand-alone custom view, or you can define a custom view that is used by another view, such

as a table view or list view. Creating a custom view is very similar to piping an object to the `Format-Custom` cmdlet. For more information about this view, see [Custom View](#).

Components of a View

The following XML examples show the basic XML components of a view. The individual XML elements vary depending on which view you want to create, but the basic components of the views are all the same.

To start with, each view has a `Name` element that specifies a user friendly name that is used to reference the view. a `ViewSelectedBy` element that defines which .NET objects are displayed by the view, and a `control` element that defines the view.

XML

```
<ViewDefinitions>
  <View>
    <Name>NameOfView</Name>
    <ViewSelectedBy>...</ViewSelectedBy>
    <TableControl>...</TableControl>
  </View>
  <View>
    <Name>NameOfView</Name>
    <ViewSelectedBy>...</ViewSelectedBy>
    <ListControl>...</ListControl>
  </View>
  <View>
    <Name>NameOfView</Name>
    <ViewSelectedBy>...</ViewSelectedBy>
    <WideControl>...</WideControl>
  </View>
  <View>
    <Name>NameOfView</Name>
    <ViewSelectedBy>...</ViewSelectedBy>
    <CustomControl>...</CustomControl>
  </View>
</ViewDefinitions>
```

Within the control element, you can define one or more `entry` elements. If you use multiple definitions, you must specify which .NET objects use each definition. Typically only one entry, with only one definition, is needed for each control.

XML

```
<ListControl>
  <ListEntries>
    <ListEntry>
```

```
<EntrySelectedBy>...</EntrySelectedBy>
<ListItems>...</ListItems>
</ListEntry>
<ListEntry>
    <EntrySelectedBy>...</EntrySelectedBy>
    <ListItems>...</ListItems>
</ListEntry>
<ListEntry>
    <EntrySelectedBy>...</EntrySelectedBy>
    <ListItems>...</ListItems>
</ListEntry>
</ListEntries>
</ListControl>
```

Within each entry element of a view, you specify the **item** elements that define the .NET properties or scripts that are displayed by that view.

XML

```
<ListItems>
    <ListItem>...</ListItem>
    <ListItem>...</ListItem>
    <ListItem>...</ListItem>
</ListItems>
```

As shown in the preceding examples, the formatting file can contain multiple views, a view can contain multiple definitions, and each definition can contain multiple items.

Example of a Table View

The following example shows the XML tags used to define a table view that contains two columns. The **ViewDefinitions** element is the container element for all the views defined in the formatting file. The **View** element defines the specific table, list, wide, or custom view. Within each **View** element, the **Name** element specifies the name of the view, the **ViewSelectedBy** element defines the objects that use the view, and the different control elements (such as the **TableControl** element shown in the following example) define the type of the view.

XML

```
<ViewDefinitions>
    <View>
        <Name>Name of View</Name>
        <ViewSelectedBy>
            <TypeName>Object to display using this view</TypeName>
```

```
<TypeName>Object to display using this view</TypeName>
</ViewSelectedBy>
<TableControl>
  <TableHeaders>
    <TableColumnHeader>
      <Width></Width>
    </TableColumnHeader>
    <TableColumnHeader>
      <Width></Width>
    </TableColumnHeader>
  </TableHeaders>
  <TableRowEntries>
    <TableRowEntry>
      <TableColumnItems>
        <TableColumnItem>
          <PropertyName>Header for column 1</PropertyName>
        </TableColumnItem>
        <TableColumnItem>
          <PropertyName>Header for column 2</PropertyName>
        </TableColumnItem>
      </TableColumnItems>
    </TableRowEntry>
  </TableRowEntries>
</TableControl>
</View>
</ViewDefinitions>
```

Formatting File Concepts

Article • 09/17/2021

The topics in this section provide information that you might need to know when creating your own formatting files, such as the different types of views that you can define and the special components of those views.

In This Section

[Creating a Table View](#) Provides an example of a displayed table view and the XML elements used to define the view.

[Creating a List View](#) Provides an example of a displayed list view and the XML elements used to define the view.

[Creating a Wide View](#) Provides an example of a displayed wide view and the XML elements used to define the view.

[Creating Custom Controls](#) Provides an example of a custom control.

[Defining Selection Sets](#) Provides information, an example, and describes the XML elements used to create a selection set.

[Defining Conditions for Displaying Data](#) When defining what data is displayed by a view or a control, you can specify a condition that must exist for the data to be displayed.

[Formatting Displayed Data](#) You can specify how the individual data points in your List, Table, or Wide view are displayed.

[PowerShell Formatting Files](#) Lists the available formatting files provided by PowerShell.

Creating a Table View

Article • 01/20/2022

A table view displays data in one or more columns. Each row in the table represents a .NET object, and each column of the table represents a property of the object or a script value. You can define a table view that displays all the properties of an object or a subset of the properties of an object.

A Table View Display

The following example shows how Windows PowerShell displays the [System.ServiceProcess.ServiceController](#) object that is returned by the [Get-Service](#) cmdlet. For this object, Windows PowerShell has defined a table view that displays the `Status` property, the `Name` property (this property is an alias property for the `ServiceName` property), and the `DisplayName` property. Each row in the table represents an object returned by the cmdlet.

Output		
Status	Name	DisplayName
Stopped	AJRouter	AllJoyn Router Service
Stopped	ALG	Application Layer Gateway Service
Stopped	AppIDSvc	Application Identity
Running	Appinfo	Application Information

Defining the Table View

The following XML shows the table view schema for displaying the [System.ServiceProcess.ServiceController](#) object. You must specify each property that you want displayed in the table view.

```
XML
<View>
  <Name>service</Name>
  <ViewSelectedBy>
    <TypeName>System.ServiceProcess.ServiceController</TypeName>
  </ViewSelectedBy>
  <TableControl>
    <TableHeaders>
      < TableColumnHeader>
        <Width>8</Width>
```

```

</TableColumnHeader>
<TableColumnHeader>
  <Width>18</Width>
</TableColumnHeader>
<TableColumnHeader>
  <Width>38</Width>
</TableColumnHeader>
</TableHeaders>
<TableRowEntries>
  <TableRowEntry>
    <TableColumnItems>
      <TableColumnItem>
        <PropertyName>Status</PropertyName>
      </TableColumnItem>
      <TableColumnItem>
        <PropertyName>Name</PropertyName>
      </TableColumnItem>
      <TableColumnItem>
        <PropertyName>DisplayName</PropertyName>
      </TableColumnItem>
    </TableColumnItems>
  </TableRowEntry>
</TableRowEntries>
</TableControl>
</View>

```

The following XML elements are used to define a list view:

- The [View](#) element is the parent element of the table view. (This is the same parent element for the list, wide, and custom control views.)
- The [Name](#) element specifies the name of the view. This element is required for all views.
- The [ViewSelectedBy](#) element defines the objects that use the view. This element is required.
- The [GroupBy](#) element (not shown in this example) defines when a new group of objects is displayed. A new group is started whenever the value of a specific property or script changes. This element is optional.
- The [Controls](#) element (not shown in this example) defines the custom controls that are defined by the table view. Controls give you a way to further specify how the data is displayed. This element is optional. A view can define its own custom controls, or it can use common controls that can be used by any view in the formatting file. For more information about custom controls, see [Creating Custom Controls](#).

- The [HideTableHeaders](#) element (not shown in this example) specifies that the table will not show any labels at the top of the table. This element is optional.
- The [TableControl](#) element that defines the header and row information of the table. Similar to all other views, a table view can display the values of object properties or values generated by scripts.

Defining Column Headers

1. The [TableHeaders](#) element and its child elements define what is displayed at the top of the table.
 2. The [TableColumnHeader](#) element defines what is displayed at the top of a column of the table. Specify these elements in the order that you want the headers displayed.
- There is no limit to the number of these elements that you can use, but the number of [TableColumnHeader](#) elements in your table view must equal the number of [TableRowEntry](#) elements that you use.
3. The [Label](#) element specifies the text that is displayed. This element is optional.
 4. The [Width](#) element specifies the width (in characters) of the column. This element is optional.
 5. The [Alignment](#) element specifies how the label is displayed. The label can be aligned to the left, to the right, or centered. This element is optional.

Defining the Table Rows

Table views can provide one or more definitions that specify what data is displayed in the rows of the table by using the child elements of the [TableRowEntries](#) element. Notice that you can specify multiple definitions for the rows of the table, but the headers for the rows remain the same, regardless of what row definition is used. Typically, a table will have only one definition.

In the following example, the view provides a single definition that displays the values of several properties of the [System.Diagnostics.Process](#) object. A table view can display the value of a property or the value of a script (not shown in the example) in its rows.

XML

```
<TableRowEntries>
  <TableRowEntry>
    <TableColumnItems>
      < TableColumnItem>
        <PropertyName>Status</PropertyName>
      </ TableColumnItem>
      < TableColumnItem>
        <PropertyName>Name</PropertyName>
      </ TableColumnItem>
      < TableColumnItem>
        <PropertyName>DisplayName</PropertyName>
      </ TableColumnItem>
    </TableColumnItems>
  </TableRowEntry>
</TableRowEntries>
```

The following XML elements can be used to provide definitions for a row:

- The **TableRowEntries** element and its child elements define what is displayed in the rows of the table.
- The **TableRowEntry** element provides a definition of the row. At least one **TableRowEntry** is required; however, there is no maximum limit to the number of elements that you can add. In most cases, a view will have only one definition.
- The **EntrySelectedBy** element specifies the objects that are displayed by a specific definition. This element is optional and is needed only when you define multiple **TableRowEntry** elements that display different objects.
- The **Wrap** element specifies that text that exceeds the column width is displayed on the next line. By default, text that exceeds the column width is truncated.
- The **TableColumnItems** element defines the properties or scripts whose values are displayed in the row.
- The **TableColumnItem** element defines the property or script whose value is displayed in the column of the row. A **TableColumnItem** element is required for each column of the row. The first entry is displayed in first column, the second entry in the second column, and so on.
- The **PropertyName** element specifies the property whose value is displayed in the row. You must specify either a property or a script, but you cannot specify both.
- The **ScriptBlock** element specifies the script whose value is displayed in the row. You must specify either a script or a property, but you cannot specify both.

- The [FormatString](#) element specifies a format pattern that defines how the property or script value is displayed. This element is optional.
- The [Alignment](#) element specifies how the value of the property or script is displayed. The value can be aligned to the left, to the right, or centered. This element is optional.

Defining the Objects That Use the Table View

There are two ways to define which .NET objects use the table view. You can use the [ViewSelectedBy](#) element to define the objects that can be displayed by all the definitions of the view, or you can use the [EntrySelectedBy](#) element to define which objects are displayed by a specific definition of the view. In most cases, a view has only one definition, so objects are typically defined by the [ViewSelectedBy](#) element.

The following example shows how to define the objects that are displayed by the table view using the [ViewSelectedBy](#) and [TypeName](#) elements. There is no limit to the number of [TypeName](#) elements that you can specify, and their order is not significant.

```
XML

<View>
  <Name>System.ServiceProcess.ServiceController</Name>
  <ViewSelectedBy>
    <TypeName>System.ServiceProcess.ServiceController</TypeName>
  </ViewSelectedBy>
  <TableControl>...</TableControl>
</View>
```

The following XML elements can be used to specify the objects that are used by the table view:

- The [ViewSelectedBy](#) element defines which objects are displayed by the list view.
- The [TypeName](#) element specifies the .NET object that is displayed by the view. The fully qualified .NET type name is required. You must specify at least one type or selection set for the view, but there is no maximum number of elements that can be specified.

The following example uses the [ViewSelectedBy](#) and [SelectionSetName](#) elements. Use selection sets where you have a related set of objects that are displayed using multiple views, such as when you define a list view and a table view for the same objects. For more information about how to create a selection set, see [Defining Selection Sets](#).

XML

```
<View>
  <Name>System.ServiceProcess.ServiceController</Name>
  <ViewSelectedBy>
    <SelectionSetName>.NET Type Set</SelectionSetName>
  </ViewSelectedBy>
  <TableControl>...</TableControl>
</View>
```

The following XML elements can be used to specify the objects that are used by the list view:

- The [ViewSelectedBy](#) element defines which objects are displayed by the list view.
- The [SelectionSetName](#) element specifies a set of objects that can be displayed by the view. You must specify at least one selection set or type for the view, but there is no maximum number of elements that can be specified.

The following example shows how to define the objects displayed by a specific definition of the table view using the [EntrySelectedBy](#) element. Using this element, you can specify the .NET type name of the object, a selection set of objects, or a selection condition that specifies when the definition is used. For more information about how to create a selection conditions, see [Defining Conditions for Displaying Data](#).

Note

When creating multiple definitions of the table view you cannot specify different column headers. You can specify only what is displayed in the rows of the table, such as what objects are displayed.

XML

```
<TableRowEntry>
  <EntrySelectedBy>
    <TypeName>.NET Type</TypeName>
  </EntrySelectedBy>
</TableRowEntry>
```

The following XML elements can be used to specify the objects that are used by a specific definition of the list view:

- The [EntrySelectedBy](#) element defines which objects are displayed by the definition.

- The [TypeName](#) element specifies the .NET object that is displayed by the definition. When using this element, the fully qualified .NET type name is required. You must specify at least one type, selection set, or selection condition for the definition, but there is no maximum number of elements that can be specified.
- The [SelectionSetName](#) element (not shown) specifies a set of objects that can be displayed by this definition. You must specify at least one type, selection set, or selection condition for the definition, but there is no maximum number of elements that can be specified.
- The [SelectionCondition](#) element (not shown) specifies a condition that must exist for this definition to be used. You must specify at least one type, selection set, or selection condition for the definition, but there is no maximum number of elements that can be specified. For more information about defining selection conditions, see [Defining Conditions for Displaying Data](#).

Using Format Strings

Formatting strings can be added to a view to further define how the data is displayed. The following example shows how to define a formatting string for the value of the [StartTime](#) property.

```
XML

< TableColumnItem >
  < PropertyName >StartTime</PropertyName>
  < FormatString >{0:MMM} {0:DD} {0:HH}:{0:MM}</FormatString>
</ TableColumnItem >
```

The following XML elements can be used to specify a format pattern:

- The [TableColumnItem](#) element defines the property or script whose value is displayed in the column of the row. A [TableColumnItem](#) element is required for each column of the row. The first entry is displayed in first column, the second entry in the second column, and so on.
- The [PropertyName](#) element specifies the property whose value is displayed in the row. You must specify either a property or a script, but you cannot specify both.
- The [FormatString](#) element specifies a format pattern that defines how the property or script value is displayed.

In the following example, the `ToString` method is called to format the value of the script. Scripts can call any method of an object. Therefore, if an object has a method, such as `ToString`, that has formatting parameters, the script can call that method to format the output value of the script.

XML

```
<ListItem>
  <ScriptBlock>
    [string]::Format("{0,-10} {1,-8}", $_.LastWriteTime.ToString("d"),
$_.LastWriteTime.ToString("t"))
  </ScriptBlock>
</ListItem>
```

The following XML element can be used to calling the `ToString` method:

- The `TableColumnItem` element defines the property or script whose value is displayed in the column of the row. A `TableColumnItem` element is required for each column of the row. The first entry is displayed in first column, the second entry in the second column, and so on.
- The `ScriptBlock` element specifies the script whose value is displayed in the row. You must specify either a script or a property, but you cannot specify both.

[Writing a PowerShell Formatting File](#)

Creating a List View

Article • 01/20/2022

A list view displays data in a single column (in sequential order). The data displayed in the list can be the value of a .NET property or the value of a script.

A List View Display

The following output shows how Windows PowerShell displays the properties of `System.ServiceProcess.ServiceController` objects that are returned by the [Get-Service](#) cmdlet. In this example, three objects were returned, with each object separated from the preceding object by a blank line.

PowerShell

```
Get-Service | Format-List
```

Output

```
Name          : AEADIFilters
DisplayName   : Andrea ADI Filters Service
Status        : Running
DependentServices : {}
ServicesDependedOn : {}
CanPauseAndContinue : False
CanShutdown    : False
CanStop       : True
ServiceType    : Win32OwnProcess

Name          : AeLookupSvc
DisplayName   : Application Experience
Status        : Running
DependentServices : {}
ServicesDependedOn : {}
CanPauseAndContinue : False
CanShutdown    : False
CanStop       : True
ServiceType    : Win32ShareProcess

Name          : AgereModemAudio
DisplayName   : Agere Modem Call Progress Audio
Status        : Running
DependentServices : {}
ServicesDependedOn : {}
CanPauseAndContinue : False
CanShutdown    : False
CanStop       : True
```

```
ServiceType      : Win32OwnProcess  
...
```

Defining the List View

The following XML shows the list view schema for displaying several properties of the `System.ServiceProcess.ServiceController` object. You must specify each property that you want displayed in the list view.

XML

```
<View>  
  <Name>System.ServiceProcess.ServiceController</Name>  
  <ViewSelectedBy>  
    <TypeName>System.ServiceProcess.ServiceController</TypeName>  
  </ViewSelectedBy>  
  <ListControl>  
    <ListEntries>  
      <ListEntry>  
        <ListItems>  
          <ListItem>  
            <PropertyName>Name</PropertyName>  
          </ListItem>  
          <ListItem>  
            <PropertyName>DisplayName</PropertyName>  
          </ListItem>  
          <ListItem>  
            <PropertyName>Status</PropertyName>  
          </ListItem>  
          <ListItem>  
            <PropertyName>ServiceType</PropertyName>  
          </ListItem>  
        </ListItems>  
      </ListEntry>  
    </ListEntries>  
  </ListControl>  
</View>
```

The following XML elements are used to define a list view:

- The `View` element is the parent element of the list view. (This is the same parent element for the table, wide, and custom control views.)
- The `Name` element specifies the name of the view. This element is required for all views.
- The `ViewSelectedBy` element defines the objects that use the view. This element is required.

- The [GroupBy](#) element defines when a new group of objects is displayed. A new group is started whenever the value of a specific property or script changes. This element is optional.
- The [Controls](#) element defines the custom controls that are defined by the list view. Controls give you a way to further specify how the data is displayed. This element is optional. A view can define its own custom controls, or it can use common controls that can be used by any view in the formatting file. For more information about custom controls, see [Creating Custom Controls](#).
- The [ListControl](#) element defines what is displayed in the view and how it is formatted. Similar to all other views, a list view can display the values of object properties or values generated by script.

For an example of a complete formatting file that defines a simple list view, see [List View \(Basic\)](#).

Providing Definitions for Your List View

List views can provide one or more definitions by using the child elements of the [ListControl](#) element. Typically, a view will have only one definition. In the following example, the view provides a single definition that displays several properties of the [System.Diagnostics.Process](#) object. A list view can display the value of a property or the value of a script (not shown in the example).

XML

```
<ListControl>
  <ListEntries>
    <ListEntry>
      <ListItems>
        <ListItem>
          <PropertyName>Name</PropertyName>
        </ListItem>
        <ListItem>
          <PropertyName>DisplayName</PropertyName>
        </ListItem>
        <ListItem>
          <PropertyName>Status</PropertyName>
        </ListItem>
        <ListItem>
          <PropertyName>ServiceType</PropertyName>
        </ListItem>
      </ListItems>
    </ListEntry>
  </ListEntries>
```

```
</ListControl>
```

The following XML elements can be used to provide definitions for a list view:

- The [ListControl](#) element and its child elements define what is displayed in the view.
- The [ListEntries](#) element provides the definitions of the view. In most cases, a view will have only one definition. This element is required.
- The [ListEntry](#) element provides a definition of the view. At least one [ListEntry](#) is required; however, there is no maximum limit to the number of elements that you can add. In most cases, a view will have only one definition.
- The [EntrySelectedBy](#) element specifies the objects that are displayed by a specific definition. This element is optional and is needed only when you define multiple [ListEntry](#) elements that display different objects.
- The [ListItems](#) element specifies the properties and scripts whose values are displayed in the rows of the list view.
- The [ListItem](#) element specifies a property or script whose value is displayed in a row of the list view. A list view must specify at least one property or script. There is no maximum limit to the number of rows that can be specified.
- The [PropertyName](#) element specifies the property whose value is displayed in the row. You must specify either a property or a script, but you cannot specify both.
- The [ScriptBlock](#) element specifies the script whose value is displayed in the row. You must specify either a script or a property, but you cannot specify both.
- The [Label](#) element specifies the label that is displayed to the left of the property or script value in the row. This element is optional. If a label is not specified, the name of the property or the script is displayed. For a complete example, see [List View \(Labels\)](#).
- The [ItemSelectionCondition](#) element specifies a condition that must exist for the row to be displayed. For more information about adding conditions to the list view, see [Defining Conditions for Displaying Data](#). This element is optional.
- The [FormatString](#) element specifies a pattern that is used to display the value of the property or script. This element is optional.

For an example of a complete formatting file that defines a simple list view, see [List View \(Basic\)](#).

Defining the Objects That Use the List View

There are two ways to define which .NET objects use the list view. You can use the [ViewSelectedBy](#) element to define the objects that can be displayed by all the definitions of the view, or you can use the [EntrySelectedBy](#) element to define which objects are displayed by a specific definition of the view. In most cases, a view has only one definition, so objects are typically defined by the [ViewSelectedBy](#) element.

The following example shows how to define the objects that are displayed by the list view using the [ViewSelectedBy](#) and [TypeName](#) elements. There is no limit to the number of [TypeName](#) elements that you can specify, and their order is not significant.

```
XML

<View>
  <Name>System.ServiceProcess.ServiceController</Name>
  <ViewSelectedBy>
    <TypeName>System.Diagnostics.Process</TypeName>
  </ViewSelectedBy>
  <ListControl>...</ListControl>
</View>
```

The following XML elements can be used to specify the objects that are used by the list view:

- The [ViewSelectedBy](#) element defines which objects are displayed by the list view.
- The [TypeName](#) element specifies the .NET object that is displayed by the view. The fully qualified .NET type name is required. You must specify at least one type or selection set for the view, but there is no maximum number of elements that can be specified.

For an example of a complete formatting file, see [List View \(Basic\)](#).

The following example uses the [ViewSelectedBy](#) and [SelectionSetName](#) elements. Use selection sets where you have a related set of objects that are displayed using multiple views, such as when you define a list view and a table view for the same objects. For more information about how to create a selection set, see [Defining Selection Sets](#).

```
XML

<View>
  <Name>System.ServiceProcess.ServiceController</Name>
  <ViewSelectedBy>
    <SelectionSetName>.NET Type Set</SelectionSetName>
  </ViewSelectedBy>
```

```
<ListControl>...</ListControl>
</View>
```

The following XML elements can be used to specify the objects that are used by the list view:

- The [ViewSelectedBy](#) element defines which objects are displayed by the list view.
- The [SelectionSetName](#) element specifies a set of objects that can be displayed by the view. You must specify at least one selection set or type for the view, but there is no maximum number of elements that can be specified.

The following example shows how to define the objects displayed by a specific definition of the list view using the [EntrySelectedBy](#) element. Using this element, you can specify the .NET type name of the object, a selection set of objects, or a selection condition that specifies when the definition is used. For more information about how to create a selection conditions, see [Defining Conditions for Displaying Data](#).

XML

```
<ListEntry>
  <EntrySelectedBy>
    <TypeName>.NET Type</TypeName>
  </EntrySelectedBy>
</ListEntry>
```

The following XML elements can be used to specify the objects that are used by a specific definition of the list view:

- The [EntrySelectedBy](#) element defines which objects are displayed by the definition.
- The [TypeName](#) element specifies the .NET object that is displayed by the definition. When using this element, the fully qualified .NET type name is required. You must specify at least one type, selection set, or selection condition for the definition, but there is no maximum number of elements that can be specified.
- The [SelectionSetName](#) element (not shown) specifies a set of objects that can be displayed by this definition. You must specify at least one type, selection set, or selection condition for the definition, but there is no maximum number of elements that can be specified.
- The [SelectionCondition](#) element (not shown) specifies a condition that must exist for this definition to be used. You must specify at least one type, selection set, or selection condition for the definition, but there is no maximum number of

elements that can be specified. For more information about defining selection conditions, see [Defining Conditions for Displaying Data](#).

Displaying Groups of Objects in a List View

You can separate the objects that are displayed by the list view into groups. This does not mean that you define a group, only that Windows PowerShell starts a new group whenever the value of a specific property or script changes. In the following example, a new group is started whenever the value of the [System.ServiceProcess.ServiceController.ServiceType](#) property changes.

XML

```
<GroupBy>
  <Label>Service Type</Label>
  <PropertyName>ServiceType</PropertyName>
</GroupBy>
```

The following XML elements are used to define when a group is started:

- The [GroupBy](#) element defines the property or script that starts the new group and defines how the group is displayed.
- The [PropertyName](#) element specifies the property that starts a new group whenever its value changes. You must specify a property or script to start the group, but you cannot specify both.
- The [ScriptBlock](#) element specifies the script that starts a new group whenever its value changes. You must specify a script or property to start the group, but you cannot specify both.
- The [Label](#) element defines a label that is displayed at the beginning of each group. In addition to the text specified by this element, Windows PowerShell displays the value that triggered the new group and adds a blank line before and after the label. This element is optional.
- The [CustomControl](#) element defines a control that is used to display the data. This element is optional.
- The [CustomControlName](#) element specifies a common or view control that is used to display the data. This element is optional.

For an example of a complete formatting file that defines groups, see [List View \(GroupBy\)](#).

Using Format Strings

Formatting strings can be added to a view to further define how the data is displayed. The following example shows how to define a formatting string for the value of the `StartTime` property.

XML

```
<ListItem>
  <PropertyName>StartTime</PropertyName>
  <FormatString>{0:MMM} {0:DD} {0:HH}:{0:MM}</FormatString>
</ListItem>
```

The following XML elements can be used to specify a format pattern:

- The `ListItem` element specifies the data that is displayed by the view.
- The `PropertyName` element specifies the property whose value is displayed by the view. You must specify either a property or a script, but you cannot specify both.
- The `FormatString` element specifies a format pattern that defines how the property or script value is displayed in the view.
- The `ScriptBlock` element (not shown) specifies the script whose value is displayed by the view. You must specify either a script or a property, but you cannot specify both.

In the following example, the `ToString` method is called to format the value of the script. Scripts can call any method of an object. Therefore, if an object has a method, such as `ToString`, that has formatting parameters, the script can call that method to format the output value of the script.

XML

```
<ListItem>
  <ScriptBlock>
    [string]::Format("{0,-10} {1,-8}", $_.LastWriteTime.ToString("d"),
$_.LastWriteTime.ToString("t"))
  </ScriptBlock>
</ListItem>
```

The following XML element can be used to calling the `ToString` method:

- The [ListItem](#) element specifies the data that is displayed by the view.
- The [ScriptBlock](#) element (not shown) specifies the script whose value is displayed by the view. You must specify either a script or a property, but you cannot specify both.

[Writing a Windows PowerShell Cmdlet](#)

Creating a Wide View

Article • 03/13/2023

A wide view displays a single value for each object that's displayed. The displayed value can be the value of a .NET object property or the value of a script. By default, there is no label or header for this view.

A Wide View Display

The following example shows how Windows PowerShell displays the `System.Diagnostics.Process` object that's returned by the `Get-Process` cmdlet when its output is piped to the `Format-Wide` cmdlet. (By default, the `Get-Process` cmdlet returns a table view.) In this example, the two columns are used to display the name of the process for each returned object. The name of the object's property isn't displayed, only the value of the property.

```
PowerShell
Get-Process | Format-Wide

Output
AEADISRV      agrsmsvc
Ati2evxx     Ati2evxx
audiogd       CCC
CcmExec      communicator
Crypserv     csrss
csrss        DevDtct2
DM1Service   dpupdchk
dwm          DxStudio
EXCEL        explorer
GoogleToolbarNotifier GrooveMonitor
hpqwmiepx   hpservice
Idle         InoRpc
InoRT        InoTask
ipoint       lsass
lsm          MOM
MSASCui     notepad
...
...
```

Defining the Wide View

The following XML shows the wide view schema for the [System.Diagnostics.Process](#) object.

```
XML

<View>
  <Name>process</Name>
  <ViewSelectedBy>
    <TypeName>System.Diagnostics.Process</TypeName>
  </ViewSelectedBy>
  <GroupBy>...</GroupBy>
  <Controls>...</Controls>
  <WideControl>
    <WideEntries>
      <WideEntry>
        <WideItem>
          <PropertyName>ProcessName</PropertyName>
        </WideItem>
      </WideEntry>
    </WideEntries>
  </WideControl>
</View>
```

The following XML elements are used to define a wide view:

- The [View](#) element is the parent element of the wide view. (This is the same parent element for the table, list, and custom control views.)
- The [Name](#) element specifies the name of the view. This element is required for all views.
- The [ViewSelectedBy](#) element defines the objects that use the view. This element is required.
- The [GroupBy](#) element defines when a new group of objects is displayed. A new group is started whenever the value of a specific property or script changes. This element is optional.
- The [Controls](#) elements defines the custom controls that are defined by the wide view. Controls give you a way to further specify how the data is displayed. This element is optional. A view can define its own custom controls, or it can use common controls that can be used by any view in the formatting file. For more information about custom controls, see [Creating Custom Controls](#).
- The [WideControl](#) element and its child elements define what's displayed in the view. In the preceding example, the view is designed to display the [System.Diagnostics.Process.ProcessName](#) property.

For an example of a complete formatting file that defines a simple wide view, see [Wide View \(Basic\)](#).

Providing Definitions for Your Wide View

Wide views can provide one or more definitions by using the child elements of the [WideControl](#) element. Typically, a view will have only one definition. In the following example, the view provides a single definition that displays the [System.Diagnostics.Process.ProcessName](#) property. A wide view can display the value of a property or the value of a script (not shown in the example).

XML

```
<WideControl>
  <AutoSize/>
  <ColumnNumber></ColumnNumber>
  <WideEntries>
    <WideEntry>
      <WideItem>
        <PropertyName>ProcessName</PropertyName>
      </WideItem>
    </WideEntry>
  </WideEntries>
</WideControl>
```

The following XML elements can be used to provide definitions for a wide view:

- The [WideControl](#) element and its child elements define what's displayed in the view.
- The [AutoSize](#) element specifies whether the column size and the number of columns are adjusted based on the size of the data. This element is optional.
- The [ColumnName](#) element specifies the number of columns displayed in the wide view. This element is optional.
- The [WideEntries](#) element provides the definitions of the view. In most cases, a view will have only one definition. This element is required.
- The [WideEntry](#) element provides a definition of the view. At least one [WideEntry](#) is required; however, there is no maximum limit to the number of elements that you can add. In most cases, a view will have only one definition.
- The [EntrySelectedBy](#) element specifies the objects that are displayed by a specific definition. This element is optional and is needed only when you define multiple [WideEntry](#) elements that display different objects.
- The [WideItem](#) element specifies the data that's displayed by the view. In contrast to other types of views, a wide control can display only one item.
- The [PropertyName](#) element specifies the property whose value is displayed by the view. You must specify either a property or a script, but you can't specify both.
- The [ScriptBlock](#) element specifies the script whose value is displayed by the view. You must specify either a script or a property, but you can't specify both.

- The [FormatString](#) element specifies a pattern that's used to display the data. This element is optional.

For an example of a complete formatting file that defines a wide view definition, see [Wide View \(Basic\)](#).

Defining the Objects That Use the Wide View

There are two ways to define which .NET objects use the wide view. You can use the [ViewSelectedBy](#) element to define the objects that can be displayed by all the definitions of the view, or you can use the [EntrySelectedBy](#) element to define which objects are displayed by a specific definition of the view. In most cases, a view has only one definition, so objects are typically defined by the [ViewSelectedBy](#) element.

The following example shows how to define the objects that are displayed by the wide view using the [ViewSelectedBy](#) and [TypeName](#) elements. There is no limit to the number of [TypeName](#) elements that you can specify, and their order isn't significant.

XML

```
<View>
  <Name>System.ServiceProcess.ServiceController</Name>
  <ViewSelectedBy>
    <TypeName>System.Diagnostics.Process</TypeName>
  </ViewSelectedBy>
  <WideControl>...</WideControl>
</View>
```

The following XML elements can be used to specify the objects that are used by the wide view:

- The [ViewSelectedBy](#) element defines which objects are displayed by the wide view.
- The [TypeName](#) element specifies the .NET that's displayed by the view. The fully qualified .NET type name is required. You must specify at least one type or selection set for the view, but there is no maximum number of elements that can be specified.

For an example of a complete formatting file, see [Wide View \(Basic\)](#).

The following example uses the [ViewSelectedBy](#) and [SelectionSetName](#) elements. Use selection sets where you have a related set of objects that are displayed using multiple views, such as when you define a wide view and a table view for the same objects. For more information about how to create a selection set, see [Defining Selection Sets](#).

XML

```
<View>
  <Name>System.ServiceProcess.ServiceController</Name>
  <ViewSelectedBy>
    <SelectionSetName>.NET Type Set</SelectionSetName>
  </ViewSelectedBy>
  <WideControl>...</WideControl>
</View>
```

The following XML elements can be used to specify the objects that are used by the wide view:

- The [ViewSelectedBy](#) element defines which objects are displayed by the wide view.
- The [SelectionSetName](#) element specifies a set of objects that can be displayed by the view. You must specify at least one selection set or type for the view, but there is no maximum number of elements that can be specified.

The following example shows how to define the objects displayed by a specific definition of the wide view using the [EntrySelectedBy](#) element. Using this element, you can specify the .NET type name of the object, a selection set of objects, or a selection condition that specifies when the definition is used. For more information about how to create a selection conditions, see [Defining Conditions for Displaying Data](#).

XML

```
<WideEntry>
  <EntrySelectedBy>
    <TypeName>.NET Type</TypeName>
  </EntrySelectedBy>
</WideEntry>
```

The following XML elements can be used to specify the objects that are used by a specific definition of the wide view:

- The [EntrySelectedBy](#) element defines which objects are displayed by the definition.
- The [TypeName](#) element specifies the .NET that's displayed by the definition. When using this element the fully qualified .NET type name is required. You must specify at least one type, selection set, or selection condition for the definition, but there is no maximum number of elements that can be specified.
- The [SelectionSetName](#) element (not shown) specifies a set of objects that can be displayed by this definition. You must specify at least one type, selection set, or selection condition for the definition, but there is no maximum number of elements that can be specified.

- The [SelectionCondition](#) element (not shown) specifies a condition that must exist for this definition to be used. You must specify at least one type, selection set, or selection condition for the definition, but there is no maximum number of elements that can be specified. For more information about defining selection conditions, see [Defining Conditions for Displaying Data](#).

Displaying Groups of objects in a Wide View

You can separate the objects that are displayed by the wide view into groups. This doesn't mean that you define a group, only that Windows PowerShell starts a new group whenever the value of a specific property or script changes. In the following example, a new group is started whenever the value of the [System.ServiceProcess.ServiceController.ServiceType](#) property changes.

XML

```
<GroupBy>
  <Label>Service Type</Label>
  <PropertyName>ServiceType</PropertyName>
</GroupBy>
```

The following XML elements are used to define when a group is started:

- The [GroupBy](#) element defines the property or script that starts the new group and defines how the group is displayed.
- The [PropertyName](#) element specifies the property that starts a new group whenever its value changes. You must specify a property or script to start the group, but you can't specify both.
- The [ScriptBlock](#) element specifies the script that starts a new group whenever its value changes. You must specify a script or property to start the group, but you can't specify both.
- The [Label](#) element defines a label that's displayed at the beginning of each group. In addition to the text specified by this element, Windows PowerShell displays the value that triggered the new group and adds a blank line before and after the label. This element is optional.
- The [CustomControl](#) element defines a control that's used to display the data. This element is optional.
- The [CustomControlName](#) element specifies a common or view control that's used to display the data. This element is optional.

For an example of a complete formatting file that defines groups, see [Wide View \(GroupBy\)](#).

Using Format Strings

Formatting strings can be added to a wide view to further define how the data is displayed. The following example shows how to define a formatting string for the value of the `StartTime` property.

XML

```
<WideItem>
  <PropertyName>StartTime</PropertyName>
  <FormatString>{0:MMM} {0:DD} {0:HH}:{0:MM}</FormatString>
</WideItem>
```

The following XML elements can be used to specify a format pattern:

- The `WideItem` element specifies the data that's displayed by the view.
- The `PropertyName` element specifies the property whose value is displayed by the view. You must specify either a property or a script, but you can't specify both.
- The `FormatString` element specifies a format pattern that defines how the property or script value is displayed in the view
- The `ScriptBlock` element (not shown) specifies the script whose value is displayed by the view. You must specify either a script or a property, but you can't specify both.

In the following example, the `ToString` method is called to format the value of the script. Scripts can call any method of an object. Therefore, if an object has a method, such as `ToString`, that has formatting parameters, the script can call that method to format the output value of the script.

XML

```
<WideItem>
  <ScriptBlock>
    [string]::Format("{0,-10} {1,-8}", $_.LastWriteTime.ToString("d"),
    $_.LastWriteTime.ToString("t"))
  </ScriptBlock>
</WideItem>
```

The following XML element can be used to calling the `ToString` method:

- The `WideItem` element specifies the data that's displayed by the view.

- The [ScriptBlock](#) element (not shown) specifies the script whose value is displayed by the view. You must specify either a script or a property, but you can't specify both.

Creating Custom Controls

Article • 09/17/2021

Custom controls are the most flexible components of a formatting file. Unlike table, list, and wide views that define a formal structure of data, such as a table of data, custom controls allow you to define how an individual piece of data is displayed. You can define a common set of custom controls that are available to all the views of the formatting file, you can define custom controls that are available to a specific view, or you can define a set of controls that are available to a group of objects.

Custom Control Example

The following example shows a custom control that is defined in the Certificates.Format.ps1xml file. This custom control is used to separate the [System.Management.Automation.Signature](#) objects displayed in a table view.

XML

```
<Controls>
  <Control>
    <Name>SignatureTypes-GroupingFormat</Name>
    <CustomControl>
      <CustomEntries>
        <CustomEntry>
          <CustomItem>
            <Frame>
              <LeftIndent>4</LeftIndent>
              <CustomItem>
                <Text AssemblyName="System.Management.Automation"
BaseName="FileSystemProviderStrings"
                  ResourceId="DirectoryDisplayGrouping"/>
                <ExpressionBinding>
                  <ScriptBlock>Split-Path $_.Path</ScriptBlock>
                </ExpressionBinding>
                <NewLine/>
              </CustomItem>
            </Frame>
          </CustomItem>
        </CustomEntry>
      </CustomEntries>
    </CustomControl>
  </Control>
</Controls>
```

[Writing a PowerShell Formatting File](#)

Loading and Exporting Formatting Data

Article • 03/07/2023

Once you've created your formatting file, you need to update the format data of the session by loading your files into the current session. PowerShell loads a predefined set of formats. Once the format data of the current session is updated, PowerShell uses that data to display the .NET objects associated with the views defined in the loaded formats. There's no limit to the number of formats that you can load into the current session. You can also export the format data in the current session back to a formatting file.

Loading format data

Formatting files can be loaded into the current session using the following methods:

- You can import the formatting file into the current session from the command line. Use the [Update-FormatData](#) cmdlet as described in the following procedure.
- You can create a module manifest that references your formatting file. Modules allow you to package your formatting files for distribution. Use the [New-ModuleManifest](#) cmdlet to create the manifest, and the [Import-Module](#) cmdlet to load the module into the current session. For more information about modules, see [Writing a Windows PowerShell Module](#).
- You can create a snap-in that references your formatting file. Use the [System.Management.Automation.PSSnapIn.Formats](#) to reference your formatting files. However, best practice recommendation is to use modules to package cmdlets and associated formatting and types files.
- If you're invoking commands programmatically, you can add formatting files to the initial session state of the runspace where the commands are run. For more information, see the [System.Management.Automation.Runspaces.SessionStateFormatEntry](#) class.

When a formatting file is loaded, it's added to an internal list that PowerShell uses to choose the view used when displaying objects in the host. You can prepend your formatting file to the beginning of the list, or you can append it to the end of the list.

Knowing where your formatting file is added to this list is important.

- If you're loading a formatting file that defines the only view for an object, you can use any of the methods described previously.

- If you're loading a formatting file that defines a view for an object that has an existing view defined, it must be added to the beginning of the list. You must use the [Update-FormatData](#) cmdlet and prepend your file to the beginning of the list.

Storing Your Formatting File

You can store formatting files anywhere on disk. However, it's recommended that you store them in the same folder as your profile script.

Use the following command to determine the location of your profile script.

```
PowerShell
```

```
Split-Path -Path $PROFILE -Parent
```

Loading a format file

1. Store your formatting file to disk.
2. Run the [Update-FormatData](#) cmdlet using one of the following commands.

If you're changing how an object is displayed, use the following command to add your formatting file to the front of the list.

```
PowerShell
```

```
Update-FormatData -PrependPath PathToFormattingFile
```

Use the following command to add your formatting file to the end of the list.

```
PowerShell
```

```
Update-FormatData -AppendPath PathToFormattingFile
```

(!) Note

Once format data has been loaded in a session it can't be removed. You must open a new session without the format data loaded.

Exporting format data

PowerShell includes format definitions for many .NET types. You can use the [Get-FormatData](#) cmdlet to view the format data that's loaded in the current session. You can export the format data for a type to a file using the [Export-FormatData](#) cmdlet.

The following commands export the format data for the `System.Guid` type to a file named `System.Guid.format.ps1xml` in the current directory.

PowerShell

```
Get-FormatData System.Guid | Export-FormatData -Path  
./System.Guid.format.ps1xml  
Get-Content ./System.Guid.format.ps1xml
```

Output

```
<?xml version="1.0" encoding="utf-8"?>  
<Configuration>  
  <ViewDefinitions>  
    <View>  
      <Name>System.Guid</Name>  
      <ViewSelectedBy>  
        <TypeName>System.Guid</TypeName>  
      </ViewSelectedBy>  
      <TableControl>  
        <TableHeaders />  
        <TableRowEntries>  
          <TableRowEntry>  
            <TableColumnItems>  
              <TableColumnItem>  
                <PropertyName>Guid</PropertyName>  
              </TableColumnItem>  
            </TableColumnItems>  
          </TableRowEntry>  
        </TableRowEntries>  
      </TableControl>  
    </View>  
  </ViewDefinitions>  
</Configuration>
```

You can edit the exported file to create a custom format definition for that type.

Defining Selection Sets

Article • 09/17/2021

When creating multiple views and controls, you can define sets of objects that are referred to as selection sets. A selection set enables you to define the objects one time, without having to define them repeatedly for each view or control. Typically, selection sets are used when you have a set of related .NET objects. For example, The `FileSystem` formatting file (`FileSystem.format.ps1xml`) defines a selection set of the file system types that several views use.

Where Selection Sets are Defined and Referenced

You define selection sets as part of the common data that can be used by all the views and controls defined in the formatting file. The following example shows how to define three selection sets.

XML

```
<Configuration>
  <SelectionSets>
    <SelectionSet>...</SelectionSet>
    <SelectionSet>...</SelectionSet>
    <SelectionSet>...</SelectionSet>
  </SelectionSets>
</Configuration>
```

You can reference a selection sets in the following ways:

- Each view has a `ViewSelectedBy` element that defines which objects are displayed by using the view. The `ViewSelectedBy` element has a `SelectionSetName` child element that specifies the selection set that all the definitions of the view use. There is no restriction on the number of selection sets that you can reference from a view.
- In each definition of a view or control, the `EntrySelectedBy` element defines which objects are displayed by using that definition. Typically a view or control has only one definition so the objects are defined by the `ViewSelectedBy` element. The `EntrySelectedBy` element of the definition has a `SelectionSetName` child element that specifies the selection set. If you specify the selection set for a definition, you cannot specify any of the other child elements of the `EntrySelectedBy` element.

- In each definition of a view or control, the `SelectionCondition` element can be used to specify a condition for when the definition is used. The `SelectionCondition` element has a `SelectionSetName` child element that specifies the selection set that triggers the condition. The condition is triggered when any of the objects defined in the selection set are displayed. For more information about how to set these conditions, see [Defining Conditions for when Data is Displayed](#).

Selection Set Example

The following example shows a selection set that is taken directly from the `FileSystem` formatting file provided by Windows PowerShell. For more information about other Windows PowerShell formatting files, see [Windows PowerShell Formatting Files](#).

XML

```
<SelectionSets>
  <SelectionSet>
    <Name>FileSystemTypes</Name>
    <Types>
      <TypeName>System.IO.DirectoryInfo</TypeName>
      <TypeName>System.IO.FileInfo</TypeName>
      <TypeName>Deserialized.System.IO.DirectoryInfo</TypeName>
      <TypeName>Deserialized.System.IO.FileInfo</TypeName>
    </Types>
  </SelectionSet>
</SelectionSets>
```

The previous selection set is referenced in the `ViewSelectedBy` element of a table view.

XML

```
<ViewDefinitions>
  <View>
    <Name>Files</Name>
    <ViewSelectedBy>
      <SelectionSetName>FileSystemTypes</SelectionSetName>
    </ViewSelectedBy>
    <TableControl>...</TableControl>
  </View>
</ViewDefinitions>
```

XML Elements

There is no limit to the number of selection sets that you can define. The following XML elements are used to create a selection set.

- The [SelectionSets](#) element defines the sets of .NET objects that are referenced by the views and controls of the formatting file.
- The [SelectionSet](#) element defines a single set of .NET objects.
- The [Name](#) element specifies the name that is used to reference the selection set.
- The [Types](#) element specifies the .NET types of the objects of the selection set.
(Within formatting files, objects are specified by their .NET type.)

The following XML elements are used to specify a selection set.

- The following element specifies the selection set to use in all the definitions of the view:
 - [SelectionSetName Element for ViewSelectedBy \(Format\)](#)
 - [SelectionSetName Element for EntrySelectedBy for GroupBy \(Format\)](#)
- The following elements specify the selection set used by a single view definition:
 - [SelectionSetName Element for EntrySelectedBy for ListControl \(Format\)](#)
 - [SelectionSetName Element for EntrySelectedBy for TableControl \(Format\)](#)
 - [SelectionSetName Element for EntrySelectedBy for WideControl \(Format\)](#)
 - [SelectionSetName Element for EntrySelectedBy for CustomControl for View \(Format\)](#)
- The following elements specify the selection set used by common and view control definitions:
 - [SelectionSetName Element for EntrySelectedBy for Controls for View \(Format\)](#)
 - [SelectionSetName Element for EntrySelectedBy for Controls for Configuration \(Format\)](#)
- The following elements specify the selection set used when you define which object to expand:
 - [SelectionSetName Element for EntrySelectedBy for EnumerableExpansion \(Format\)](#)
- The following elements specify the selection set used by selection conditions.

- [SelectionSetName Element for SelectionCondition for Controls for Configuration \(Format\)](#)
- [SelectionSetName Element for SelectionCondition for Controls for View \(Format\)](#)
- [SelectionSetName Element for SelectionCondition for CustomControl for View \(Format\)](#)
- [SelectionSetName Element for SelectionCondition for EntrySelectedBy for EnumerableExpansion \(Format\)](#)
- [SelectionSetName Element for SelectionCondition for EntrySelectedBy for ListEntry \(Format\)](#)
- [SelectionSetName Element for SelectionCondition for EntrySelectedBy for TableControl \(Format\)](#)
- [SelectionSetName Element for SelectionCondition for EntrySelectedBy for WideEntry \(Format\)](#)
- [SelectionSetName Element for SelectionCondition for GroupBy \(Format\)](#)

Defining Conditions for Displaying Data

Article • 09/17/2021

When defining what data is displayed by a view or a control, you can specify a condition that must exist for the data to be displayed. The condition can be triggered by a specific property, or when a script or property value evaluates to `true`. When the selection condition is met, the definition of the view or control is used.

Specifying a Selection Condition for a Definition

When creating a definition for a view or control, the `EntrySelectedBy` element is used to specify which objects will use the definition or what condition must exist for the definition to be used. The condition is specified by the `SelectionCondition` element.

In the following example, a selection condition is specified for a definition of a table view. In this example, the definition is used only when the specified script is evaluated to `true`.

XML

```
<TableRowEntry>
  <EntrySelectedBy>
    <SelectionCondition>
      <ScriptBlock>ScriptToEvaluate</ScriptBlock>
    </SelectionCondition>
  </EntrySelectedBy>
  <TableColumnItems>
  </TableColumnItems>
</TableRowEntry>
```

There is no limit to the number of selection conditions that you can specify for a definition of a view or control. The only requirements are the following:

- The selection condition must specify one property name or script to trigger the condition, but cannot specify both.
- The selection condition can specify any number of .NET types or selection sets, but cannot specify both.

Specifying a Selection Condition for an Item

You can also specify when an item of a list view or control is used by including the `ItemSelectionCondition` element in the item definition. In the following example, a selection condition is specified for an item of a list view. In this example, the item is used only when the script is evaluated to `true`.

XML

```
<ListItem>
  <ItemSelectionCondition>
    <ScriptBlock>ScriptToEvaluate</ScriptBlock>
  </ItemSelectionCondition>
</ListItem>
```

You can specify only one selection condition for an item. And the condition must specify one property name or script to trigger the condition, but cannot specify both.

XML Elements

The following XML elements are used to create a selection condition.

- The following elements specify selection conditions for view definitions:
 - [SelectionCondition Element for EntrySelectedBy for TableControl \(Format\)](#)
 - [SelectionCondition Element for EntrySelectedBy for ListControl \(Format\)](#)
 - [SelectionCondition Element for EntrySelectedBy for WideControl \(Format\)](#)
 - [SelectionCondition Element for EntrySelectedBy for CustomControl \(Format\)](#)
- The following elements specify selection conditions for common and view control definitions:
 - [SelectionCondition Element for EntrySelectedBy for Controls for Configuration \(Format\)](#)
 - [SelectionCondition Element for EntrySelectedBy for Controls for View \(Format\)](#)
- The following element specifies the selection condition for expanding collection objects:
 - [SelectionCondition Element for EntrySelectedBy for EnumerableExpansion \(Format\)](#)

- The following element specifies the selection condition for displaying a new group of data:
 - [SelectionCondition Element for EntrySelectedBy for GroupBy \(Format\)](#)
- The following element specifies an item selection condition for a list view:
 - [ItemSelectionCondition Element for ListItem for ListControl \(Format\)](#)
- The following elements specify an item selection condition for controls:
 - [ItemSelectionCondition Element for ExpressionBinding for Controls for Configuration \(Format\)](#)
 - [ItemSelectionCondition Element for ExpressionBinding for Controls for View \(Format\)](#)
 - [ItemSelectionCondition Element for ExpressionBinding for CustomControl \(Format\)](#)

Formatting Displayed Data

Article • 03/13/2023

You can specify how the individual data points in your List, Table, or Wide view are displayed. You can use the `FormatString` element when defining the items of your view, or you can use the `ScriptBlock` element to call the `FormatString` method on the data.

Using the `FormatString` Element

In the following example the value of the `TotalProcessorTime` property of the `System.Diagnostics.Process` object is formatted using the `FormatString` element. the `TotalProcessorTime` property

XML

```
<TableColumnItem>
  <PropertyName>TotalProcessorTime</PropertyName>
  <FormatString>{0:MMM}{0:dd}{0:HH}:{0:mm}</FormatString>
</TableColumnItem>
```

Windows PowerShell Formatting Files

Article • 09/17/2021

Windows PowerShell provides several formatting files (.format.ps1xml) that are located in the installation directory (`$PSHOME`). Each of these files defines the default display for a specific set of .NET objects. These files should never be changed. However, you can use them as a reference for creating your own custom formatting files.

`Certificate.Format.ps1xml` Defines the display of objects in the Certificate store such as x.509 certificates and certificate stores.

`DotNetTypes.Format.ps1xml` Defines the display of miscellaneous .NET objects such as `CultureInfo`, `FileVersionInfo`, and `EventLogEntry` objects.

`FileSystem.Format.ps1xml` Defines the display of file system objects such as file and directory objects.

`Help.Format.ps1xml` Defines the different views used by the [Get-Help](#) cmdlet, such as the detailed, full, parameters, and example views.

`PowerShellCore.Format.ps1xml` Defines the display of the objects generated by Windows PowerShell core cmdlets, such as the objects returned by the [Get-Member](#) and [Get-History](#) cmdlets.

`PowerShellTrace.Format.ps1xml` Defines the display of trace objects such as those generated by the [Trace-Command](#) cmdlet.

`Registry.Format.ps1xml` Defines the display of registry objects such as key and entry objects.

How to Create a Formatting File (.format.ps1xml)

Article • 09/17/2021

This topic describes how to create a formatting file (.format.ps1xml).

ⓘ Note

You can also create a formatting file by making a copy of one of the files provided by Windows PowerShell. If you make a copy of an existing file, delete the existing digital signature, and add your own signature to the new file.

Create a .format.ps1xml file.

1. Create a text file (.txt) using a text editor such as Notepad.

2. Copy the following lines into the formatting file.

XML

```
<?xml version="1.0" encoding="utf-8" ?>
<Configuration>
<ViewDefinitions>
</ViewDefinitions>
</Configuration>
```

- The `<Configuration></Configuration>` tags define the root `Configuration` node. All additional XML tags will be enclosed within this node.
- The `<ViewDefinitions></ViewDefinitions>` tags define the `ViewDefinitions` node. All views are defined within this node.

3. Save the file to the Windows PowerShell installation folder, to your module folder, or to a subfolder of the module folder. Use the following name format when you save the file: `MyFile.format.ps1xml`. Formatting files must use the `.format.ps1xml` extension.

You are now ready to add views to the formatting file. There is no limit to the number of views that can be defined in a formatting file. You can add a single view for each object, multiple views for the same object, or a single view that is used by multiple objects.

Wide View (Basic)

Article • 03/24/2025

This example shows how to implement a basic wide view that displays the [System.ServiceProcess.ServiceController](#) objects returned by the `Get-Service` cmdlet. For more information about the components of a wide view, see [Creating a Wide View](#).

Load this formatting file

1. Copy the XML from the Example section of this topic into a text file.
2. Save the text file. Be sure to add the `format.ps1xml` extension to the file to identify it as a formatting file.
3. Open Windows PowerShell, and run the following command to load the formatting file into the current session: `Update-FormatData -PrependPath <PathToFormattingFile>`.

⚠ Warning

This formatting file defines the display of an object that is already defined by a Windows PowerShell formatting file. You must use the `PrependPath` parameter when you run the cmdlet, and you cannot load this formatting file as a module.

Demonstrates

This formatting file demonstrates the following XML elements:

- The [Name](#) element for the view.
- The [ViewSelectedBy](#) element that defines what objects are displayed by the view.
- The [WideItem](#) element that defines what property is displayed by the view.

Example

The following XML defines a wide view that displays the value of the [System.ServiceProcess.ServiceController.ServiceName](#) property.

XML

```
<?xml version="1.0" encoding="utf-8" ?>

<Configuration>
  <ViewDefinitions>
    <View>
      <Name>ServiceWideView</Name>
      <ViewSelectedBy>
        <TypeName>System.ServiceProcess.ServiceController</TypeName>
      </ViewSelectedBy>
      <WideControl>
        <WideEntries>
          <WideEntry>
            <WideItem>
              <PropertyName>ServiceName</PropertyName>
            </WideItem>
          </WideEntry>
        </WideEntries>
      </WideControl>
    </View>
  </ViewDefinitions>
</Configuration>
```

The following example shows how Windows PowerShell displays the `System.ServiceProcess.ServiceController` objects after this format file is loaded.

PowerShell

```
Get-Service f*
```

Output

Fax	FCSAM
fdPHost	FDResPub
FontCache	FontCache3.0.0.0
FSysAgent	FwcAgent

Wide View (GroupBy)

Article • 03/24/2025

This example shows how to implement a wide view that displays groups of [System.ServiceProcess.ServiceController](#) objects returned by the `Get-Service` cmdlet. For more information about the components of a wide view, see [Creating a Wide View](#).

Load this formatting file

1. Copy the XML from the Example section of this topic into a text file.
2. Save the text file. Be sure to add the `.ps1xml` extension to the file to identify it as a formatting file.
3. Open Windows PowerShell, and run the following command to load the formatting file into the current session: `Update-FormatData -PrependPath <Path to file>`.

⚠ Warning

This formatting file defines the display of an object that is already defined by a Windows PowerShell formatting files. You must use the `PrependPath` parameter when you run the cmdlet, and you cannot load this formatting file as a module.

Demonstrates

This formatting file demonstrates the following XML elements:

- The [Name](#) element for the view.
- The [ViewSelectedBy](#) element that defines what objects are displayed by the view.
- The [GroupBy](#) element that defines when a new group is displayed.
- The [WideItem](#) element that defines what property is displayed by the view.

Example

The following XML defines a wide view that displays groups of objects. Each new group is started when the value of the [System.ServiceProcess.ServiceController.ServiceType](#)

property changes.

XML

```
<?xml version="1.0" encoding="utf-8" ?>

<Configuration>
  <ViewDefinitions>
    <View>
      <Name>ServiceWideView</Name>
      <ViewSelectedBy>
        <TypeName>System.ServiceProcess.ServiceController</TypeName>
      </ViewSelectedBy>
      <GroupBy>
        <Label>Service Type</Label>
        <PropertyName>ServiceType</PropertyName>
      </GroupBy>
      <WideControl>
        <WideEntries>
          <WideEntry>
            <WideItem>
              <PropertyName>ServiceName</PropertyName>
            </WideItem>
          </WideEntry>
        </WideEntries>
      </WideControl>
    </View>
  </ViewDefinitions>
</Configuration>
```

The following example shows how Windows PowerShell displays the [System.ServiceProcess.ServiceController](#) objects after this format file is loaded.

PowerShell

```
Get-Service f*
```

Output

```
Service Type: Win32OwnProcess
```

```
Fax
```

```
FCSAM
```

```
Service Type: Win32ShareProcess
```

```
fdPHost
```

```
FDResPub
```

```
FontCache
```

```
Service Type: Win32OwnProcess
```

[Writing a PowerShell Formatting File](#)

List View (Basic)

Article • 03/24/2025

This example shows how to implement a basic list view that displays the `System.ServiceProcess.ServiceController` objects returned by the `Get-Service` cmdlet. For more information about the components of a list view, see [Creating a List View](#).

Load this formatting file

1. Copy the XML from the Example section of this topic into a text file.
2. Save the text file. Be sure to add the `.ps1xml` extension to the file to identify it as a formatting file.
3. Open Windows PowerShell, and run the following command to load the formatting file into the current session: `Update-FormatData -PrependPath PathToFormattingFile.`

⚠️ Warning

This formatting file defines the display of an object that is already defined by a Windows PowerShell formatting file. You must use the `PrependPath` parameter when you run the cmdlet, and you cannot load this formatting file as a module.

Demonstrates

This formatting file demonstrates the following XML elements:

- The `Name` element for the view.
- The `ViewSelectedBy` element that defines what objects are displayed by the view.
- The `ListControl` element that defines what property is displayed by the view.
- The `ListItem` element that defines what is displayed in a row of the list view.
- The `PropertyName` element that defines which property is displayed.

Example

The following XML defines a list view that displays four properties of the [System.ServiceProcess.ServiceController](#) object. In each row, the name of the property is displayed followed by the value of the property.

XML

```
<Configuration>
  <View>
    <Name>System.ServiceProcess.ServiceController</Name>
    <ViewSelectedBy>
      <TypeName>System.ServiceProcess.ServiceController</TypeName>
    </ViewSelectedBy>
    <ListControl>
      <ListEntries>
        <ListEntry>
          <ListItems>
            <ListItem>
              <PropertyName>Name</PropertyName>
            </ListItem>
            <ListItem>
              <PropertyName>DisplayName</PropertyName>
            </ListItem>
            <ListItem>
              <PropertyName>Status</PropertyName>
            </ListItem>
            <ListItem>
              <PropertyName>ServiceType</PropertyName>
            </ListItem>
          </ListItems>
        </ListEntry>
      </ListEntries>
    </ListControl>
  </View>
</Configuration>
```

The following example shows how Windows PowerShell displays the [System.ServiceProcess.ServiceController](#) objects after this format file is loaded.

PowerShell

```
Get-Service f*
```

Output

```
Name      : Fax
DisplayName : Fax
Status    : Stopped
ServiceType : Win32OwnProcess

Name      : FCSAM
```

```
DisplayName : Microsoft Antimalware Service
Status      : Running
ServiceType : Win32OwnProcess

Name       : fdPHost
DisplayName : Function Discovery Provider Host
Status     : Stopped
ServiceType : Win32ShareProcess

Name       : FDResPub
DisplayName : Function Discovery Resource Publication
Status     : Running
ServiceType : Win32ShareProcess

Name       : FontCache
DisplayName : Windows Font Cache Service
Status     : Running
ServiceType : Win32ShareProcess

Name       : FontCache3.0.0.0
DisplayName : Windows Presentation Foundation Font Cache 3.0.0.0
Status     : Stopped
ServiceType : Win32OwnProcess

Name       : FSysAgent
DisplayName : Microsoft Forefront System Agent
Status     : Running
ServiceType : Win32OwnProcess

Name       : FwcAgent
DisplayName : Firewall Client Agent
Status     : Running
ServiceType : Win32OwnProcess
```

[Writing a PowerShell Formatting File](#)

List View (Labels)

Article • 03/24/2025

This example shows how to implement a list view that displays a custom label for each row of the list. This list view displays the properties of the [System.ServiceProcess.ServiceController](#) object that is returned by the [Get-Service](#) cmdlet. For more information about the components of a list view, see [Creating a List View](#).

Load this formatting file

1. Copy the XML from the Example section of this topic into a text file.
2. Save the text file. Be sure to add the `format.ps1xml` extension to the file to identify it as a formatting file.
3. Open Windows PowerShell, and run the following command to load the formatting file into the current session: `Update-FormatData -PrependPath PathToFormattingFile.`

Warning

This formatting file defines the display of an object that is already defined by a Windows PowerShell formatting file. You must use the `PrependPath` parameter when you run the cmdlet, and you cannot load this formatting file as a module.

Demonstrates

This formatting file demonstrates the following XML elements:

- The [Name](#) element for the view.
- The [ViewSelectedBy](#) element that defines what objects are displayed by the view.
- The [ListControl](#) element that defines what property is displayed by the view.
- The [ListItem](#) element that defines what is displayed in a row of the list view.
- The [Label](#) element that defines what is displayed in a row of the list view.
- The [PropertyName](#) element that defines which property is displayed.

Example

The following XML defines a list view that displays a custom label in each row. In this case, the label includes the property name with each letter capitalized and the word "property". In each row, the name of the property is displayed followed by the value of the property.

XML

```
<Configuration>
  <ViewDefinitions>
    <View>
      <Name>System.ServiceProcess.ServiceController</Name>
      <ViewSelectedBy>
        <TypeName>System.ServiceProcess.ServiceController</TypeName>
      </ViewSelectedBy>
      <ListControl>
        <ListEntries>
          <ListEntry>
            <ListItems>
              <ListItem>
                <Label>NAME property</Label>
                <PropertyName>Name</PropertyName>
              </ListItem>
              <ListItem>
                <Label>DISPLAYNAME property</Label>
                <PropertyName>DisplayName</PropertyName>
              </ListItem>
              <ListItem>
                <Label>STATUS property</Label>
                <PropertyName>Status</PropertyName>
              </ListItem>
              <ListItem>
                <Label>SERVICETYPE property</Label>
                <PropertyName>ServiceType</PropertyName>
              </ListItem>
            </ListItems>
          </ListEntry>
        </ListEntries>
      </ListControl>
    </View>
  </ViewDefinitions>
</Configuration>
```

The following example shows how Windows PowerShell displays the [System.ServiceProcess.ServiceController](#) objects after this format file is loaded.

PowerShell

```
Get-Service f*
```

Output

```
NAME property      : Fax
DISPLAYNAME property : Fax
STATUS property     : Stopped
SERVICETYPE property : Win32OwnProcess

NAME property      : FCSAM
DISPLAYNAME property : Microsoft Antimalware Service
STATUS property     : Running
SERVICETYPE property : Win32OwnProcess

NAME property      : fdPHost
DISPLAYNAME property : Function Discovery Provider Host
STATUS property     : Stopped
SERVICETYPE property : Win32ShareProcess

NAME property      : FDResPub
DISPLAYNAME property : Function Discovery Resource Publication
STATUS property     : Running
SERVICETYPE property : Win32ShareProcess

NAME property      : FontCache
DISPLAYNAME property : Windows Font Cache Service
STATUS property     : Running
SERVICETYPE property : Win32ShareProcess

NAME property      : FontCache3.0.0.0
DISPLAYNAME property : Windows Presentation Foundation Font Cache 3.0.0.0
STATUS property     : Stopped
SERVICETYPE property : Win32OwnProcess

NAME property      : FSysAgent
DISPLAYNAME property : Microsoft Forefront System Agent
STATUS property     : Running
SERVICETYPE property : Win32OwnProcess

NAME property      : FwcAgent
DISPLAYNAME property : Firewall Client Agent
STATUS property     : Running
SERVICETYPE property : Win32OwnProcess
```

[Writing a PowerShell Formatting File](#)

List View (GroupBy)

Article • 03/24/2025

This example shows how to implement a list view that separates the rows of the list into groups. This list view displays the properties of the [System.ServiceProcess.ServiceController](#) objects returned by the [Get-Service](#) cmdlet. For more information about the components of a list view, see [Creating a List View](#).

Load this formatting file

1. Copy the XML from the Example section of this topic into a text file.
2. Save the text file. Be sure to add the `format.ps1xml` extension to the file to identify it as a formatting file.
3. Open Windows PowerShell, and run the following command to load the formatting file into the current session: `Update-FormatData -PrependPath PathToFormattingFile`.

Warning

This formatting file defines the display of an object that is already defined by a Windows PowerShell formatting file. You must use the `PrependPath` parameter when you run the cmdlet, and you cannot load this formatting file as a module.

Demonstrates

This formatting file demonstrates the following XML elements:

- The [Name](#) element for the view.
- The [ViewSelectedBy](#) element that defines what objects are displayed by the view.
- The [GroupBy](#) element that defines how a new group of objects is displayed.
- The [ListControl](#) element that defines what property is displayed by the view.
- The [ListItem](#) element that defines what is displayed in a row of the list view.
- The [PropertyName](#) element that defines which property is displayed.

Example

The following XML defines a list view that starts a new group whenever the value of the `System.ServiceProcess.ServiceController.Status` property changes. When each group is started, a custom label is displayed that includes the new value of the property.

XML

```
<Configuration>
  <ViewDefinitions>
    <View>
      <Name>System.ServiceProcess.ServiceController</Name>
      <ViewSelectedBy>
        <TypeName>System.ServiceProcess.ServiceController</TypeName>
      </ViewSelectedBy>
      <GroupBy>
        <PropertyName>Status</PropertyName>
        <Label>New Service Status</Label>
      </GroupBy>
      <ListControl>
        <ListEntries>
          <ListEntry>
            <ListItems>
              <ListItem>
                <PropertyName>Name</PropertyName>
              </ListItem>
              <ListItem>
                <PropertyName>DisplayName</PropertyName>
              </ListItem>
              <ListItem>
                <PropertyName>ServiceType</PropertyName>
              </ListItem>
            </ListItems>
          </ListEntry>
        </ListEntries>
      </ListControl>
    </View>
  </ViewDefinitions>
</Configuration>
```

The following example shows how Windows PowerShell displays the `System.ServiceProcess.ServiceController` objects after this format file is loaded. The blank lines added before and after the group label are automatically added by Windows PowerShell.

PowerShell

```
Get-Service f*
```

Output

```
New Service Status: Stopped
```

```
Name      : Fax
DisplayName : Fax
ServiceType : Win32OwnProcess
```

```
New Service Status: Running
```

```
Name      : FCSAM
DisplayName : Microsoft Antimalware Service
ServiceType : Win32OwnProcess
```

```
New Service Status: Stopped
```

```
Name      : fdPHost
DisplayName : Function Discovery Provider Host
ServiceType : Win32ShareProcess
```

```
New Service Status: Running
```

```
Name      : FDResPub
DisplayName : Function Discovery Resource Publication
ServiceType : Win32ShareProcess
```

```
Name      : FontCache
DisplayName : Windows Font Cache Service
ServiceType : Win32ShareProcess
```

```
New Service Status: Stopped
```

```
Name      : FontCache3.0.0.0
DisplayName : Windows Presentation Foundation Font Cache 3.0.0.0
ServiceType : Win32OwnProcess
```

```
New Service Status: Running
```

```
Name      : FSysAgent
DisplayName : Microsoft Forefront System Agent
ServiceType : Win32OwnProcess
```

```
Name      : FwcAgent
DisplayName : Firewall Client Agent
ServiceType : Win32OwnProcess
```

[Writing a PowerShell Formatting File](#)

Format Schema XML Reference

Article • 09/17/2021

The topics in this section describe the XML elements used by formatting files (Format.ps1xml files). Formatting files define how the .NET object is displayed; they do not change the object itself.

In This Section

[Alignment Element for TableColumnHeader for TableControl \(Format\)](#) Defines how the data in a column header is displayed.

[Alignment Element for TableColumnItem for TableControl \(Format\)](#) Defines how the data in the row is displayed.

[AutoSize Element for TableControl \(Format\)](#) Specifies whether the column size and the number of columns are adjusted based on the size of the data.

[Autosize Element for WideControl \(Format\)](#) Specifies whether the column size and the number of columns are adjusted based on the size of the data.

[ColumnNumber Element for WideControl \(Format\)](#) Specifies the number of columns displayed in the wide view.

[Configuration Element \(Format\)](#) Represents the top-level element of the formatting file.

[Control Element for Controls for Configuration \(Format\)](#) Defines a common control that can be used by all the views of the formatting file and the name that is used to reference the control.

[Control Element for Controls for View \(Format\)](#) Defines a control that can be used by the view and the name that is used to reference the control.

[Controls Element for Configuration \(Format\)](#) Defines the common controls that can be used by all views of the formatting file.

[Controls Element for View \(Format\)](#) Defines the view controls that can be used by a specific view.

[CustomControl Element for Control for Configuration \(Format\)](#) Defines a control. This element is used when defining a common control that can be used by all the views in the formatting file.

[CustomControl Element for Control for Controls for View \(Format\)](#) Defines a control that is used by the view.

[CustomControl Element for GroupBy \(Format\)](#) Defines the custom control that displays the new group.

[CustomControl Element \(Format\)](#) Defines a custom control format for the view.

[CustomControlName Element for ExpressionBinding for Controls for Configuration \(Format\)](#) Specifies the name of a common control. This element is used when defining a common control that can be used by all the views in the formatting file.

[CustomControlName Element for ExpressionBindine for Controls for View \(Format\)](#) Specifies the name of a common control or a view control. This element is used when defining controls that can be used by a view.

[CustomControlName Element of GroupBy \(Format\)](#) Specifies the name of a custom control that is used to display the new group. This element is used when defining a table, list, wide or custom control view.

[CustomEntry Element for CustomControl for Configuration \(Format\)](#) Provides a definition of the common control. This element is used when defining a common control that can be used by all the views in the formatting file.

[CustomEntry Element for CustomEntries for Controls for View \(Format\)](#) Provides a definition of the control. This element is used when defining controls that can be used by a view.

[CustomEntry Element for CustomEntries for View \(Format\)](#) Provides a definition of the custom control view.

[CustomEntry Element for CustomControl for GroupBy \(Format\)](#) Provides a definition of the control. This element is used when defining how a new group of objects is displayed.

[CustomEntries Element for CustomControl for Configuration \(Format\)](#) Provides the definitions of a common control. This element is used when defining a common control that can be used by all the views in the formatting file.

[CustomEntries Element for CustomControl for Controls for View \(Format\)](#) Provides the definitions for the control. This element is used when defining controls that can be used by a view.

[CustomEntries Element for CustomControl for GroupBy \(Format\)](#) Provides the definitions for the control. This element is used when defining how a new group of objects is displayed.

[CustomEntries Element for CustomControl for View \(Format\)](#) Provides the definitions of the custom control view. The custom control view must specify one or more definitions.

[CustomItem Element for CustomEntry for Controls for Configuration](#) Defines what data is displayed by the control and how it is displayed. This element is used when defining a common control that can be used by all the views in the formatting file.

[CustomItem Element for CustomEntry for Controls for View \(Format\)](#) Defines what data is displayed by the control and how it is displayed. This element is used when defining controls that can be used by a view.

[CustomItem Element for CustomEntry for View \(Format\)](#) Defines what data is displayed by the custom control view and how it is displayed. This element is used when defining a custom control view.

[CustomItem Element for CustomEntry for GroupBy \(Format\)](#) Defines what data is displayed by the custom control view and how it is displayed. This element is used when defining how a new group of objects is displayed.

[DefaultSettings Element \(Format\)](#) Defines common settings that apply to all the views of the formatting file. Common settings include displaying errors, wrapping text in tables, defining how collections are expanded, and more.

[DisplayError Element \(Format\)](#) Specifies that the string #ERR is displayed when an error occurs displaying a piece of data.

[EntrySelectedBy Element for CustomEntry for Controls for Configuration \(Format\)](#) Defines the .NET types that use the definition of the common control or the condition that must exist for this control to be used. This element is used when defining a common control that can be used by all the views in the formatting file.

[EntrySelectedBy Element for CustomEntry for Controls for View \(Format\)](#) Defines the .NET types that use this control definition or the condition that must exist for this definition to be used. This element is used when defining controls that can be used by a view.

[EntrySelectedBy Element for CustomEntry for View \(Format\)](#) Defines the .NET types that use this custom entry or the condition that must exist for this entry to be used.

[EntrySelectedBy Element for EnumerableExpansion \(Format\)](#) Defines the .NET types that use this definition or the condition that must exist for this definition to be used.

[EntrySelectedBy Element for CustomEntry for GroupBy \(Format\)](#) Defines the .NET types that use this control definition or the condition that must exist for this definition to be used. This element is used when defining how a new group of objects is displayed.

[EntrySelectedBy Element for ListEntry for ListControl \(Format\)](#) Defines the .NET types that use this list view definition or the condition that must exist for this definition to be used. In most cases only one definition is needed for a list view. However, you can provide multiple definitions for the list view if you want to use the same list view to display different data for different objects.

[EntrySelectedBy Element for TableRowEntry \(Format\)](#) Defines the .NET types whose property values are displayed in the row.

[EntrySelectedBy Element for WideEntry \(Format\)](#) Defines the .NET types that use this definition of the wide view or the condition that must exist for this definition to be used.

[EnumerableExpansion Element \(Format\)](#) Defines how specific .NET collection objects are expanded when they are displayed in a view.

[EnumerableExpansions Element \(Format\)](#) Defines how .NET collection objects are expanded when they are displayed in a view.

[EnumerateCollection Element for ExpressionBinding for Controls for Configuration \(Format\)](#) Specified that the elements of collections are displayed by the control. This element is used when defining a common control that can be used by all the views in the formatting file.

[EnumerateCollection Element for ExpressionBinding for Controls for View \(Format\)](#) Specified that the elements of collections are displayed. This element is used when defining controls that can be used by a view.

[EnumerateCollection Element for Expression Binding for CustomControl for View \(Format\)](#) Specifies that the elements of collections are displayed. This element is used when defining a custom control view.

[EnumerateCollection Element for ExpressionBinding for GroupBy \(Format\)](#) Specifies that the elements of collections are displayed. This element is used when defining how a new group of objects is displayed.

[Expand Element \(Format\)](#) Specifies how the collection object is expanded for this definition.

[ExpressionBinding Element for CustomItem for Controls for Configuration \(Format\)](#) Defines the data that is displayed by the control. This element is used when defining a common control that can be used by all the views in the formatting file.

[ExpressionBinding Element for CustomItem for Controls for View \(Format\)](#) Defines the data that is displayed by the control. This element is used when defining controls that can be used by a view.

[ExpressionBinding Element for CustomItem for CustomControl for View \(Format\)](#) Defines the data that is displayed by the control. This element is used when defining a custom control view.

[ExpressionBinding Element for CustomItem for GroupBy \(Format\)](#) Defines the data that is displayed by the control. This element is used when defining how a new group of objects is displayed.

[FirstLineHanging Element for Frame for Controls for Configuration \(Format\)](#) Specifies how many characters the first line of data is shifted to the left. This element is used when defining a common control that can be used by all the views in the formatting file.

[FirstLineHanging Element of Frame of Controls of View \(Format\)](#) Specifies how many characters the first line of data is shifted to the left. This element is used when defining controls that can be used by a view.

[FirstLineHanging Element for Frame for CustomControl for View \(Format\)](#) Specifies how many characters the first line of data is shifted to the left. This element is used when defining a custom control view.

[FirstLineHanging Element for Frame for GroupBy \(Format\)](#) Specifies how many characters the first line of data is shifted to the left. This element is used when defining how a new group of objects is displayed.

[FirstLineIndent Element for Frame for Controls for Configuration \(Format\)](#) Specifies how many characters the first line of data is shifted to the right. This element is used when defining a common control that can be used by all the views in the formatting file.

[FirstLineIndent Element of Frame of Controls of View \(Format\)](#) Specifies how many characters the first line of data is shifted to the right. This element is used when defining controls that can be used by a view.

[FirstLineIndent Element](#) Specifies how many characters the first line of data is shifted to the right. This element is used when defining a custom control view.

[FirstLineIndent Element for Frame for GroupBy \(Format\)](#) Specifies how many characters the first line of data is shifted to the right. This element is used when defining how a new group of objects is displayed.

[FormatString Element for ListItem \(Format\)](#) Specifies a format pattern that defines how the property or script value is displayed.

[FormatString Element for TableColumnItem \(Format\)](#) Specifies a format pattern that defines how the property or script value of the table is displayed.

[FormatString Element for WideItem for WideControl \(Format\)](#) Specifies a format pattern that defines how the property or script value is displayed in the view.

[Frame Element for CustomItem for Controls for Configuration \(Format\)](#) Defines how the data is displayed, such as shifting the data to the left or right. This element is used when defining a common control that can be used by all the views in the formatting file.

[Frame Element for CustomItem for Controls for View \(Format\)](#) Defines how the data is displayed, such as shifting the data to the left or right. This element is used when defining controls that can be used by a view.

[Frame Element for CustomItem for CustomControl for View \(Format\)](#) Defines how the data is displayed, such as shifting the data to the left or right. This element is used when defining a custom control view.

[Frame Element for CustomItem for GroupBy \(Format\)](#) Defines how the data is displayed, such as shifting the data to the left or right. This element is used when defining how a new group of objects is displayed.

[GroupBy Element for View \(Format\)](#) Defines how Windows PowerShell displays a new group of objects.

[HideTableHeaders Element \(Format\)](#) Specifies that the headers of the table are not displayed.

[ItemSelectionCondition Element for ExpressionBinding for Controls for Configuration \(Format\)](#) Defines the condition that must exist for this control to be used. This element is used when defining a common control that can be used by all the views in the formatting file.

[ItemSelectionCondition Element of ExpressionBinding for Controls for View \(Format\)](#) Defines the condition that must exist for this control to be used. This element is used when defining controls that can be used by a view.

[ItemSelectionCondition Element for Expression Binding for CustomControl for View \(Format\)](#) Defines the condition that must exist for this control to be used. There is no limit to the number of selection conditions that can be specified for a control item. This element is used when defining a custom control view.

[ItemSelectionCondition Element for ExpressionBinding for GroupBy \(Format\)](#) Defines the condition that must exist for this control to be used. There is no limit to the number of selection conditions that can be specified for a control item. This element is used when defining how a new group of objects is displayed.

[ItemSelectionCondition Element for ListItem \(Format\)](#) Defines the condition that must exist for this list item to be used.

[Label Element for ListItem for ListControl\(Format\)](#) Specifies the label for the property or script value in the row.

[Label Element for GroupBy \(Format\)](#) Specifies a label that is displayed when a new group is encountered.

[Label Element for TableColumnHeader \(Format\)](#) Defines the label that is displayed at the top of a column.

[LeftIndent Element for Frame for Controls for Configuration \(Format\)](#) Specifies how many characters the data is shifted away from the left margin. This element is used when defining a common control that can be used by all the views in the formatting file.

[LeftIndent Element of Frame of Controls of View \(Format\)](#) Specifies how many characters the data is shifted away from the left margin. This element is used when defining controls that can be used by a view.

[LeftIndent Element for Frame for CustomControl for View \(Format\)](#) Specifies how many characters the data is shifted away from the left margin. This element is used when defining a custom control view.

[LeftIndent Element for Frame for GroupBy \(Format\)](#) Specifies how many characters the data is shifted away from the left margin. This element is used when defining how a new group of objects is displayed.

[ListControl Element \(Format\)](#) Defines a list format for the view.

[ListEntry Element \(Format\)](#) Provides a definition of the list view.

[ListEntries Element \(Format\)](#) Defines how the rows of the list view are displayed.

[ListItem Element \(Format\)](#) Defines the property or script whose value is displayed in a row of the list view.

[ListItems Element \(Format\)](#) Defines the properties and scripts that are displayed in the list view.

[Name Element for Control for Controls for Configuration \(Format\)](#) Specifies the name of the control. This element is used when defining a common control that can be used by all the views in the formatting file.

[Name Element for SelectionSet \(Format\)](#) Specifies the name used to reference the selection set.

[Name Element for View \(Format\)](#) Specifies the name that is used to identify the view.

[NewLine Element for CustomItem for Controls for Configuration \(Format\)](#) Adds a blank line to the display of the control. This element is used when defining a common control that can be used by all the views in the formatting file.

[NewLine Element for CustomItem for Controls for View \(Format\)](#) Adds a blank line to the display of the control. This element is used when defining controls that can be used by a view.

[NewLine Element for CustomItem for CustomControl for View \(Format\)](#) Adds a blank line to the display of the control. This element is used when defining a custom control view.

[NewLine Element for CustomItem for GroupBy \(Format\)](#) Adds a blank line to the display of the control. This element is used when defining how a new group of objects is displayed.

[PropertyName Element for ExpressionBinding for Controls for Configuration \(Format\)](#) Specifies the .NET property whose value is displayed by the common control. This element is used when defining a common control that can be used by all the views in the formatting file.

[PropertyName Element for ExpressionBinding for Controls for View \(Format\)](#) Specifies the .NET property whose value is displayed by the control. This element is used when defining controls that can be used by a view.

[PropertyName Element for ExpressionBinding for CustomControl for View \(Format\)](#) Specifies the .NET property whose value is displayed by the control. This element is used when defining a custom control view

[PropertyName Element for ExpressionBinding for GroupBy \(Format\)](#) Specifies the .NET property whose value is displayed by the control. This element is used when defining how a new group of objects is displayed.

[PropertyName Element for GroupBy \(Format\)](#) Specifies the .NET property that starts a new group whenever its value changes.

[PropertyName Element for ItemSelectionCondition for Controls for Configuration \(Format\)](#) Specifies the .NET property that triggers the condition. When this property is present or when it evaluates to `true`, the condition is met, and the control is used. This element is used when defining a common control that can be used by all the views in the formatting file.

[PropertyName Element for ItemSelectionCondition for Controls for View \(Format\)](#)

Specifies the .NET property that triggers the condition. When this property is present or when it evaluates to `true`, the condition is met, and the control is used. This element is used when defining controls that can be used by a view.

[PropertyName Element for ItemSelectionCondition for CustomControl for View \(Format\)](#)

Specifies the .NET property that triggers the condition. When this property is present or when it evaluates to `true`, the condition is met, and the control is used. This element is used when defining a custom control view.

[PropertyName Element for ItemSelectionCondition for GroupBy \(Format\)](#) Specifies the .NET property that triggers the condition. When this property is present or when it evaluates to `true`, the condition is met, and the control is used. This element is used when defining how a new group of objects is displayed.

[PropertyName Element for ItemSelectionCondition for ListItem \(Format\)](#) Specifies the .NET property that triggers the condition. When this property is present or when it evaluates to `true`, the condition is met, and the view is used. This element is used when defining a list view.

[PropertyName Element for ListItem for ListControl \(Format\)](#) Specifies the .NET property whose value is displayed in the list.

[PropertyName Element for SelectionCondition for EntrySelectedBy for ListEntry \(Format\)](#) Specifies the .NET property that triggers the condition. When this property is present or when it evaluates to `true`, the condition is met, and the entry is used. This element is used when defining a common control that can be used by all the views in the formatting file.

[PropertyName Element for SelectionCondition for Controls for View \(Format\)](#) Specifies the .NET property that triggers the condition. When this property is present or when it evaluates to `true`, the condition is met, and the entry is used. This element is used when defining controls that can be used by a view.

[PropertyName Element for SelectionCondition for CustomControl for View \(Format\)](#)

Specifies the .NET property that triggers the condition. When this property is present or when it evaluates to `true`, the condition is met, and the definition is used. This element is used when defining a custom control view.

[PropertyName Element for SelectionCondition for EntrySelectedBy for](#)

[EnumerableExpansion \(Format\)](#) Specifies the .NET property that triggers the condition. When this property is present or when it evaluates to `true`, the condition is met, and the definition is used.

[PropertyName Element for SelectionCondition for GroupBy \(Format\)](#) Specifies the .NET property that triggers the condition. When this property is present or when it evaluates to `true`, the condition is met, and the definition is used. This element is used when defining how a new group of objects is displayed.

[PropertyName Element for SelectionCondition for EntrySelectedBy for ListEntry \(Format\)](#) Specifies the .NET property that triggers the condition. When this property is present or when it evaluates to `true`, the condition is met, and the list entry is used.

[PropertyName Element for SelectionCondition for EntrySelectedBy for TableRowEntry \(Format\)](#) Specifies the .NET property that triggers the condition. When this property is present or when it evaluates to `true`, the condition is met, and the table entry is used.

[PropertyName Element for SelectionCondition for EntrySelectedBy for WideEntry \(Format\)](#) Specifies the .NET property that triggers the condition. When this property is present or when it evaluates to `true`, the condition is met, and the definition is used.

[PropertyName Element for TableColumnItem \(Format\)](#) Specifies the property whose value is displayed in the column of the row.

[PropertyName Element for Wideltem \(Format\)](#) Specifies the property of the object whose value is displayed in the wide view.

[RightIndent Element for Frame for Controls for Configuration \(Format\)](#) Specifies how many characters the data is shifted away from the right margin. This element is used when defining a common control that can be used by all the views in the formatting file.

[RightIndent Element of Frame of Controls of View \(Format\)](#) Specifies how many characters the data is shifted away from the right margin. This element is used when defining controls that can be used by a view.

[RightIndent Element](#) Specifies how many characters the data is shifted away from the right margin. This element is used when defining a custom control view.

[RightIndent Element for Frame for GroupBy \(Format\)](#) Specifies how many characters the data is shifted away from the right margin. This element is used when defining how a new group of objects is displayed.

[ScriptBlock Element for ExpressionBinding for Controls for Configuration \(Format\)](#) Specifies the script whose value is displayed by the common control. This element is used when defining a common control that can be used by all the views in the formatting file.

[ScriptBlock Element for ExpressionBinding for Controls for View \(Format\)](#) Specifies the script whose value is displayed by the control. This element is used when defining controls that can be used by a view.

[ScriptBlock Element for ExpressionBinding for CustomCustomControl for View \(Format\)](#) Specifies the script whose value is displayed by the control. This element is used when defining a custom control view.

[ScriptBlock Element for ExpressionBinding for GroupBy \(Format\)](#) Specifies the script whose value is displayed by the control. This element is used when defining how a new group of objects is displayed.

[ScriptBlock Element for GroupBy \(Format\)](#) Specifies the script that starts a new group whenever its value changes.

[ScriptBlock Element for ItemSelectionCondition for Controls for Configuration \(Format\)](#) Specifies the script that triggers the condition. When this script is evaluated to `true`, the condition is met, and the control is used. This element is used when defining a common control that can be used by all the views in the formatting file.

[ScriptBlock Element for ItemSelectionCondition for Controls for View \(Format\)](#) Specifies the script that triggers the condition. When this script is evaluated to `true`, the condition is met, and the control is used. This element is used when defining controls that can be used by a view.

[ScriptBlock Element for ItemSelectionCondition for CustomControl for View \(Format\)](#) Specifies the script that triggers the condition. When this script is evaluated to `true`, the condition is met, and the control is used. This element is used when defining a custom control view.

[ScriptBlock Element for ItemSelectionCondition for GroupBy \(Format\)](#) Specifies the script that triggers the condition. When this script is evaluated to `true`, the condition is met, and the control is used. This element is used when defining how a new group of objects is displayed.

[ScriptBlock Element for ItemSelectionCondition for ListControl \(Format\)](#) Specifies the script that triggers the condition. When this script is evaluated to `true`, the condition is met, and the list item is used. This element is used when defining a list view.

[ScriptBlock Element for ListItem \(Format\)](#) Specifies the script whose value is displayed in the row of the list.

[ScriptBlock Element for SelectionCondition for Controls for Configuration \(Format\)](#) Specifies the script that triggers the condition. When this script is evaluated to `true`, the

condition is met, and the definition is used. This element is used when defining a common control that can be used by all the views in the formatting file.

[ScriptBlock Element for SelectionCondition for Controls for View \(Format\)](#) Specifies the script that triggers the condition. When this script is evaluated to `true`, the condition is met, and the definition is used. This element is used when defining controls that can be used by a view.

[ScriptBlock Element for SelectionCondition for CustomControl for View \(Format\)](#) Specifies the script that triggers the condition. When this script is evaluated to `true`, the condition is met, and the definition is used. This element is used when defining a custom control view.

[ScriptBlock Element for SelectionCondition for EntrySelectedBy for EnumerableExpansion \(Format\)](#) Specifies the script that triggers the condition.

[ScriptBlock Element for SelectionCondition for GroupBy \(Format\)](#) Specifies the script that triggers the condition. When this script is evaluated to `true`, the condition is met, and the definition is used. This element is used when defining how a new group of objects is displayed.

[ScriptBlock Element for SelectionCondition for EntrySelectedBy for ListEntry \(Format\)](#) Specifies the script that triggers the condition. When this script is evaluated to `true`, the condition is met, and the list entry is used.

[ScriptBlock Element for SelectionCondition for EntrySelectedBy for TableRowEntry \(Format\)](#) Specifies the script block that triggers the condition. When this script is evaluated to `true`, the condition is met, and the table entry is used.

[ScriptBlock Element for SelectionCondition for EntrySelectedBy for WideEntry \(Format\)](#) Specifies the script that triggers the condition. When this script is evaluated to `true`, the condition is met, and the wide entry definition is used.

[ScriptBlock Element for TableColumnItem \(Format\)](#) Specifies the script whose value is displayed in the column of the row.

[ScriptBlock Element for Wideltem \(Format\)](#) Specifies the script whose value is displayed in the wide view.

[SelectionCondition Element for EntrySelectedBy for CustomEntry for Configuration \(Format\)](#) Defines a condition that must exist for a common control definition to be used. This element is used when defining a common control that can be used by all the views in the formatting file.

[SelectionCondition Element for EntrySelectedBy for Controls for View \(Format\)](#) Defines a condition that must exist for the control definition to be used. This element is used when defining controls that can be used by a view.

[SelectionCondition Element for EntrySelectedBy for CustomControl for View \(Format\)](#) Defines a condition that must exist for a control definition to be used. This element is used when defining a custom control view.

[SelectionCondition Element for EntrySelectedBy for EnumerableExpansion \(Format\)](#) Defines the condition that must exist to expand the collection objects of this definition.

[SelectionCondition Element for EntrySelectedBy for GroupBy \(Format\)](#) Defines a condition that must exist for a control definition to be used. This element is used when defining how a new group of objects is displayed.

[SelectionCondition Element for EntrySelectedBy for ListEntry \(Format\)](#) Defines the condition that must exist to use this definition of the list view. There is no limit to the number of selection conditions that can be specified for a list definition.

[SelectionCondition Element for EntrySelectedBy for TableRowEntry \(Format\)](#) Defines the condition that must exist to use for this definition of the table view. There is no limit to the number of selection conditions that can be specified for a table definition.

[SelectionCondition Element for EntrySelectedBy for WideEntry \(Format\)](#) Defines the condition that must exist for this definition to be used. There is no limit to the number of selection conditions that can be specified for a wide entry definition.

[SelectionSet Element \(Format\)](#) Defines a set of .NET objects that can be referenced by the name of the set.

[SelectionSetName Element for EntrySelectedBy for Controls for Configuration \(Format\)](#) Specifies a set of .NET types that use this definition of the control. This element is used when defining a common control that can be used by all the views in the formatting file.

[SelectionSetName Element for EntrySelectedBy for Controls for View \(Format\)](#) Specifies a set of .NET types that use this definition of the control. This element is used when defining controls that can be used by a view.

[SelectionSetName Element for EntrySelectedBy for CustomEntry \(Format\)](#) Specifies a set of .NET objects for the list entry. There is no limit to the number of selection sets that can be specified for an entry.

[SelectionSetName Element for EntrySelectedBy for EnumerableExpansion \(Format\)](#) Specifies the set of .NET types that are expanded by this definition.

[SelectionSetName Element for EntrySelectedBy for GroupBy \(Format\)](#) Specifies a set of .NET objects for the list entry. There is no limit to the number of selection sets that can be specified for an entry. This element is used when defining how a new group of objects is displayed.

[SelectionSetName Element for EntrySelectedBy for ListEntry \(Format\)](#) Specifies a set of .NET objects for the list entry. There is no limit to the number of selection sets that can be specified for an entry.

[SelectionSetName Element for EntrySelectedBy for TableRowEntry \(Format\)](#) Specifies a set of .NET types the use this entry of the table view. There is no limit to the number of selection sets that can be specified for an entry.

[SelectionSetName Element for EntrySelectedBy for WideEntry \(Format\)](#) Specifies a set of .NET objects for the definition. The definition is used whenever one of these objects is displayed.

[SelectionSetName Element for SelectionCondition for Controls for Configuration \(Format\)](#) Specifies the set of .NET types that trigger the condition. When any of the types in this set are present, the condition is met, and the object is displayed by using this control. This element is used when defining a common control that can be used by all the views in the formatting file.

[SelectionSetName Element for SelectionCondition for Controls for View \(Format\)](#) Specifies the set of .NET types that trigger the condition. When any of the types in this set are present, the condition is met and the object is displayed using this control. This element is used when defining controls that can be used by a view.

[EntrySelectedBy Element for CustomEntry for View \(Format\)](#) Specifies the set of .NET types that trigger the condition. When any of the types in this set are present, the condition is met and the object is displayed using this control. This element is used when defining a custom control view.

[SelectionSetName Element for SelectionCondition for EntrySelectedBy for EnumerableExpansion \(Format\)](#) Specifies the set of .NET types that trigger the condition. When any of the types in this set are present, the condition is met.

[SelectionSetName Element for SelectionCondition for GroupBy \(Format\)](#) Specifies the set of .NET types that trigger the condition. When any of the types in this set are present, the condition is met, and the object is displayed by using this control. This element is used when defining how a new group of objects is displayed.

[SelectionSetName Element for SelectionCondition for EntrySelectedBy for ListEntry \(Format\)](#) Specifies the set of .NET types that trigger the condition. When any of the

types in this set are present, the condition is met, and the object is displayed by using this definition of the list view.

[SelectionSetName Element for SelectionCondition for EntrySelectedBy for TableRowEntry \(Format\)](#) Specifies the set of .NET types that trigger the condition. When any of the types in this set are present, the condition is met, and the object is displayed by using this definition of the table view.

[SelectionSetName Element for SelectionCondition for EntrySelectedBy for WideEntry \(Format\)](#) Specifies the set of .NET types that trigger the condition. When any of the types in this set are present, the condition is met, and the object is displayed by using this definition of the wide view.

[SelectionSetName Element for ViewSelectedBy \(Format\)](#) Specifies a set of .NET objects that are displayed by the view.

[SelectionSets Element \(Format\)](#) Defines the sets of .NET objects that can be used by individual format views.

[ShowError Element \(Format\)](#) Specifies that the full error record is displayed when an error occurs while displaying a piece of data.

[TableColumnHeader Element for TableHeaders for TableControl \(Format\)](#) Defines the label, the width of the column, and the alignment of the label for a column of the table.

[TableColumnItem Element \(Format\)](#) Defines the property or script whose value is displayed in the column of the row.

[TableColumnItems Element \(Format\)](#) Defines the properties or scripts whose values are displayed in the row.

[TableControl Element \(Format\)](#) Defines a table format for a view.

[TableHeaders Element \(Format\)](#) Defines the headers for the columns of a table.

[TableRowEntries Element \(Format\)](#) Defines the rows of the table.

[TableRowEntry Element \(Format\)](#) Defines the data that is displayed in a row of the table.

[Text Element for CustomItem for Controls for Configuration \(Format\)](#) Specifies text that is added to the data that is displayed by the control, such as a label, brackets to enclose the data, and spaces to indent the data. This element is used when defining a common control that can be used by all the views in the formatting file.

[Text Element for CustomItem for Controls for View \(Format\)](#) Specifies text that is added to the data that is displayed by the control, such as a label, brackets to enclose the data,

and spaces to indent the data. This element is used when defining controls that can be used by a view.

[Text Element for CustomItem \(Format\)](#) Specifies text that is added to the data that is displayed by the control, such as a label, brackets to enclose the data, and spaces to indent the data. This element is used when defining a custom control view.

[Text Element for CustomItem for GroupBy \(Format\)](#) Specifies text that is added to the data that is displayed by the control, such as a label, brackets to enclose the data, and spaces to indent the data. This element is used when defining how a new group of objects is displayed.

[TypeName Element for EntrySelectedBy for Controls for Configuration \(Format\)](#) Specifies a .NET type that uses this definition of the control. This element is used when defining a common control that can be used by all the views in the formatting file.

[TypeName Element for EntrySelectedBy for Controls for View \(Format\)](#) Specifies a .NET type that uses this definition of the control. This element is used when defining controls that can be used by a view.

[TypeName Element for EntrySelectedBy for CustomEntry for View \(Format\)](#) Specifies a .NET type that uses this definition of the custom control view. There is no limit to the number of types that can be specified for a definition.

[TypeName Element for EntrySelectedBy for EnumerableExpansion \(Format\)](#) Specifies a .NET type that is expanded by this definition. This element is used when defining a default settings.

[TypeName Element for EntrySelectedBy for GroupBy \(Format\)](#) Specifies a .NET type that uses this definition of the custom control. This element is used when defining how a new group of objects is displayed.

[TypeName Element for EntrySelectedBy for ListControl \(Format\)](#) Specifies a .NET type that uses this entry of the list view. There is no limit to the number of types that can be specified for a list entry.

[TypeName Element for EntrySelectedBy for TableRowEntry \(Format\)](#) Specifies a .NET type that uses this entry of the table view. There is no limit to the number of types that can be specified for a table entry.

[TypeName Element for EntrySelectedBy for WideEntry \(Format\)](#) Specifies a .NET type for the definition. The definition is used whenever this object is displayed.

[TypeName Element for SelectionCondition for Controls for Configuration \(Format\)](#) Specifies a .NET type that triggers the condition. This element is used when defining a

common control that can be used by all the views in the formatting file.

[TypeName Element for SelectionCondition for Controls for View \(Format\)](#) Specifies a .NET type that triggers the condition. This element is used when defining controls that can be used by a view.

[TypeName Element for SelectionCondition for CustomControl for View \(Format\)](#)

Specifies a .NET type that triggers the condition. This element is used when defining a custom control view.

[TypeName Element for SelectionCondition for EntrySelectedBy for EnumerableExpansion \(Format\)](#) Specifies a .NET type that triggers the condition.

[TypeName Element for SelectionCondition for GroupBy \(Format\)](#) Specifies a .NET type that triggers the condition. This element is used when defining how a new group of objects is displayed.

[TypeName Element for SelectionCondition for EntrySelectedBy for ListControl \(Format\)](#) Specifies a .NET type that triggers the condition. When this type is present, the list entry is used.

[TypeName Element for SelectionCondition for EntrySelectedBy for TableRowEntry \(Format\)](#) Specifies a .NET type that triggers the condition. When this type is present, the condition is met, and the table row is used.

[TypeName Element for SelectionCondition for EntrySelectedBy for WideEntry \(Format\)](#) Specifies a .NET type that triggers the condition. When this type is present, the definition is used.

[TypeName Element for Types \(Format\)](#) Specifies the .NET type of an object that belongs to the selection set.

[TypeName Element for ViewSelectedBy \(Format\)](#) Specifies a .NET object that is displayed by the view.

[Types Element \(Format\)](#) Defines the .NET objects that are in the selection set.

[View Element \(Format\)](#) Defines a view that is used to display one or more .NET objects.

[ViewDefinitions Element \(Format\)](#) Defines the views used to display objects.

[ViewSelectedBy Element \(Format\)](#) Defines the .NET objects that are displayed by the view.

[WideControl Element \(Format\)](#) Defines a wide (single value) list format for the view. This view displays a single property value or script value for each object.

[WideEntries Element \(Format\)](#) Provides the definitions of the wide view. The wide view must specify one or more definitions.

[WideEntry Element \(Format\)](#) Provides a definition of the wide view.

[WideItem Element \(Format\)](#) Defines the property or script whose value is displayed.

[Width Element \(Format\)](#) Defines the width (in characters) of a column.

[Wrap Element \(Format\)](#) Specifies that text that exceeds the column width is displayed on the next line.

[WrapTables Element \(Format\)](#) Specifies that data in a table cell is moved to the next line if the data is longer than the width of the column.

Configuration Element

Article • 09/17/2021

Represents the top-level element of a formatting file.

Schema

- Configuration Element

Syntax

XML

```
<Configuration>
  <DefaultSettings>...</DefaultSettings>
  <SelectionSets>...</SelectionSets>
  <Controls>...</Controls>
  <ViewDefinitions>...</ViewDefinitions>
</Configuration>
```

Attributes and Elements

The following sections describe the attributes, child elements, and the parent element of the `Configuration` element. This element must be the root element for each formatting file, and this element must contain at least one child element.

Attributes

None.

Child Elements

[] Expand table

Element	Description
Controls Element for Configuration	Optional element.

Element	Description
	Defines the common controls that can be used by all views of the formatting file.
DefaultSettings Element	Optional element. Defines common settings that apply to all the views of the formatting file.
SelectionSets Element Format	Optional element. Defines the common sets of .NET objects that can be used by all views of the formatting file.
ViewDefinitions Element	Optional element. Defines the views used to display objects.

Parent Elements

None.

Remarks

Formatting files define how objects are displayed. In most cases, this root element contains a [ViewDefinitions](#) element that defines the table, list, and wide views of the formatting file. In addition to the view definitions, the formatting file can define common selection sets, settings, and controls that those views can use.

Controls Element for Configuration

Article • 09/17/2021

Defines the common controls that can be used by all views of the formatting file.

Schema

- Configuration Element
- Controls Element

Syntax

XML

```
<Controls>
  <Control>...</Control>
</Controls>
```

Attributes and Elements

The following sections describe the attributes, child elements, and the parent element of the `Controls` element.

Attributes

None.

Child Elements

[+] Expand table

Element	Description
Control Element for Controls for Configuration	Required element. Defines a common control that can be used by all views of the formatting file.

Parent Elements

Element	Description
Configuration Element	Represents the top-level element of a formatting file.

Remarks

You can create any number of common controls. For each control, you must specify the name that is used to reference the control and the components of the control.

CustomControl Element for Control for Controls for Configuration

Article • 09/17/2021

Defines a control. This element is used when defining a common control that can be used by all the views in the formatting file.

Schema

- Configuration Element
- Controls Element
- Control Element
- CustomControl Element

Syntax

XML

```
<CustomControl>
  <CustomEntries>...</CustomEntries>
</CustomControl>
```

Attributes and Elements

The following sections describe the attributes, child elements, and the parent element of the `CustomControl` element. This element must have at least one child element. There is no maximum limit to the number of child elements that can be specified.

Attributes

None.

Child Elements

CustomEntries Element for CustomControl for Controls for Configuration

Article • 09/17/2021

Provides the definitions of a common control. This element is used when defining a common control that can be used by all the views in the formatting file.

Schema

- Configuration Element
- Controls Element
- Control Element
- CustomControl Element
- CustomEntries Element

Syntax

XML

```
<CustomEntries>
  <CustomEntry>...</CustomEntry>
</CustomEntries>
```

Attributes and Elements

The following sections describe attributes, child elements, and the parent element of the `CustomEntries` element. You must specify one or more child elements.

Attributes

None.

Child Elements

[+] Expand table

Element	Description
CustomEntry Element for CustomControl for Controls for Configuration	Provides a definition of the common control.

Parent Elements

[+] Expand table

Element	Description
CustomControl Element for Control for Configuration	Defines a common control.

Remarks

In most cases, a control has only one definition, which is defined in a single `CustomEntry` element. However it is possible to have multiple definitions if you want to use the same control to display different .NET objects. In those cases, you can define a `CustomEntry` element for each object or set of objects.

CustomEntry Element for CustomControl for Controls for Configuration

Article • 09/17/2021

Provides a definition of the common control. This element is used when defining a common control that can be used by all the views in the formatting file.

Schema

- Configuration Element
- Controls Element
- Control Element
- CustomControl Element
- CustomEntries Element
- CustomEntry Element

Syntax

XML

```
<CustomEntry>
  <EntrySelectedBy>...</EntrySelectedBy>
  <CustomItem>...</CustomItem>
</CustomEntry>
```

Attributes and Elements

The following sections describe attributes, child elements, and the parent element of the `CustomEntry` element. You must specify the items displayed by the definition.

Attributes

None.

Child Elements

[+] Expand table

Element	Description
EntrySelectedBy Element for CustomEntry for Controls for Configuration	Optional element. Defines the .NET types that use the definition of the common control or the condition that must exist for this control to be used.
CustomItem Element for CustomEntry for Controls for Configuration	Required element. Defines what data is displayed by the control and how it is displayed.

Parent Elements

[+] Expand table

Element	Description
CustomEntries Element for CustomControl for Configuration	Provides the definitions of the common control.

Remarks

In most cases, only one definition is required for each common custom control, but it is possible to have multiple definitions if you want to use the same control to display different .NET objects. In those cases, you can provide a separate definition for each object or set of objects.

CustomItem Element for CustomEntry for Controls for Configuration

Article • 09/17/2021

Defines what data is displayed by the control and how it is displayed. This element is used when defining a common control that can be used by all the views in the formatting file.

Schema

- Configuration Element
- Controls Element
- Control Element
- CustomControl Element
- CustomEntries Element
- CustomEntry Element
- CustomItem Element

Syntax

XML

```
<CustomItem>
  <ExpressionBinding>...</ExpressionBinding>
  <NewLine/>
  <Text>TextToDisplay</Text>
  <Frame>...</Frame>
</CustomItem>
```

Attributes and Elements

The following sections describe attributes, child elements, and the parent element of the `CustomItem` element. For more information, see Remarks.

Attributes

None.

Child Elements

[+] Expand table

Element	Description
ExpressionBinding Element for CustomItem for Controls for Configuration	Optional element. Defines the data that is displayed by the control.
Frame Element for CustomItem for Controls for Configuration	Optional element. Defines how the data is displayed, such as shifting the data to the left or right.
NewLine Element for CustomItem for Controls for Configuration	Optional element. Adds a blank line to the display of the control.
Text Element for CustomItem for Controls for Configuration	Optional element. Adds text, such as parentheses or brackets, to the display of the control.

Parent Elements

[+] Expand table

Element	Description
CustomEntry Element for CustomControl for Controls for Configuration	Provides a definition of the control.

Remarks

When specifying the child elements of the `CustomItem` element, keep the following in mind:

- The child elements must be added in the following sequence: `ExpressionBinding`, `NewLine`, `Text`, and `Frame`.
- There is no maximum limit to the number of sequences that you can specify.
- In each sequence, there is no maximum limit to the number of `ExpressionBinding` elements that you can use.

ExpressionBinding Element for CustomItem for Controls for Configuration

Article • 09/17/2021

Defines the data that is displayed by the control. This element is used when defining a common control that can be used by all the views in the formatting file.

Schema

- Configuration Element
- Controls Element
- Control Element
- CustomControl Element
- CustomEntries Element
- CustomEntry Element
- CustomItem Element
- ExpressionBinding Element

Syntax

XML

```
<ExpressionBinding>
  <CustomControl>...</CustomControl>
  <CustomControlName>NameofCommonCustomControl</CustomControlName>
  <EnumerateCollection/>
  <ItemSelectionCondition>...</ItemSelectionCondition>
  <PropertyName>Nameof.NetTypeProperty</PropertyName>
  <ScriptBlock>ScriptToEvaluate</ScriptBlock>
</ExpressionBinding>
```

Attributes and Elements

The following sections describe attributes, child elements, and the parent element of the `ExpressionBinding` element.

Attributes

None.

Child Elements

[] Expand table

Element	Description
CustomControl Element	Optional element. Defines a control that is used by this control.
CustomControlName Element for ExpressionBinding for Controls for Configuration	Optional element. Specifies the name of a common control or a view control.
EnumerateCollection Element for ExpressionBinding for Controls for Configuration	Optional element. Specified that the elements of collections are displayed by the control.
ItemSelectionCondition Element for ExpressionBinding for Controls for Configuration	Optional element. Defines the condition that must exist for this common control to be used.
PropertyName Element for ExpressionBinding for Controls for Configuration	Optional element. Specifies the .NET property whose value is displayed by the common control.
ScriptBlock Element for ExpressionBinding for Controls for Configuration	Optional element. Specifies the script whose value is displayed by the common control.

Parent Elements

[] Expand table

Element	Description
CustomItem Element for CustomEntry for Controls for Configuration	Defines what data is displayed by the custom control view and how it is displayed.

CustomControlName Element for ExpressionBinding for Controls for Configuration

Article • 09/17/2021

Specifies the name of a common control. This element is used when defining a common control that can be used by all the views in the formatting file.

Schema

- Configuration Element
- Controls Element
- Control Element
- CustomControl Element
- CustomEntries Element
- CustomEntry Element
- CustomItem Element
- ExpressionBinding Element
- CustomControlName Element

Syntax

XML

```
<CustomControlName>NameofCustomControl</CustomControlName>
```

Attributes and Elements

The following sections describe attributes, child elements, and the parent element of the `CustomControlName` element.

Attributes

None.

Child Elements

None.

Parent Elements

 Expand table

Element	Description
ExpressionBinding Element for CustomItem for Controls for Configuration	Defines the data that is displayed by the control.

Text Value

Specify the name of the control.

Remarks

You can create common controls that can be used by all the views of a formatting file, and you can create view controls that can be used by a specific view. The following elements specify the names of these controls:

- [Name Element for Control for Controls for Configuration](#)
- [Name Element for Control for Controls for View](#)

ItemSelectionCondition Element for ExpressionBinding for Controls for Configuration

Article • 09/17/2021

Defines the condition that must exist for this control to be used. This element is used when defining a common control that can be used by all the views in the formatting file.

Schema

- Configuration Element
- Controls Element
- Control Element
- CustomControl Element
- CustomEntries Element
- CustomEntry Element
- CustomItem Element
- ExpressionBinding Element
- ItemSelectionCondition Element

Syntax

XML

```
<ItemSelectionCondition>
  <PropertyName>.NetTypeProperty</PropertyName>
  <ScriptBlock>ScriptToEvaluate</ScriptBlock>
</ItemSelectionCondition>
```

Attributes and Elements

The following sections describe attributes, child elements, and the parent element of the `ItemSelectionCondition` element.

Attributes

None.

Child Elements

[Expand table](#)

Element	Description
PropertyName Element for ItemSelectionCondition for Controls for Configuration	Optional element. Specifies the .NET property that triggers the condition.
ScriptBlock Element for ItemSelectionCondition for Controls for Configuration	Optional element. Specifies the script that triggers the condition.

Parent Elements

SelectionCondition Element for EntrySelectedBy for Controls for Configuration

Article • 09/17/2021

Defines a condition that must exist for a common control definition to be used. This element is used when defining a common control that can be used by all the views in the formatting file.

Schema

- Configuration Element
- Controls Element
- Control Element
- CustomControl Element
- CustomEntries Element
- CustomEntry Element
- EntrySelectedBy Element
- SelectionCondition Element

Syntax

XML

```
<SelectionCondition>
  <TypeName>Nameof.NetType</TypeName>
  <SelectionSetName>NameofSelectionSet</SelectionSetName>
  <PropertyName>.NetTypeProperty</PropertyName>
  <ScriptBlock>ScriptToEvaluate</ScriptBlock>
</SelectionCondition>
```

Attributes and Elements

The following sections describe attributes, child elements, and the parent element of the `SelectionCondition` element.

Attributes

None.

Child Elements

 Expand table

Element	Description
PropertyName Element for SelectionCondition for Controls for Configuration	Optional element. Specifies a .NET property that triggers the condition.
ScriptBlock Element for SelectionCondition for Controls for Configuration	Optional element. Specifies the script that triggers the condition.
SelectionSetName Element for SelectionCondition for Controls for Configuration	Optional element. Specifies the set of .NET types that triggers the condition.
TypeName Element for SelectionCondition for Controls for Configuration	Optional element. Specifies a .NET type that triggers the condition.

Parent Elements

 Expand table

Element	Description
EntrySelectedBy Element for CustomEntry for Controls for Configuration	Defines the .NET types that use this entry of the common control definition.

Remarks

The following guidelines must be followed when defining a selection condition:

- The selection condition must specify at least one property name or a script block, but cannot specify both.
- The selection condition can specify any number of .NET types or selection sets, but cannot specify both.

For more information about how selection conditions can be used, see [Defining Conditions for when Data is Displayed](#).

SelectionSetName Element for EntrySelectedBy for Controls for Configuration

Article • 09/17/2021

Specifies a set of .NET types that use this definition of the control. This element is used when defining a common control that can be used by all the views in the formatting file.

Schema

- Configuration Element
- Controls Element of Configuration
- Control Element for Controls for Configuration
- CustomControl Element for Control for Configuration
- CustomEntries Element for CustomControl for Configuration
- CustomEntry Element for CustomControl for Controls for Configuration
- EntrySelectedBy Element for CustomEntry for Controls for Configuration
- SelectionSetName Element for EntrySelectedBy for Controls for Configuration

Syntax

XML

```
<SelectionSetName>NameofSelectionSet</SelectionSetName>
```

Attributes and Elements

The following sections describe attributes, child elements, and the parent element of the `SelectionSetName` element.

Attributes

None

Child Elements

None.

Parent Elements

 Expand table

Element	Description
EntrySelectedBy Element for CustomEntry for Controls for Configuration	Defines the .NET types that use this control definition or the condition that must exist for this definition to be used.

Text Value

Specify the name of the selection set.

Remarks

Each control definition must have at least one type name, selection set, or selection condition defined.

Selection sets are typically used when you want to define a group of objects that are used in multiple views. For more information about defining selection sets, see [Defining Selection Sets](#).

Name Element for Control for Controls for Configuration

Article • 09/17/2021

Specifies the name of the control. This element is used when defining a common control that can be used by all the views in the formatting file.

Schema

- Configuration Element
- Controls Element
- Control Element
- Name Element

Syntax

XML

```
<Name>NameOfControl</Name>
```

Attributes and Elements

The following sections describe attributes, child elements, and the parent element of the `Name` element.

Attributes

None.

Child Elements

None.

Parent Elements

 Expand table

Element	Description
Control Element for Controls for Configuration	Defines a common control that can be used by all the views of the formatting file and the name that is used to reference the control.

Text Value

Specify the name that is used to reference this control.

Remarks

The name specified here can be used in the following elements to reference this control.

- When creating a table, list, wide or custom control view, the control can be specified by the following element: [GroupBy Element for View](#)
- When creating another common control, this control can be specified by the following element: [ExpressionBinding Element for CustomItem for Controls for Configuration](#)
- When creating a control that can be used by a view, this control can be specified by the following element: [ExpressionBinding Element for CustomItem for Controls for View](#)

EntrySelectedBy Element for EnumerableExpansion

Article • 09/17/2021

Defines the .NET types that use this definition or the condition that must exist for this definition to be used.

Schema

- Configuration Element
- DefaultSettings Element
- EnumerableExpansions Element
- EnumerableExpansion Element
- EntrySelectedBy Element for EnumerableExpansion

Syntax

XML

```
<EntrySelectedBy>
  <TypeName>Nameof.NetType</TypeName>
  <SelectionSetName>NameofSelectionSet</SelectionSetName>
  <SelectionCondition>...</SelectionCondition>
</EntrySelectedBy>
```

Attributes and Elements

The following sections describe attributes, child elements, and the parent element of the `EntrySelectedBy` element.

Attributes

None.

Child Elements

[+] Expand table

Element	Description
SelectionCondition Element for EntrySelectedBy for EnumerableExpansion	Optional element. Defines the condition that must exist to expand the collection objects of this definition.
SelectionSetName Element for EntrySelectedBy for EnumerableExpansion	Optional element. Specifies a set of .NET types that use this definition of how collection objects are expanded.
TypeName Element for EntrySelectedBy for EnumerableExpansion	Optional element. Specifies a .NET type that uses this definition of how collection objects are expanded.

Parent Elements

[\[\] Expand table](#)

Element	Description
EnumerableExpansion Element	Defines how specific .NET collection objects are expanded when they are displayed in a view.

Remarks

You must specify at least one type, selection set, or selection condition for a definition entry. There is no maximum limit to the number of child elements that you can use.

Selection conditions are used to define a condition that must exist for the definition to be used, such as when an object has a specific property or that a specific property value or script evaluates to `true`. For more information about selection conditions, see

[Defining Conditions for Displaying Data](#).

SelectionCondition Element for EntrySelectedBy for EnumerableExpansion

Article • 12/18/2023

Defines the condition that must exist to expand the collection objects of this definition.

Schema

- Configuration Element
- DefaultSettings Element
- EnumerableExpansions Element
- EnumerableExpansion Element
- EntrySelectedBy Element
- SelectionCondition Element

Syntax

XML

```
<SelectionCondition>
  <TypeName>Nameof.NetType</TypeName>
  <SelectionSetName>NameofSelectionSet</SelectionSetName>
  <PropertyName>.NetTypeProperty</PropertyName>
  <ScriptBlock>ScriptToEvaluate</ScriptBlock>
</SelectionCondition>
```

Attributes and Elements

The following sections describe attributes, child elements, and the parent element of the `SelectionCondition` element. You must specify a single `PropertyName` or `ScriptBlock` element. The `SelectionSetName` and `TypeName` elements are optional. You can specify one of either element.

Attributes

None.

Child Elements

[Expand table](#)

Element	Description
PropertyName Element for SelectionCondition for EntrySelectedBy for EnumerableExpansion	Optional element. Specifies the .NET property that triggers the condition.
ScriptBlock Element for SelectionCondition for EntrySelectedBy for EnumerableExpansion	Optional element. Specifies the script that triggers the condition.
SelectionSetName Element for SelectionCondition for EntrySelectedBy for EnumerableExpansion	Optional element. Specifies the set of .NET types that triggers the condition.
TypeName Element for SelectionCondition for EntrySelectedBy for EnumerableExpansion	Optional element. Specifies a .NET type that triggers the condition.

Parent Elements

[Expand table](#)

Element	Description
EntrySelectedBy Element for EnumerableExpansion	Defines which .NET collection objects are expanded by this definition.

Remarks

Each definition must have at least one type name, selection set, or selection condition defined.

When you are defining a selection condition, the following requirements apply:

- The selection condition must specify a least one property name or a script block, but cannot specify both.

- The selection condition can specify any number of .NET types or selection sets, but cannot specify both.

For more information about how to use selection conditions, see [Defining Conditions for Displaying Data](#).

TypeName Element for SelectionCondition for EntrySelectedBy for EnumerableExpansion

Article • 09/17/2021

Specifies a .NET type that triggers the condition.

Schema

- Configuration Element
- DefaultSettings Element
- EnumerableExpansions Element
- EnumerableExpansions Element
- EntrySelectedBy Element
- SelectionCondition Element
- TypeName Element

Syntax

XML

```
<TypeName>Nameof.NetType</TypeName>
```

Attributes and Elements

The following sections describe attributes, child elements, and the parent element of the `TypeName` element.

Attributes

None.

Child Elements

None.

Parent Elements

[] [Expand table](#)

Element	Description
SelectionCondition Element for EntrySelectedBy for EnumerableExpansion	Defines the condition that must exist to expand the collection objects of this definition.

Text Value

Specify the fully qualified name of the .NET type, such as `System.IO DirectoryInfo`.

Remarks

See Also

SelectionSetName Element for EntrySelectedBy for EnumerableExpansion

Article • 09/17/2021

Specifies the set of .NET types that are expanded by this definition.

Schema

- Configuration Element
- DefaultSettings Element
- EnumerableExpansions Element
- EnumerableExpansion Element
- EntrySelectedBy Element
- SelectionSetName Element

Syntax

XML

```
<SelectionSetName>NameofSelectionSet</SelectionSetName>
```

Attributes and Elements

The following sections describe attributes, child elements, and the parent element of the `SelectionSetName` element.

Attributes

None.

Child Elements

None.

Parent Elements

[+] Expand table

Element	Description
EntrySelectedBy Element for EnumerableExpansion	Defines the .NET collection objects that are expanded by this definition.

Text Value

Specify the name of the selection set.

Remarks

Each definition must specify one or more type names, a selection set, or a selection condition.

Selection sets are typically used when you want to define a group of objects that are used in multiple views. For example, you might want to create a table view and a list view for the same set of objects. For more information about defining selection sets, see [Defining Sets of Objects for a View](#).

TypeName Element for EntrySelectedBy for EnumerableExpansion

Article • 09/17/2021

Specifies a .NET type that is expanded by this definition. This element is used when defining a default settings.

Schema

- Configuration Element
- DefaultSettings Element
- EnumerableExpansions Element
- EnumerableExpansion Element
- EntrySelectedBy Element
- TypeName Element

Syntax

XML

```
<TypeName>Nameof .NetType</TypeName>
```

Attributes and Elements

The following sections describe attributes, child elements, and the parent element of the `TypeName` element.

Attributes

None.

Child Elements

None.

Parent Elements

Element	Description
EntrySelectedBy Element for EnumerableExpansion	Defines the .NET types that use this definition or the condition that must exist for this definition to be used.

Text Value

Specify the fully qualified name of the .NET type, such as `System.IO.DirectoryInfo`.

Remarks

Expand Element

Article • 09/17/2021

Specifies how the collection object is expanded for this definition.

Schema

- Configuration Element
- DefaultSettings Element
- EnumerableExpansions Element
- EnumerableExpansion Element
- Expand Element

Syntax

XML

```
<Expand>EnumOnly, CoreOnly, Both</Expand>
```

Attributes and Elements

The following sections describe attributes, child elements, and the parent element of the `Expand` element.

Attributes

None.

Child Elements

None.

Parent Elements

[] [Expand table](#)

Element	Description
EnumerableExpansion Element	Defines how specific .NET collection objects are expanded when they are displayed in a view.

Text Value

Specify one of the following values:

- `EnumOnly`: Displays only the properties of the objects in the collection.
- `CoreOnly`: Displays only the properties of the collection object.
- `Both`: Displays the properties of the objects in the collection and the properties of the collection object.

Remarks

This element is used to define how collection objects and the objects in the collection are displayed. In this case, a collection object refers to any object that supports the [System.Collections.ICollection](#) interface.

The default behavior is to display only the properties of the objects in the collection.

SelectionSets Element

Article • 09/17/2021

Defines the common sets of .NET objects that can be used by all views of the formatting file. The views and controls of the formatting file can reference the complete set of objects by using only the name of the selection set.

Schema

- Configuration Element
- SelectionSets Element

Syntax

XML

```
<SelectionSets>
  <SelectionSet>...</SelectionSet>
</SelectionSets>
```

Attributes and Elements

The following sections describe the attributes, child elements, and parent element of the `SelectionSets` element. Each child element defines a set of objects that can be referenced by the name of the set. The order of the child elements is not significant.

Attributes

None.

Child Elements

[+] Expand table

Element	Description
<code>SelectionSet</code> Element	Required element.

Element	Description
	Defines a single set of .NET objects that can be referenced by the name of the set.

Parent Elements

[\[+\] Expand table](#)

Element	Description
Configuration Element	Represents the top-level element of a formatting file.

Remarks

You can use selection sets when you have a set of related objects that you want to reference by using a single name, such as a set of objects that are related through inheritance. When defining your views, you can specify the set of objects by using the name of the selection set instead of listing all the objects within each view.

Common selection sets are specified by their name when defining the views of the formatting file or the definitions of the views. In these cases, the `SelectionSetName` child element of the `ViewSelectedBy` and `EntrySelectedBy` elements specifies the set to be used. For more information about selection sets, see [Defining Sets of Objects](#).

SelectionSet Element

Article • 09/17/2021

Defines a set of .NET objects that can be referenced by the name of the set.

Schema

- Configuration Element
- SelectionSets Element
- SelectionSet Element

Syntax

XML

```
<SelectionSet>
  <Name>SelectionSetName</Name>
  <Types>...</Types>
</SelectionSet>
```

Attributes and Elements

The following sections describe the attributes, child elements, and the parent element of the `SelectionSet` element. Each selection set must have a name, and it must specify the .NET objects of the set.

Attributes

None.

Child Elements

[+] Expand table

Element	Description
Name Element for SelectionSet	Required element. Specifies the name used to reference the selection set.

Element	Description
Types Element	<p>Required element.</p> <p>Defines the .NET objects that are in the selection set.</p>

Parent Elements

[\[+\] Expand table](#)

Element	Description
SelectionSets Element	Defines the common sets of .NET objects that can be used by all views
Format	of the formatting file.

Remarks

You can use selection sets when you have a set of related objects that you want to reference by using a single name, such as a set of objects that are related through inheritance. When defining your views, you can specify the set of objects by using the name of the selection set instead of listing all the objects within each view.

Common selection sets are specified by their name when defining the views of the formatting file or the definitions of the views. In these cases, the `SelectionSetName` child element of the `ViewSelectedBy` and `EntrySelectedBy` elements specifies the set to be used. For more information about selection sets, see [Defining Sets of Objects](#).

Example

The following example shows a `SelectionSet` element that defines four .NET types.

XML

```
<SelectionSets>
  <SelectionSet>
    <Name>FileSystemTypes</Name>
    <Types>
      <TypeName>System.IO.DirectoryInfo</TypeName>
      <TypeName>System.IO.FileInfo</TypeName>
      <TypeName>Deserialized.System.IO.DirectoryInfo</TypeName>
      <TypeName>Deserialized.System.IO.FileInfo</TypeName>
    </Types>
```

```
</SelectionSet>  
</SelectionSets>
```

Types Element for SelectionSet

Article • 09/17/2021

Defines the .NET objects that are in the selection set.

Schema

- Configuration Element
- SelectionSets Element
- SelectionSet Element
- Types Element

Syntax

XML

```
<Types>
  <TypeName>Nameof.NetType</TypeName>
</Types>
```

Attributes and Elements

The following sections describe the attributes, child elements, and the parent element of the `Types` element. There must be at least one child element, but there is no maximum limit to the number of child elements that can be added.

Attributes

None.

Child Elements

[+] Expand table

Element	Description
TypeName Element of Types	Required element.

Element	Description
	Specifies the .NET object that belongs to the selection set.

Parent Elements

[+] Expand table

Element	Description
SelectionSet Element	Defines a set of .NET objects that can be referenced by the name of the set.

Remarks

The objects defined by this element make up a selection set that can be used by a view, by a definition of a view (views can have multiple definitions), or when specifying a selection condition. For more information about selection sets, see [Defining Sets of Objects](#).

Example

This example shows a `SelectionSet` element that defines four .NET types.

XML

```
<SelectionSets>
  <SelectionSet>
    <Name>FileSystemTypes</Name>
    <Types>
      <TypeName>System.IO.DirectoryInfo</TypeName>
      <TypeName>System.IO.FileInfo</TypeName>
      <TypeName>Deserialized.System.IO.DirectoryInfo</TypeName>
      <TypeName>Deserialized.System.IO.FileInfo</TypeName>
    </Types>
  </SelectionSet>
</SelectionSets>

TypeName Element for Types

Article • 09/17/2021

Specifies the .NET type of an object that belongs to the selection set.

Schema

- Configuration Element
- SelectionSets Element
- SelectionSet Element
- Types Element
- TypeName Element

Syntax

XML

```
<TypeName>Nameof.NetType</Name>
```

Attributes and Elements

The following sections describe the attributes, child elements, and the parent element of the `TypeName` element. At least one `TypeName` element must be included in the selection set.

Attributes

None.

Child Elements

None.

Parent Elements

 Expand table

Element	Description
Types Element	Defines the .NET objects that are in the selection set.

Text Value

Specify the fully qualified name for the .NET type.

Remarks

You can use selection sets when you have a set of related objects that you want to reference by using a single name, such as a set of objects that are related through inheritance. When defining your views, you can specify the set of objects by using the name of the selection set instead of listing all the objects within each view.

Common selection sets are specified by their name when defining the views of the formatting file. In these cases, the `SelectionSetName` child element of the `ViewSelectedBy` element for the view specifies the set. However, different entries of a view can also specify a selection set that applies to only that entry of the view. For more information about selection sets, see [Defining Sets of Objects](#).

Example

The following example shows a `SelectionSet` element that defines four .NET types.

```
<SelectionSets>
  <SelectionSet>
    <Name>FileSystemTypes</Name>
    <Types>
      <TypeName>System.IO.DirectoryInfo</TypeName>
      <TypeName>System.IO.FileInfo</TypeName>
      <TypeName>Deserialized.System.IO.DirectoryInfo</TypeName>
      <TypeName>Deserialized.System.IO.FileInfo</TypeName>
    </Types>
  </SelectionSet>
</SelectionSets>
```

ViewDefinitions Element

Article • 09/17/2021

Defines the views used to display .NET objects. These views can display the properties and script values of an object in a table format, list format, wide format, and custom control format.

Schema

- Configuration Element
- ViewDefinitions

Syntax

XML

```
<ViewDefinitions>
  <View>...</View>
</ViewDefinitions>
```

Attributes and Elements

The following sections describe the attributes, child elements, and parent element of the `ViewDefinitions` element. There is no limit to the number of views that can be defined in a formatting file, and they can be added in any order.

Attributes

None.

Child Elements

[+] Expand table

Element	Description
View Element	Defines a view that is used to display one or more .NET objects.

Parent Elements

[] [Expand table](#)

Element	Description
Configuration Element	Represents the top-level element of a formatting file.

Remarks

For more information about the components of the different types of views, see the following topics:

- [Creating a Table View](#)
- [Creating a List View](#)
- [Creating a Wide View](#)
- [Custom Controls](#)

Example

This example shows a `ViewDefinitions` element that contains the parent elements for a table view and a list view.

XML

```
<Configuration>
  <ViewDefinitions>
    <View>
      <TableControl>...</TableControl>
    </View>
    <View>
      <ListControl>...</ListControl>

View Element

Article • 09/17/2021

Defines a view that displays one or more .NET objects. There is no limit to the number of views that can be defined in a formatting file.

Schema

- Configuration Element
- ViewDefinitions Element
- View Element

Syntax

XML

```
<View>
  <Name>Friendly name of view.</Name>
  <OutOfBand />
  <ViewSelectedBy>...</ViewSelectedBy>
  <Controls>...</Controls>
  <GroupBy>...</GroupBy>
  <TableControl>...</TableControl>
  <ListControl>...</ListControl>
  <WideControl>...</WideControl>
  <CustomControl>...</CustomControl>
</View>
```

Attributes and Elements

The following sections describe the attributes, child elements, and the parent element of the `View` element. You must specify one and only one of the control child elements, and you must specify the name of the view and the objects that use the view. Defining custom controls, how to group objects, and specifying if the view is out-of-band are optional.

Attributes

None.

Child Elements

[+] Expand table

Element	Description
Controls Element for View	Optional element. Defines a set of controls that can be referenced by their name from within the view.
CustomControl Element	Optional element. Defines a custom control format for the view.
GroupBy Element for View	Optional element. Defines how the members of the .NET objects are grouped.
ListControl Element	Optional element. Defines a list format for the view.
Name Element for View	Required element. Specifies the name used to reference the view.
OutOfBand	Optional element When OutOfBand is true, the view applies regardless of previous objects that may have selected a different view.
TableControl Element	Optional element. Defines a table format for the view.
ViewSelectedBy Element for View	Required element. Defines the .NET objects that this view displays.
WideControl Element	Optional element. Defines a wide (single value) list format for the view.

Parent Elements

[+] Expand table

Element	Description
ViewDefinitions Element	Defines the views used to display objects.

Remarks

For more information about the components of different views and custom controls, see the following topics:

- [Table View Components](#)
- [List View Components](#)
- [Wide View Components](#)
- [Custom Controls](#)

Example

This example shows a `View` element that defines a table view for the [System.ServiceProcess.ServiceController](#) object.

XML

```
<ViewDefinitions>
  <View>
    <Name>service</Name>
    <ViewSelectedBy>
      <TypeName>System.ServiceProcess.ServiceController</TypeName>
    </ViewSelectedBy>

- CustomControl Element
- CustomEntries Element

Syntax

XML

```
<CustomEntries>
  <CustomEntry>...</CustomEntry>
</CustomEntries>
```

Attributes and Elements

The following sections describe attributes, child elements, and parent elements of the `CustomEntries` element. There is no maximum limit to the number of child elements that can be specified.

Attributes

None.

Child Elements

[+] Expand table

Element	Description
CustomEntry Element for CustomEntries for Controls for View	Required element. Provides a definition of the control.

Parent Elements

[+] Expand table

Element	Description
CustomControl Element for Control for Controls for View	Defines the control used by the view.

Remarks

In most cases, a control has only one definition, which is specified in a single `CustomEntry` element. However, it is possible to provide multiple definitions if you want to use the same control to display different .NET objects. In those cases, you can define a `CustomEntry` element for each object or set of objects.

CustomEntry Element for CustomEntries for Controls for View

Article • 09/17/2021

Provides a definition of the control. This element is used when defining controls that can be used by a view.

Schema

- Configuration Element
- ViewDefinitions Element
- View Element
- Controls Element
- Control Element
- CustomControl Element
- CustomEntries Element
- CustomEntry Element

Syntax

XML

```
<CustomEntry>
  <EntrySelectedBy>...</EntrySelectedBy>
  <CustomItem>...</CustomItem>
</CustomEntry>
```

Attributes and Elements

The following sections describe attributes, child elements, and the parent elements of the `CustomEntry` element.

Attributes

None.

Child Elements

[+] Expand table

Element	Description
EntrySelectedBy Element for CustomEntry for Controls for View	Optional element. Defines the .NET types that use this control definition or the condition that must exist for this definition to be used.
CustomItem Element for CustomEntry for Controls for View	Required element. Defines how the control displays the data.

Parent Elements

[+] Expand table

Element	Description
CustomEntries Element for CustomControl for View	Provides the definitions for the control.

Remarks

CustomItem Element for CustomEntry for Controls for View

Article • 09/17/2021

Defines what data is displayed by the control and how it is displayed. This element is used when defining controls that can be used by a view.

Schema

- Configuration Element
- ViewDefinitions Element
- View Element
- Controls Element
- Control Element
- CustomControl Element
- CustomEntries Element
- CustomEntry Element
- CustomItem Element

Syntax

XML

```
<CustomItem>
  <ExpressionBinding>...</ExpressionBinding>
  <NewLine/>
  <Text>TextToDisplay</Text>
  <Frame>...<Frame>
</CustomItem>
```

Attributes and Elements

The following sections describe attributes, child elements, and the parent element of the `CustomItem` element. For more information, see Remarks.

Attributes

None.

Child Elements

[+] Expand table

Element	Description
ExpressionBinding Element for CustomItem for Controls for View	Optional element. Defines the data that is displayed by the control.
Frame Element for CustomItem for Controls for View	Optional element. Defines how the data is displayed, such as shifting the data to the left or right.
NewLine Element for CustomItem for Controls for View	Optional element. Adds a blank line to the display of the control.
Text Element for CustomItem for Controls for View	Optional element. Adds text, such as parentheses or brackets, to the display of the control.

Parent Elements

[+] Expand table

Element	Description
CustomEntry Element for CustomEntries for Controls for View	Provides a definition of the control.

Remarks

When specifying the child elements of the `CustomItem` element, keep the following in mind:

- The child elements must be added in the following sequence: `ExpressionBinding`, `NewLine`, `Text`, and `Frame`.
- There is no maximum limit to the number of sequences that you can specify.
- In each sequence, there is no maximum limit to the number of `ExpressionBinding` elements that you can use.

ExpressionBinding Element for CustomItem for Controls for View

Article • 09/17/2021

Defines the data that is displayed by the control. This element is used when defining controls that can be used by a view.

Schema

- Configuration Element
- ViewDefinitions Element
- View Element
- Controls Element
- Control Element
- CustomControl Element
- CustomEntries Element
- CustomEntry Element
- CustomItem Element
- ExpressionBinding Element

Syntax

XML

```
<ExpressionBinding>
  <CustomControl>...</CustomControl>
  <CustomControlName>NameofCommonCustomControl</CustomControlName>
  <EnumerateCollection/>
  <ItemSelectionCondition>...</ItemSelectionCondition>
  <PropertyName>Nameof .NetTypeProperty</PropertyName>
  <ScriptBlock>ScriptToEvaluate</ScriptBlock>
</ExpressionBinding>
```

Attributes and Elements

The following sections describe attributes, child elements, and the parent element of the `ExpressionBinding` element.

Attributes

None.

Child Elements

[] [Expand table](#)

Element	Description
CustomControl Element	Optional element. Defines a control that is used by this control.
CustomControlName Element for ExpressionBinding for Controls for View	Optional element. Specifies the name of a common control or a view control.
EnumerateCollection Element for ExpressionBinding for Controls for View	Optional element. Specifies that the elements of collections are displayed.
ItemSelectionCondition Element of ExpressionBinding for Controls for View	Optional element. Defines the condition that must exist for this control to be used.
PropertyName Element for ExpressionBinding for Controls for View	Optional element. Specifies the .NET property whose value is displayed by the control.
ScriptBlock Element for ExpressionBinding for Controls for View	Optional element. Specifies the script whose value is displayed by the control.

Parent Elements

[] [Expand table](#)

Element	Description
CustomItem Element for CustomEntry for Controls for View	Defines what data is displayed by the control and how it is displayed.

EntrySelectedBy Element for CustomEntry for Controls for View

Article • 09/17/2021

Defines the .NET types that use this control definition or the condition that must exist for this definition to be used. This element is used when defining controls that can be used by a view.

Schema

- Configuration Element
- ViewDefinitions Element
- View Element
- Controls Element
- Control Element
- CustomControl Element
- CustomEntries Element
- CustomEntry Element
- EntrySelectedBy Element

Syntax

XML

```
<EntrySelectedBy>
  <TypeName>Nameof.NetType</TypeName>
  <SelectionSetName>NameofSelectionSet</SelectionSetName>
  <SelectionCondition>...</SelectionCondition>
</EntrySelectedBy>
```

Attributes and Elements

The following sections describe attributes, child elements, and parent element of the `EntrySelectedBy` element. You must specify at least one type, selection set, or selection condition for a definition. There is no maximum limit to the number of child elements that you can use.

Attributes

None.

Child Elements

[+] Expand table

Element	Description
SelectionCondition Element for EntrySelectedBy for Controls for View	Optional element. Defines the condition that must exist for this definition to be used.
SelectionSetName Element for EntrySelectedBy for Controls for View	Optional element. Specifies a set of .NET types that use this definition of the control.
TypeName Element for EntrySelectedBy for Controls for View	Optional element. Specifies a .NET type that uses this definition of the control.

Element	Description
CustomEntry Element for CustomEntries for Controls for View	Provides a definition of the control.

Remarks

Selection conditions are used to define a condition that must exist for the definition to be used, such as when an object has a specific property or when a specific property value or script evaluates to `true`. For more information about selection conditions, see [Defining Conditions for when a View Entry or Item is Used](#).

SelectionCondition Element for EntrySelectedBy for Controls for View

Article • 09/17/2021

Defines a condition that must exist for the control definition to be used. This element is used when defining controls that can be used by a view.

Schema

- Configuration Element
- ViewDefinitions Element
- View Element
- Controls Element
- Control Element
- CustomControl Element
- CustomEntries Element
- CustomEntry Element
- EntrySelectedBy Element
- SelectionCondition Element

Syntax

XML

```
<SelectionCondition>
  <TypeName>Nameof.NetType</TypeName>
  <SelectionSetName>NameofSelectionSet</SelectionSetName>
  <PropertyName>.NetTypeProperty</PropertyName>
  <ScriptBlock>ScriptToEvaluate</ScriptBlock>
</SelectionCondition>
```

Attributes and Elements

The following sections describe attributes, child elements, and the parent element of the `SelectionCondition` element.

Attributes

None.

Child Elements

[+] Expand table

Element	Description
PropertyName Element for SelectionCondition for Controls for View	Optional element. Specifies a .NET property that triggers the condition.
ScriptBlock Element for SelectionCondition for Controls for View	Optional element. Specifies the script that triggers the condition.
SelectionSetName Element for SelectionCondition for Controls for View	Optional element. Specifies the set of .NET types that triggers the condition.
TypeName Element for SelectionCondition for Controls for View	Optional element. Specifies a .NET type that triggers the condition.

Parent Elements

[+] Expand table

Element	Description
EntrySelectedBy Element for CustomEntry for Controls for View	Defines the .NET types that use this control definition or the condition that must exist for this definition to be used.

Remarks

When you are defining a selection condition, the following requirements apply:

- The selection condition must specify at least one property name or a script block, but cannot specify both.
- The selection condition can specify any number of .NET types or selection sets, but cannot specify both.

For more information about how to use selection conditions, see [Defining Conditions for when Data is Displayed](#).

PropertyName Element for SelectionCondition for CustomControl for View

Article • 09/17/2021

Specifies the .NET property that triggers the condition. When this property is present or when it evaluates to `true`, the condition is met, and the definition is used. This element is used when defining a custom control view.

Schema

- Configuration Element
- ViewDefinitions Element
- View Element
- CustomControl Element
- CustomEntries Element
- CustomEntry Element
- CustomItem Element
- EntrySelectedBy Element
- SelectionCondition Element
- PropertyName Element

Syntax

XML

```
<PropertyName>.NetTypeProperty</PropertyName>
```

Attributes and Elements

The following sections describe attributes, child elements, and the parent element of the `PropertyName` element.

Attributes

None.

Child Elements

None.

Parent Elements

ScriptBlock Element for SelectionCondition for CustomControl for View

Article • 09/17/2021

Specifies the script that triggers the condition. When this script is evaluated to `true`, the condition is met, and the definition is used. This element is used when defining a custom control view.

Schema

- Configuration Element
- ViewDefinitions Element
- View Element
- CustomControl Element
- CustomEntries Element
- CustomEntry Element
- CustomItem Element
- SelectionCondition Element
- ScriptBlock Element

Syntax

XML

```
<ScriptBlock>ScriptToEvaluate</ScriptBlock>
```

Attributes and Elements

The following sections describe attributes, child elements, and the parent element of the `ScriptBlock` element.

Attributes

None.

Child Elements

None.

Parent Elements

 Expand table

Element	Description
SelectionCondition Element for EntrySelectedBy for CustomControl for View	Defines a condition that must exist for the control definition to be used.

Text Value

Specify the script that is evaluated.

Remarks

The selection condition must specify at least one script or property name to evaluate, but cannot specify both. For more information about how selection conditions can be used, see [Defining Conditions for Displaying Data](#).

SelectionSetName Element for SelectionCondition for Controls for View

Article • 09/17/2021

Specifies the set of .NET types that trigger the condition. When any of the types in this set are present, the condition is met and the object is displayed using this control. This element is used when defining controls that can be used by a view.

Schema

- Configuration Element
- ViewDefinitions Element
- View Element
- Controls Element
- Control Element
- CustomControl Element
- CustomEntries Element
- CustomEntry Element
- EntrySelectedBy Element
- SelectionCondition Element
- SelectionSetName Element

Syntax

XML

```
<SelectionSetName>NameofSelectionSet</SelectionSetName>
```

Attributes and Elements

The following sections describe attributes, child elements, and the parent element of the `SelectionSetName` element.

Attributes

None.

Child Elements

None.

Parent Elements

 Expand table

Element	Description
SelectionCondition Element for EntrySelectedBy for Controls for View	Defines a condition that must exist for the control definition to be used.

Text Value

Specify the name of the selection set.

Remarks

Selection sets are common groups of .NET objects that can be used by any view that the formatting file defines. For more information about creating and referencing selection sets, see [Defining Selection Sets](#).

The selection condition can specify a selection set or .NET type, but cannot specify both. For more information about how to use selection conditions, see [Defining Conditions for Displaying Data](#).

Frame Element for CustomItem for CustomControl for View

Article • 09/17/2021

Defines how the data is displayed, such as shifting the data to the left or right. This element is used when defining a custom control view.

Schema

- Configuration Element
- ViewDefinitions Element
- View Element
- CustomControl Element
- CustomEntries Element
- CustomEntry Element
- CustomItem Element
- Frame Element

Syntax

XML

```
<Frame>
  <LeftIndent>NumberOfCharactersToShift</LeftIndent>
  <RightIndent>NumberOfCharactersToShift</RightIndent>
  <FirstLineHanging>NumberOfCharactersToShift</FirstLineHanging>
  <FirstLineIndent>NumberOfCharactersToShift</FirstLineIndent>
  <CustomItem>...</CustomItem>
</Frame>
```

Attributes and Elements

The following sections describe attributes, child elements, and the parent element of the `Frame` element.

Attributes

None.

Child Elements

 Expand table

Element	Description
CustomItem Element	Required Element
FirstLineHanging Element	<p>Optional element.</p> <p>Specifies how many characters the first line of data is shifted to the left.</p>
FirstLineIndent Element	<p>Optional element.</p> <p>Specifies how many characters the first line of data is shifted to the right.</p>
LeftIndent Element	<p>Optional element.</p> <p>Specifies how many characters the data is shifted away from the left margin.</p>
RightIndent Element	<p>Optional element.</p> <p>Specifies how many characters the data is shifted away from the right margin.</p>

EntrySelectedBy Element for CustomEntry for CustomControl for View

Article • 09/17/2021

Defines the .NET types that use this custom entry or the condition that must exist for this entry to be used.

Schema

- Configuration Element
- ViewDefinitions Element
- View Element
- CustomControl Element
- CustomEntries Element
- CustomEntry Element
- EntrySelectedBy Element

Syntax

XML

```
<EntrySelectedBy>
  <TypeName>Nameof.NetType</TypeName>
  <SelectionSetName>NameofSelectionSet</SelectionSetName>
  <SelectionCondition>...</SelectionCondition>
</EntrySelectedBy>
```

Attributes and Elements

The following sections describe attributes, child elements, and the parent element of the `EntrySelectedBy` element.

Attributes

None.

Child Elements

[+] Expand table

Element	Description
SelectionCondition Element for EntrySelectedBy for CustomEntry	Optional element. Defines the condition that must exist for this definition to be used.
SelectionSetName Element for EntrySelectedBy for CustomEntry	Optional element. Specifies a set of .NET types that use this definition of the control view.
TypeName Element for EntrySelectedBy for CustomEntry	Optional element. Specifies a .NET type that uses this definition of the control view.

Parent Elements

[+] Expand table

Element	Description
CustomEntry Element for CustomEntries for View	Defines the controls used by specific .NET objects.

Remarks

You must specify at least one type, selection set, or selection condition for an entry. There is no maximum limit to the number of child elements that you can use.

Selection conditions are used to define a condition that must exist for the entry to be used, such as when an object has a specific property or when a specific property value or script evaluates to `true`. For more information about selection conditions, see [Defining Conditions for when a View Entry or Item is Used](#).

For more information about the components of a custom control view, see [Custom Control View](#).

SelectionCondition Element for EntrySelectedBy for CustomControl

Article • 02/06/2023

Defines a condition that must exist for a control definition to be used. This element is used when defining a custom control view.

- Configuration Element
- ViewDefinitions Element
- View Element
- CustomControl Element
- CustomEntries Element
- CustomEntry Element
- CustomItem Element
- EntrySelectedBy Element
- SelectionCondition Element

Syntax

XML

```
<SelectionCondition>
  <TypeName>Nameof.NetType</TypeName>
  <SelectionSetName>NameofSelectionSet</SelectionSetName>
  <PropertyName>.NetTypeProperty</PropertyName>
  <ScriptBlock>ScriptToEvaluate</ScriptBlock>
</SelectionCondition>
```

Attributes and Elements

The following sections describe attributes, child elements, and the parent element of the `SelectionCondition` element.

Attributes

None.

Child Elements

[+] Expand table

Element	Description
PropertyName Element for SelectionCondition for CustomControl for View	Optional element. Specifies a .NET property that triggers the condition.
ScriptBlock Element for SelectionCondition for CustomControl for View	Optional element. Specifies the script that triggers the condition.
SelectionSetName Element for SelectionCondition for Custom Control for View	Optional element. Specifies the set of .NET types that triggers the condition.
TypeName Element for SelectionCondition for CustomControl for View	Optional element. Specifies a .NET type that triggers the condition.

Parent Elements

[+] Expand table

Element	Description
EntrySelectedBy Element for CustomEntry for CustomControl for View	Defines the .NET types that use this control definition or the condition that must exist for this definition to be used.

Remarks

When you are defining a selection condition, the following requirements apply:

- The selection condition must specify at least one property name or a script block, but cannot specify both.
- The selection condition can specify any number of .NET types or selection sets, but cannot specify both.

For more information about how to use selection conditions, see [Defining Conditions for when Data is Displayed](#).

SelectionSetName Element for EntrySelectedBy for CustomControl for View

Article • 09/17/2021

Specifies a set of .NET objects for the list entry. There is no limit to the number of selection sets that can be specified for an entry.

Schema

- Configuration Element
- ViewDefinitions Element
- View Element
- CustomControl Element
- CustomEntries Element
- CustomEntry Element
- EntrySelectedBy Element
- SelectionSetName Element

Syntax

XML

```
<SelectionSetName>NameofSelectionSet</SelectionSetName>
```

Attributes and Elements

The following sections describe attributes, child elements, and the parent element of the `SelectionSetName` element.

Attributes

None.

Child Elements

None.

Parent Elements

 Expand table

Element	Description
EntrySelectedBy Element for CustomEntry for View	Defines the .NET types that use this custom entry or the condition that must exist for this entry to be used.

Text Value

Specify the name of the selection set.

Remarks

Each custom control entry must have at least one type name, selection set, or selection condition defined.

Selection sets are typically used when you want to define a group of objects that are used in multiple views. For example, you might want to create a table view and a list view for the same set of objects. For more information about defining selection sets, see [Defining Selection Sets](#).

For more information about the components of a custom control view, see [Creating Custom Controls](#).

GroupBy Element for View

Article • 09/17/2021

Defines how a new group of objects is displayed. This element is used when defining a table, list, wide, or custom control view.

Schema

- Configuration Element
- ViewDefinitions Element
- View Element
- GroupBy Element

Syntax

XML

```
<GroupBy>
  <PropertyName>.NetTypeProperty</PropertyName>
  <ScriptBlock>ScriptToEvaluate</ScriptBlock>
  <Label>TextToDisplay</Label>
  <CustomControl>...</CustomControl>
  <CustomControlName>NameOfControl</CustomControlName>
</GroupBy>
```

Attributes and Elements

The following sections describe attributes, child elements, and parent elements.

Attributes

None.

Child Elements

[+] Expand table

Element	Description
CustomControl Element for GroupBy	Optional element. Defines the custom control that displays new groups.
CustomControlName Element for GroupBy	Optional element. Specifies the name of a control that is used to display the new group.
Label Element for GroupBy	Optional element. Specifies a label that is displayed when a new group is encountered.
PropertyName Element for GroupBy	Optional element. Specifies the .NET property that starts a new group whenever its value changes.
ScriptBlock Element for GroupBy	Optional element. Specifies the script that starts a new group whenever its value changes.

Parent Elements

[View Element](#) Expand table

Element	Description
View Element	Defines a view that displays one or more .NET objects.

Remarks

When defining how a new group of objects is displayed, you must specify the property or script that will start the new group; however, you cannot specify both.

CustomEntries Element for CustomControl for GroupBy

Article • 09/17/2021

Provides the definitions for the control. This element is used when defining how a new group of objects is displayed.

Schema

- Configuration Element
- ViewDefinitions Element
- View Element
- GroupBy Element
- CustomControl Element
- CustomEntries Element

Syntax

XML

```
<CustomEntries>
  <CustomEntry>...</CustomEntry>
</CustomEntries>
```

Attributes and Elements

The following sections describe attributes, child elements, and parent elements of the `CustomEntries` element. There is no maximum limit to the number of child elements that can be specified.

Attributes

None.

Child Elements

[+] Expand table

Element	Description
CustomEntry Element for CustomControl for GroupBy	Required element. Provides a definition of the control.

Parent Elements

[\[+\] Expand table](#)

Element	Description
CustomControl Element for GroupBy	Defines the custom control that displays the new group.

Remarks

In most cases, a control has only one definition, which is specified in a single `CustomEntry` element. However, it is possible to provide multiple definitions if you want to use the same control to display different groups. In those cases, you can define a `CustomEntry` element for a group.

SelectionCondition Element for EntrySelectedBy for GroupBy

Article • 09/17/2021

Defines a condition that must exist for a control definition to be used. This element is used when defining how a new group of objects is displayed.

Schema

- Configuration Element
- ViewDefinitions Element
- View Element
- GroupBy Element for View
- CustomControl Element
- CustomEntries Element
- CustomEntry Element
- EntrySelectedBy Element
- SelectionCondition Element

Syntax

XML

```
<SelectionCondition>
  <TypeName>Nameof.NetType</TypeName>
  <SelectionSetName>NameofSelectionSet</SelectionSetName>
  <PropertyName>.NetTypeProperty</PropertyName>
  <ScriptBlock>ScriptToEvaluate</ScriptBlock>
</SelectionCondition>
```

Attributes and Elements

The following sections describe attributes, child elements, and the parent element of the `SelectionCondition` element.

Attributes

None.

Child Elements

[+] Expand table

Element	Description
PropertyName Element for SelectionCondition for GroupBy	Optional element. Specifies a .NET property that triggers the condition.
ScriptBlock Element for SelectionCondition for GroupBy	Optional element. Specifies the script that triggers the condition.
SelectionSetName Element for SelectionCondition for GroupBy	Optional element. Specifies the set of .NET types that triggers the condition.
TypeName Element for SelectionCondition for GroupBy	Optional element. Specifies a .NET type that triggers the condition.

Parent Elements

[+] Expand table

Element	Description
EntrySelectedBy Element for CustomEntry for GroupBy	Defines the .NET types that use this control definition or the condition that must exist for this definition to be used.

Remarks

When you are defining a selection condition, the following requirements apply:

- The selection condition must specify at least one property name or a script block, but cannot specify both.
- The selection condition can specify any number of .NET types or selection sets, but cannot specify

both. For more information about how to use selection conditions, see [Defining Conditions for when Data is Displayed](#).

PropertyName Element for SelectionCondition for GroupBy

Article • 09/17/2021

Specifies the .NET property that triggers the condition. When this property is present or when it evaluates to `true`, the condition is met, and the definition is used. This element is used when defining how a new group of objects is displayed.

Schema

- Configuration Element
- ViewDefinitions Element
- View Element
- GroupBy Element
- CustomControl Element
- CustomEntries Element
- CustomEntry Element
- EntrySelectedBy Element
- SelectionCondition Element
- PropertyName Element

Syntax

XML

```
<PropertyName>.NetTypeProperty</PropertyName>
```

Attributes and Elements

The following sections describe attributes, child elements, and the parent element of the `PropertyName` element.

Attributes

None.

Child Elements

None.

Parent Elements

 Expand table

Element	Description
SelectionCondition Element for EntrySelectedBy for GroupBy	Defines a condition that must exist for the control definition to be used.

Text Value

Specify the .NET property name.

Remarks

The selection condition must specify at least one property name or a script, but cannot specify both. For more information about how selection conditions can be used, see [Defining Conditions for Displaying Data](#).

ScriptBlock Element for SelectionCondition for EntrySelectedBy for GroupBy

Article • 09/17/2021

Specifies the script that triggers the condition. When this script is evaluated to `true`, the condition is met, and the definition is used. This element is used when defining how a new group of objects is displayed.

Schema

- Configuration Element
- ViewDefinitions Element
- View Element
- GroupBy Element
- CustomControl Element
- CustomEntries Element
- CustomEntry Element
- EntrySelectedBy Element
- SelectionCondition Element
- ScriptBlock Element

Syntax

XML

```
<ScriptBlock>ScriptToEvaluate</ScriptBlock>
```

Attributes and Elements

The following sections describe attributes, child elements, and the parent element of the `ScriptBlock` element.

Attributes

None.

Child Elements

None.

Parent Elements

 Expand table

Element	Description
SelectionCondition Element for EntrySelectedBy for GroupBy	Defines a condition that must exist for the control definition to be used.

Text Value

Specify the script that is evaluated.

Remarks

The selection condition must specify at least one script or property name to evaluate, but cannot specify both. For more information about how selection conditions can be used, see [Defining Conditions for Displaying Data](#).

SelectionSetName Element for SelectionCondition for GroupBy

Article • 09/17/2021

Specifies the set of .NET types that trigger the condition. When any of the types in this set are present, the condition is met, and the object is displayed by using this control. This element is used when defining how a new group of objects is displayed.

Schema

- Configuration Element
- ViewDefinitions Element
- View Element
- GroupBy Element
- CustomControl Element
- CustomEntries Element
- CustomEntry Element
- EntrySelectedBy Element
- SelectionCondition Element
- SelectionSetName Element

Syntax

XML

```
<SelectionSetName>NameofSelectionSet</SelectionSetName>
```

Attributes and Elements

The following sections describe attributes, child elements, and the parent element of the `SelectionSetName` element.

Attributes

None.

Child Elements

None.

Parent Elements

 Expand table

Element	Description
SelectionCondition Element for EntrySelectedBy for GroupBy	Defines a condition that must exist for the control definition to be used.

Text Value

Specify the name of the selection set.

Remarks

Selection sets are common groups of .NET objects that can be used by any view that the formatting file defines. For more information about creating and referencing selection sets, see [Defining Selection Sets](#).

When this element is specified, you cannot specify the [TypeName](#) element. For more information about defining selection conditions, see [Defining Conditions for Displaying Data](#).

SelectionSetName Element for EntrySelectedBy for GroupBy

Article • 09/17/2021

Specifies a set of .NET objects for the list entry. There is no limit to the number of selection sets that can be specified for an entry. This element is used when defining how a new group of objects is displayed.

Schema

- Configuration Element
- ViewDefinitions Element
- View Element
- GroupBy Element
- CustomControl Element
- CustomEntries Element
- CustomEntry Element
- EntrySelectedBy Element
- SelectionSetName Element

Syntax

XML

```
<SelectionSetName>NameofSelectionSet</SelectionSetName>
```

Attributes and Elements

The following sections describe attributes, child elements, and the parent element of the `SelectionSetName` element.

Attributes

None.

Child Elements

None.

Parent Elements

 Expand table

Element	Description
EntrySelectedBy Element for CustomEntry for GroupBy	Defines the .NET types that use this custom entry or the condition that must exist for this entry to be used.

Text Value

Specify the name of the selection set.

Remarks

Each custom control definition must have at least one type name, selection set, or selection condition defined.

Selection sets are typically used when you want to define a group of objects that are used in multiple views. For example, you may want to create a table view and a list view for the same set of objects. For more information about defining selection sets, see [Defining Selection Sets](#).

For more information about the components of a custom control view, see [Creating Custom Controls](#).

CustomControlName Element for GroupBy

Article • 09/17/2021

Specifies the name of a custom control that is used to display the new group. This element is used when defining a table, list, wide or custom control view.

Schema

- Configuration Element
- ViewDefinitions Element
- View Element
- GroupBy Element
- CustomControlName Element

Syntax

XML

```
<CustomControlName>ControlName</CustomControlName>
```

Attributes and Elements

The following sections describe the attributes, child elements, and parent elements of the `CustomControlName` element.

Attributes

None.

Child Elements

None.

Parent Elements

Element	Description
GroupBy Element for View	Defines how Windows PowerShell displays a new group of objects.

Text Value

Specify the name of the custom control that is used to display a new group.

Remarks

You can create common controls that can be used by all the views of a formatting file, and you can create view controls that can be used by a specific view. The following elements specify the names of these custom controls:

- [Name Element for Control for Controls for Configuration](#)
- [Name Element for Control for Controls for View](#)

Label Element for GroupBy

Article • 09/17/2021

Specifies a label that is displayed when a new group is encountered.

Schema

- Configuration Element
- ViewDefinitions Element
- View Element
- GroupBy Element
- Label Element

Syntax

XML

```
<Label>DisplayedLabel</Label>
```

Attributes and Elements

The following sections describe the attributes, child elements, and parent element of the `Label` element.

Attributes

None.

Child Elements

None.

Parent Elements

[+] Expand table

Element	Description
GroupBy Element for View	Defines how a new group of objects is displayed.

Text Value

Specify the text that is displayed whenever Windows PowerShell encounters a new property or script value.

Remarks

In addition to the text specified by this element, Windows PowerShell displays the new value that starts the group, and adds a blank line before and after the group.

Example

The following example shows the label for a new group. The displayed label would look similar to this: `Service Type: NewValueofProperty`

XML

```
<GroupBy>
  <Label>Service Type</Label>
  <PropertyName>ServiceType</PropertyName>
</GroupBy>
```

For an example of a complete formatting file that includes this element, see [Wide View \(GroupBy\)](#).

ListEntry Element

Article • 09/17/2021

Provides a definition of the list view.

- Configuration Element
- ViewDefinitions Element
- View Element
- ListControl Element
- ListEntries Element
- ListEntry Element

Syntax

XML

```
<ListEntry>
  <EntrySelectedBy>...</EntrySelectedBy>
  <ListItems>...</ListItems>
</ListEntry>
```

Attributes and Elements

The following sections describe the attributes, child elements, and the parent element of the `ListEntry` element.

Attributes

None.

Child Elements

[+] Expand table

Element	Description
<code>EntrySelectedBy</code> Element for <code>ListEntry</code>	Optional element. Defines the .NET objects that use this list view definition or the condition that must exist for this definition to be used.

Element	Description
ListItems Element	<p>Required element.</p> <p>Defines the properties and scripts whose values are displayed by the list view.</p>

Parent Elements

[+] Expand table

Element	Description
ListEntries Element	Provides the definitions of the list view.

Remarks

A list view is a list format that displays property values or script values for each object. For more information about list views, see [Creating a List View](#).

Example

This example shows the XML elements that define the list view for the [System.ServiceProcess.ServiceController](#) object.

XML

```
<View>
  <Name>System.ServiceProcess.ServiceController</Name>
  <ViewSelectedBy>
    <TypeName>System.ServiceProcess.ServiceController</TypeName>
  </ViewSelectedBy>
  <ListControl>
    <ListEntries>
      <ListEntry>
        <ListItems>...</ListItems>
      </ListEntry>
    </ListEntries>
  </ListControl>
</View>
```

EntrySelectedBy Element for ListEntry

Article • 09/17/2021

Defines the .NET types that use this list view definition or the condition that must exist for this definition to be used. In most cases only one definition is needed for a list view. However, you can provide multiple definitions for the list view if you want to use the same list view to display different data for different objects.

Schema

- Configuration Element
- ViewDefinitions Element
- View Element
- ListControl Element
- ListEntries Element
- ListEntry Element
- EntrySelectedBy Element

Syntax

XML

```
<EntrySelectedBy>
  <TypeName>Nameof.NetType</TypeName>
  <SelectionSetName>NameofSelectionSet</SelectionSetName>
  <SelectionCondition>...</SelectionCondition>
</EntrySelectedBy>
```

Attributes and Elements

The following sections describe the attributes, child elements, and the parent element of the `EntrySelectedBy` element.

Attributes

None.

Child Elements

[+] Expand table

Element	Description
SelectionCondition Element for EntrySelectedBy for ListControl	Optional element. Defines the condition that must exist for this list view definition to be used.
SelectionSetName Element for EntrySelectedBy for ListControl	Optional element. Specifies a set of .NET types that use this list view definition.
TypeName Element for EntrySelectedBy for ListControl	Optional element. Specifies a .NET type that uses this list view definition.

Parent Elements

[+] Expand table

Element	Description
ListEntry Element for ListControl	Defines how the rows of the list are displayed.

Remarks

You must specify at least one type, selection set, or selection condition for a list view definition. There is no maximum limit to the number of child elements that you can use.

Selection conditions are used to define a condition that must exist for the definition to be used, such as when an object has a specific property or that a specific property value or script evaluates to `true`. For more information about selection conditions, see [Defining Conditions for when Data is displayed](#).

For more information about the components of a list view, see [Creating a List View](#).

Example

The following example shows how to define the objects for a list view using their .NET type name.

XML

```
<ListEntry>
  <EntrySelectedBy>
    <TypeName>NameofDotNetType</TypeName>
  </EntrySelectedBy>
</ListEntry>
```

SelectionCondition Element for EntrySelectedBy for ListControl

Article • 09/17/2021

Defines the condition that must exist to use this definition of the list view. There is no limit to the number of selection conditions that can be specified for a list definition.

Schema

- Configuration Element
- ViewDefinitions Element
- View Element
- ListControl Element
- ListEntries Element
- ListEntry Element
- EntrySelectedBy Element
- SelectionCondition Element

Syntax

XML

```
<SelectionCondition>
  <TypeName>Nameof.NetType</TypeName>
  <SelectionSetName>NameofSelectionSet</SelectionSetName>
  <PropertyName>.NetTypeProperty</PropertyName>
  <ScriptBlock>ScriptToEvaluate</ScriptBlock>
</SelectionCondition>
```

Attributes and Elements

The following sections describe attributes, child elements, and the parent element of the `SelectionCondition` element.

Attributes

None.

Child Elements

[+] Expand table

Element	Description
PropertyName Element for SelectionCondition for EntrySelectedBy for ListEntry	Optional element. Specifies the .NET property that triggers the condition.
ScriptBlock Element for SelectionCondition for EntrySelectedBy for ListEntry	Optional element. Specifies the script that triggers the condition.
SelectionSetName Element for SelectionCondition for EntrySelectedBy for ListEntry	Optional element. Specifies the set of .NET types that trigger the condition.
TypeName Element for SelectionCondition for EntrySelectedBy for ListEntry	Optional element. Specifies a .NET type that triggers the condition.

Parent Elements

[+] Expand table

Element	Description
EntrySelectedBy Element for TableRowEntry	Defines the .NET types that use this table entry or the condition that must exist for this entry to be used.

Remarks

When you are defining a selection condition, the following requirements apply:

- The selection condition must specify at least one property name or a script block, but cannot specify both.
- The selection condition can specify any number of .NET types or selection sets, but cannot specify both.

For more information about how to use selection conditions, see [Defining Conditions for when Data is Displayed](#).

For more information about other components of a list view, see [Creating a List View](#).

SelectionSetName Element for SelectionCondition for EntrySelectedBy for ListEntry

Article • 09/17/2021

Specifies the set of .NET types that trigger the condition. When any of the types in this set are present, the condition is met, and the object is displayed by using this definition of the list view.

Schema

- Configuration Element
- ViewDefinitions Element
- View Element
- ListControl Element
- ListEntries Element
- ListEntry Element
- EntrySelectedBy Element
- SelectionCondition Element
- SelectionSetName Element

Syntax

XML

```
<SelectionSetName>NameofSelectionSet</SelectionSetName>
```

Attributes and Elements

The following sections describe attributes, child elements, and the parent element of the `SelectionSetName` element.

Attributes

None.

Child Elements

None.

Parent Elements

 Expand table

Element	Description
SelectionCondition Element for EntrySelectedBy for ListEntry	Defines the condition that must exist to use this definition of the list view.

Text Value

Specify the name of the selection set.

Remarks

The selection condition can specify a selection set or .NET type, but cannot specify both. For more information about how to use selection conditions, see [Defining Conditions for when Data is Displayed](#).

Selection sets are common groups of .NET objects that can be used by any view that the formatting file defines. For more information about creating and referencing selection sets, see [Defining Sets of Objects](#).

For more information about other components of a list view, see [Creating a List View](#).

SelectionSetName Element for EntrySelectedBy for ListControl

Article • 09/17/2021

Specifies a set of .NET objects for the list entry. There is no limit to the number of selection sets that can be specified for an entry.

Schema

- Configuration Element
- ViewDefinitions Element
- View Element
- ListControl Element
- ListEntries Element
- ListEntry Element
- EntrySelectedBy Element
- SelectionSetName Element

Syntax

XML

```
<SelectionSetName>NameofSelectionSet</SelectionSetName>
```

Attributes and Elements

The following sections describe attributes, child elements, and parent element of the `SelectionSetName` element.

Attributes

None.

Child Elements

None.

Parent Elements

 Expand table

Element	Description
EntrySelectedBy Element for ListEntry	Defines the .NET types that use this list entry or the condition that must exist for this entry to be used.

Text Value

Specify the name of the selection set.

Remarks

Each list entry must have at least one type name, selection set, or selection condition defined.

Selection sets are typically used when you want to define a group of objects that are used in multiple views. For example, you might want to create a table view and a list view for the same set of objects. For more information about defining selection sets, see [Defining Sets of objects for a View](#).

For more information about the components of a list view, see [Creating a List View](#).

Example

The following example shows how to specify a selection set for an entry of a list view.

XML

```
<ListEntry>
  <EntrySelectedBy>
    <SelectionSetName>NameofSelectionSet</SelectionSetName>
  </EntrySelectedBy>
  <ListItems>...</ListItems>
</ListEntry>
```

ListItems Element

Article • 09/17/2021

Defines the properties and scripts whose values are displayed in the rows of the list view.

- Configuration Element
- ViewDefinitions Element
- View Element
- ListControl Element
- ListEntries Element
- ListEntry Element
- ListItems Element

Syntax

XML

```
<ListItems>
  <ListItem>...</ListItem>
</ListItems>
```

Attributes and Elements

The following sections describe the attributes, child elements, and parent element of the `ListItems` element. There is no limit to the number of child elements that can be specified. The order of the child elements defines the order that values are displayed in the list view.

Attributes

None.

Child Elements

[+] Expand table

Element	Description
ListItem Element for ListControl	Required element. Defines the property or script whose value is displayed by the list view.

Parent Elements

[\[+\] Expand table](#)

Element	Description
ListEntry Element for ListControl	Provides a definition of the list view.

Remarks

For more information about this type of view, see [Creating a List View](#).

Example

This example shows the XML elements that define three rows of the list view.

XML

```
<ListEntry>
  <ListItems>
    <ListItem>
      <Label>Property1: </Label>
      <PropertyName>.NetTypeProperty1</PropertyName>
    </ListItem>
    <ListItem>
      <PropertyName>.NetTypeProperty2</PropertyName>
    </ListItem>
    <ListItem>
      <ScriptBlock>$_.ProcessName + ":" $_.Id</ScriptBlock>
    </ListItem>
  </ListItems>
</ListEntry>
```

FormatString Element for ListItem for ListControl

Article • 01/18/2022

Specifies a format pattern that defines how the property or script value is displayed.

Schema

- Configuration Element
- ViewDefinitions Element
- View Element
- ListControl Element
- ListEntries Element
- ListEntry Element
- ListItems Element
- ListItem Element
- FormatString Element

Syntax

XML

```
<FormatString>PropertyPattern</FormatString>
```

Attributes and Elements

The following sections describe the attributes, child elements, and the parent element of the `FormatString` element.

Attributes

None.

Child Elements

None.

Parent Elements

[+] Expand table

Element	Description
ListItem Element	Defines the property or script whose value is displayed in a row of the list view.

Text Value

Specify the pattern that is used to format the data. For example, you can use this pattern to format the value of any property that is of type [System.TimeSpan](#): {0:MMM}{0:dd}{0:HH}:{0:mm}.

Remarks

Format strings can be used when creating table views, list views, wide views, or custom views. For more information about formatting a value displayed in a view, see [Formatting Displayed Data](#).

For more information about using format strings in list views, see [Creating List View](#).

Example

The following example shows how to define a formatting string for the value of the `StartTime` property.

XML

```
<ListItem>
  <PropertyName>StartTime</PropertyName>
  <FormatString>{0:MMM} {0:DD} {0:HH}:{0:MM}</FormatString>
</ListItem>
```

Name Element for View

Article • 03/24/2025

Specifies the name that is used to identify the view.

Schema

- Configuration Element
- ViewDefinitions Element
- View Element
- Name Element

Syntax

XML

```
<Name>ViewName</Name>
```

Attributes and Elements

The following sections describe attributes, child elements, and the parent element of the `Name` element. Only one `Name` element is allowed for each view.

Attributes

None.

Child Elements

None.

Parent Elements

[+] Expand table

Element	Description
View Element	Defines a view that is used to display the members of one or more .NET objects.

Text Value

Specify a unique friendly name for the view. This name can include a reference to the type of the view (such as a table view or list view), which object or set of objects use the view, what command returns the objects, or a combination of these.

Remarks

For more information about the different types of views, see the following topics: [Table View](#), [List View](#), [Wide View](#), and [Custom View](#).

Example

The following example shows a `View` element that defines a table view for the `System.ServiceProcess.ServiceController` object. The name of the view is "service".

```
XML

<View>
  <Name>service</Name>
  <ViewSelectedBy>
    <TypeName>System.ServiceProcess.ServiceController</TypeName>
  </ViewSelectedBy>
  <TableControl>...</TableControl>
</View>
```

OutOfBand Element

Article • 09/17/2021

In a pipeline, the first object emitted is chosen as the type to format the output of the pipeline. PowerShell attempts to format subsequent objects using the same view. If the object does not fit the view, it is not displayed. You can create OutOfBand views that can be used to format these other types.

Schema

- Configuration Element
- ViewDefinitions Element
- View Element
- OutOfBand Element

Syntax

XML

```
<OutOfBand/>
```

Attributes and Elements

The following sections describe attributes, child elements, and the parent element of the `OutOfBand` element.

Attributes

None.

Child Elements

None.

Parent Elements

[] Expand table

Element	Description
View Element	Defines a view that displays one or more .NET objects.

Remarks

When the "shape" of formatting (view) has been determined by previous objects, you may want objects of different types to continue using that shape (table, list, or whatever) even if they specify their own views. Or sometimes you want your view to take over. When `OutOfBand` is true, the view applies regardless of previous objects that may have selected a different view.

TableControl Element

Article • 09/17/2021

Defines a table format for a view.

Schema

- ViewDefinitions Element
- View Element
- TableControl Element

Syntax

XML

```
<TableControl>
  <AutoSize/>
  <HideTableHeaders/>
  <TableHeaders>...</TableHeaders>
  <TableRowEntries>...</TableRowEntries>
</TableControl>
```

Attributes and Elements

The following sections describe attributes, child elements, and parent element of the `TableControl` element. You must specify the rows of the table. All other child elements are optional.

Attributes

None.

Child Elements

[+] Expand table

Element	Description
AutoSize Element for TableControl	Optional element. Specifies whether the column size and the number of columns are adjusted based on the size of the data.
HideTableHeaders Element for TableControl	Optional element. Indicates whether the header of the table is not displayed.
TableHeaders Element for TableControl	Required element. Defines the labels, the widths, and the alignment of the data for the columns of the table view.
TableRowEntries Element for TableControl	Optional element. Provides the definitions of the table view.

Parent Elements

[\[\] Expand table](#)

Element	Description
View Element	Defines a view that is used to display the members of one or more objects.

Remarks

For more information about the components of a table view, see [Creating a Table View](#).

Example

This example shows a `TableControl` element that is used to display the properties of the `System.ServiceProcess.ServiceController` object.

XML

```
<View>
  <Name>service</Name>
  <ViewSelectedBy>
    <TypeName>System.ServiceProcess.ServiceController</TypeName>
  </ViewSelectedBy>
  <TableControl>
```

```
<TableHeaders>...</TableHeaders>
<TableRowEntries>...</TableRowEntries>
</TableControl>
</View>
```

AutoSize Element for TableControl

Article • 09/17/2021

Specifies whether the column size and the number of columns are adjusted based on the size of the data.

Schema

- Configuration Element
- ViewDefinitions Element
- View Element
- TableControl Element
- AutoSize Element

Syntax

XML

```
<AutoSize/>
```

Attributes and Elements

The following sections describe attributes, child elements, and the parent element of the `AutoSize` element.

Attributes

None.

Child Elements

None.

Parent Elements

 Expand table

Element	Description
TableControl Element	Defines a table format for a view.

Remarks

For more information about the components of a table view, see [Creating a Table View](#).

HideTableHeaders Element

Article • 09/17/2021

Specifies that the headers of the table are not displayed.

Schema

- ViewDefinitions Element
- View Element
- TableControl Element
- HideTableHeaders Element

Syntax

VB

```
<HideTableHeaders/>
```

Attributes and Elements

The following sections describe the attributes, child elements, and parent element of the `HideTableHeaders` element.

Attributes

None.

Child Elements

None.

Parent Elements

 Expand table

Element	Description
TableControl Element	Defines a table format for a view.

Text Value

Specify `true` to hide the headers of the table.

Remarks

For more information about the components of a table view, see [Creating a Table View](#).

TableHeaders Element

Article • 09/17/2021

Defines the headers for the columns of a table.

Schema

- ViewDefinitions Element
- View Element
- TableControl Element
- TableHeaders Element for TableControl

Syntax

XML

```
<TableHeaders>
  <TableColumnHeader>...</TableColumnHeader>
</TableHeaders>
```

Attributes and Elements

The following sections describe the attributes, child elements, and parent elements of the `TableHeaders` element. There must be a child element for each property of the object that is to be displayed. The column header information is displayed in the order that the child elements are specified.

Attributes

None.

Child Elements

[+] Expand table

Element	Description
TableColumnHeader Element	Defines the label, the width, and the alignment of the data for a column of a table view.

Parent Elements

[\[+\] Expand table](#)

Element	Description
TableControl Element	Defines a table format for a view.

Remarks

For more information about the components of a table view, see [Creating a Table View](#).

Example

This example shows a `TableHeaders` element that defines two column headers.

XML
<pre><TableHeaders> <TableColumnHeader> <Label>Column 1</Label> <Width>16</Width> <Alignment>Left</Alignment> </TableColumnHeader> <TableColumnHeader> <Label>Column 2</Label> <Width>10</Width> <Alignment>Centered</Alignment> </TableColumnHeader> </TableHeaders></pre>

[TableColumnHeader Element](#)

TableControl Element

Writing a PowerShell Formatting File

TableColumnHeader Element

Article • 09/17/2021

Defines the label, the width of the column, and the alignment of the label for a column of the table.

Schema

- Configuration Element
- ViewDefinitions Element
- View Element
- TableControl Element
- TableHeaders Element
- TableColumnHeader Element

Syntax

XML

```
<TableColumnHeader>
  <Label>DisplayedLabel</Label>
  <Width>NumberOfCharacters</Width>
  <Alignment>Left, Right, or Centered</Alignment>
</TableColumnHeader>
```

Attributes and Elements

The following sections describe attributes, child elements, and the parent element of the `TableColumnHeader` element.

Attributes

None.

Child Elements

 Expand table

Element	Description
Label Element For TableColumnHeader for TableControl	Optional element. Defines the label that is displayed at the top of the column. If no label is specified, the name of the property whose value is displayed in the rows is used.
Width Element for TableColumnHeader for TableControl	Required element. Specifies the width (in characters) of the column.
Alignment Element for TableColumnHeader for TableControl	Optional element. Specifies how the label of the column is displayed. If no alignment is specified, the label is aligned on the left.

Parent Elements

[\[\] Expand table](#)

Element	Description
TableHeaders Element	Defines the columns of a table view.

Remarks

Specify a header for each column of the table. The columns are displayed in the order in which the `TableColumnHeader` elements are defined.

A table must have the same number of `TableColumnHeader` elements as `TableRowEntry` elements. The column header defines how the text at the top of the table is displayed. The row entries define what data is displayed in the rows of the table.

For more information about the components of a table view, see [Table View](#).

Example

The following example shows two `TableColumnHeader` elements. The first element defines a column whose label is "Column 1", has a width of 16 characters, and whose label is aligned on the left. The second element defines a column whose label is "Column 2", has a width of 10 characters, and whose label is centered in the column.

XML

```
<TableHeaders>
  <TableColumnHeader>
    <Label>Column 1</Label>
    <Width>16</Width>
    <Alignment>Left</Alignment>
  </TableColumnHeader>
  <TableColumnHeader>
    <Label>Column 2</Label>
    <Width>10</Width>
    <Alignment>Centered</Alignment>
  </TableColumnHeader>
</TableHeaders>
```

Alignment Element for TableColumnHeader

Article • 09/17/2021

Defines how the data in a column header is displayed.

Schema

- Configuration Element
- ViewDefinitions Element
- View Element
- TableControl Element
- TableHeaders Element
- TableColumnHeader Element
- Alignment Element

Syntax

XML

```
<Alignment>AlignmentType</Alignment>
```

Attributes and Elements

The following sections describe the attributes, child elements, and parent element of the `Alignment` element.

Attributes

None.

Child Elements

None.

Parent Elements

Element	Description
TableColumnHeader Element	Defines a label, the width, and the alignment of the data for a column of the table.

Text Value

Specify one of the following values. These values are not case-sensitive.

- Left - Aligns the data displayed in the column on the left. This is the default if this element is not specified.
- Right - Aligns the data displayed in the column on the right.
- Center - Centers the data displayed in the column.

Remarks

For more information about the components of a table view, see [Creating a Table View](#).

Example

This example shows a `TableColumnHeader` element whose data is aligned on the center.

XML

```
<TableColumnHeader>
  <Label>Column 1</Label>
  <Width>16</Width>
  <Alignment>Center</Alignment>
</TableColumnHeader>
```

Label Element for TableColumnHeader for TableControl

Article • 09/17/2021

Defines the label that is displayed at the top of a column. This element is used when defining a table view.

Schema

- Configuration Element
- ViewDefinitions Element
- View Element
- TableControl Element
- TableHeaders Element
- TableColumnHeader Element
- Label Element

Syntax

XML

```
<Label>DisplayedLabel</Label>
```

Attributes and Elements

The following sections describe the attributes, child elements, and the parent element of the `Label` element. Only one label is allowed for each column.

Attributes

None.

Child Elements

None.

Parent Elements

[] [Expand table](#)

Element	Description
TableColumnHeader Element for TableHeaders for TableControl	Defines a label, the width, and the alignment of the data for a column of the table.

Text Value

Specify the text that is displayed at the top of the column of the table. There are no restricted characters for the column label.

Remarks

If no label is specified, the name of the property whose value is displayed in the rows is used.

For more information about the components of a table view, see [Creating a Table View](#).

Example

This example shows a `TableColumnHeader` element whose label is "Column 1".

XML

```
<TableColumnHeader>
  <Label>Column 1</Label>
  <Width>16</Width>
  <Alignment>Left</Alignment>
</TableColumnHeader>
```

Width Element for TableColumnHeader

Article • 09/17/2021

Defines the width (in characters) of a column.

Schema

- Configuration Element
- ViewDefinitions Element
- View Element
- TableControl Element
- TableHeaders Element
- TableColumnHeader
- Width Element

Syntax

XML

```
<Width>NumberOfCharacters</Width>
```

Attributes and Elements

The following sections describe the attributes, child elements, and parent element of the `Width` element used when defining column headers.

Attributes

None.

Child Elements

None.

Parent Elements

[+] Expand table

Element	Description
TableColumnHeader Element for TableHeaders for TableControl	Defines a label, width, and alignment of the data for a column of the table.

Text Value

When at all possible, specify a width (in characters) that is greater than the length of the displayed property values.

Remarks

For more information about the components of a table view, see [Creating a Table View](#).

Example

The following example shows a `TableColumnHeader` element whose width is 16 characters.

XML

```
<TableColumnHeader>
  <Label>Column 1</Label>
  <Width>16</Width>
  <Alignment>Left</Alignment>
</TableColumnHeader>
```

TableRowEntries Element

Article • 09/17/2021

Defines the rows of the table.

Schema

- Configuration Element
- ViewDefinitions Element
- View Element
- TableControl Element
- TableRowEntries Element

Syntax

XML

```
<TableRowEntries>
  <TableRowEntry>...</TableRowEntry>
</TableRowEntries>
```

Attributes and Elements

The following sections describe the attributes, child elements, and parent element of the `TableRowEntries` element.

Attributes

None.

Child Elements

[] Expand table

Element	Description
TableRowEntry Element for TableRowEntries for TableControl	Required element.

Element	Description
	Defines the data that is displayed in a row of the table.

Parent Elements

[\[+\] Expand table](#)

Element	Description
TableControl Element	Defines a table format for a view.

Remarks

You must specify one or more `TableRowEntry` elements for the table view. There is no maximum limit to the number of `TableRowEntry` elements that can be added nor is their order significant.

For more information about the components of a table view, see [Creating a Table View](#).

Example

The following example shows a `TableRowEntries` element that defines a row that displays the values of two properties of the `System.Diagnostics.Process` object.

XML
<pre><TableRowEntries> <TableRowEntry> <EntrySelectedBy> <TypeName>System.Diagnostics.Process</TypeName> </EntrySelectedBy> <TableColumnItems> < TableColumnItem> <PropertyName> Property for first column</PropertyName> </ TableColumnItem> < TableColumnItem> <PropertyName> Property for second column</PropertyName> </ TableColumnItem> </TableColumnItems> </TableRowEntry> </TableRowEntries></pre>

TableColumnItems Element

Article • 02/03/2023

Defines the properties or scripts whose values are displayed in a row.

Schema

- Configuration Element
- ViewDefinitions Element
- View Element
- TableControl Element
- TableRowEntries Element for TableControl
- TableRowEntry Element for TableRowEntries for TableControl
- TableColumnItems Element for TableControlEntry for TableControl

Syntax

XML

```
<TableColumnItems>
  <TableColumnItem>...</TableColumnItem>
</TableColumnItems>
```

Attributes and Elements

The following sections describe the attributes, child elements, and parent element of the `TableColumnItems` element.

Attributes

None.

Child Elements

 Expand table

Element	Description
TableColumnItem Element for TableColumnItems for TableControl	Required element. Defines the property or script whose value is displayed in a column of the row.

Parent Elements

 Expand table

Element	Description
TableRowEntry Element for TableRowEntries for TableControl	Defines the data that is displayed in a row of the table.

Remarks

A `TableColumnItem` element is required for each column of the row. The first entry is displayed in first column, the second entry in the second column, and so on.

For more information about the components of a table view, see [Creating a Table View](#).

Example

The following example shows a `TableColumnItems` element that defines three properties of the `System.Diagnostics.Process` object.

XML

```
<TableColumnItems>
  < TableColumnItem>
    <PropertyName>Status</PropertyName>
  </ TableColumnItem>
  < TableColumnItem>
    <PropertyName>Name</PropertyName>
  </ TableColumnItem>
  < TableColumnItem>
    <PropertyName>DisplayName</PropertyName>
  </ TableColumnItem>
</TableColumnItems>
```

TableColumnItem Element

Article • 09/17/2021

Defines the property or script whose value is displayed in the column of the row.

Schema

- Configuration Element
- ViewDefinitions Element
- View Element
- TableControl Element
- TableRowEntries Element
- TableRowEntry Element
- TableColumnItems Element
- TableColumnItem Element

Syntax

XML

```
<TableColumnItem>
  <Alignment>Left, Right, or Center</Alignment>
  <FormatString>FormatPattern</FormatString>
  <PropertyName>Nameof.NetProperty</PropertyName>
  <ScriptBlock>ScriptToEvaluate</ScriptBlock>
</TableColumnItem>
```

Attributes and Elements

The following sections describe the attributes, child elements, and parent element of the `TableColumnItem` element.

Attributes

None.

Child Elements

[+] Expand table

Element	Description
Alignment Element for TableColumnItem for TableControl	Optional element. Defines how the data in a column of the row is displayed.
FormatString Element for TableColumnItem for TableControl	Specifies a format pattern that is used to format the data in the column of the row.
PropertyName Element for TableColumnItem for TableControl	Optional element. Specifies the name of the property whose value is displayed.
ScriptBlock Element for TableColumnItem for TableControl	Optional element. Specifies the script whose value is displayed in the column of a row.

Parent Elements

[+] Expand table

Element	Description
TableColumnItems Element for TableControlEntry for TableControl	Defines the properties or scripts whose values are displayed in the row.

Remarks

You can specify a property of an object or a script in each column of the row. If no child elements are specified, the item is a placeholder, and no data is displayed.

For more information about the components of a table view, see [Creating a Table View](#).

Example

This example shows a `TableColumnItem` element that displays the value of the `Status` property of the `System.Diagnostics.Process` object.

XML

```
<TableColumnItem>
  <Alignment>Centered</Alignment>
  <PropertyName>Status</PropertyName>
</TableColumnItem>
```

Alignment Element for TableColumnItem

Article • 09/17/2021

Defines how the data in a column of the row is displayed.

Schema

- Configuration Element
- ViewDefinitions Element
- View Element
- TableControl Element
- TableRowEntries Element
- TableRowEntry Element
- TableColumnItems Element
- TableColumnItem Element
- Alignment Element

Syntax

XML

```
<Alignment>AlignmentType</Alignment>
```

Attributes and Elements

The following sections describe the attributes, child elements, and parent element of the `Alignment` element.

Attributes

None.

Child Elements

None.

Parent Elements

 Expand table

Element	Description
TableColumnItem Element	Defines a label, the width, and the alignment of the data for a column of the table.

Text Value

Specify one of the following values. (These values are not case-sensitive.)

- Left - Shifts the data displayed in the column to the left. (This is the default if this element is not specified.)
- Right - Shifts the data displayed in the column to the right.
- Center - Centers the data displayed in the column.

Remarks

For more information about the components of a table view, see [Table View](#).

FormatString Element for TableColumnItem for TableControl

Article • 01/18/2022

Specifies a format pattern that defines how the property or script value of the table is displayed.

Schema

- Configuration Element
- ViewDefinitions Element
- View Element
- TableControl Element
- TableRowEntries Element
- TableRowEntry Element
- TableColumnItems Element
- TableColumnItem Element
- FormatString Element

Syntax

XML

```
<FormatString>FormatPattern</FormatString>
```

Attributes and Elements

The following sections describe attributes, child elements, and the parent element of the `FormatString` element.

Attributes

None.

Child Elements

None.

Parent Elements

[+] Expand table

Element	Description
TableColumnItem Element	Defines the property or script whose value is displayed in the column of the row.

Text Value

Specify the pattern that is used to format the data. For example, this pattern can be used to format the value of any property that is of type [System.TimeSpan](#): {0:MMM}{0:dd}{0:HH}:{0:mm}.

Remarks

Format strings can be used when creating table views, list views, wide views, or custom views. For more information about formatting a value displayed in a view, see [Formatting Displayed Data](#).

For more information about the components of a table view, see [Table View](#).

Example

The following example shows how to define a formatting string for the value of the `StartTime` property.

XML

```
<TableColumnItem>
  <PropertyName>StartTime</PropertyName>
  <FormatString>{0:MMM} {0:DD} {0:HH}:{0:MM}</FormatString>
</TableColumnItem>
```

TableRowEntry Element

Article • 09/17/2021

Defines the data that is displayed in a row of the table.

Schema

- Configuration Element
- ViewDefinitions Element
- View Element
- TableControl Element
- TableRowEntries Element for TableControl
- TableRowEntry Element for TableRowEntries

Syntax

XML

```
<TableRowEntry>
  <Wrap/>
  <EntrySelectedBy>...</EntrySelectedBy>
  <TableColumnItems>...</TableColumnItems>
</TableRowEntry>
```

Attributes and Elements

The following sections describe attributes, child elements, and parent element of the `TableRowEntry` element.

Attributes

None.

Child Elements

 Expand table

Element	Description
EntrySelectedBy Element for TableRowEntry for TableControl	Required element. Defines the objects whose property values are displayed in the row.
TableColumnItems Element for TableRowEntry for TableControl	Required element. Defines the properties or scripts whose values are displayed.
Wrap Element for TableRowEntry for TableControl	Optional element. Specifies that text that exceeds the column width is displayed on the next line.

Parent Elements

[\[\] Expand table](#)

Element	Description
TableRowEntries Element for TableControl	Defines the rows of the table.

Remarks

One [TableColumnItems](#) element and one [EntrySelectedBy](#) element must be specified.

For more information about the components of a table view, see [Creating a Table View](#).

Example

The following example shows a [TableRowEntry](#) element that defines a row that displays the values of two properties of the [System.Diagnostics.Process](#) object.

XML

```

<TableRowEntry>
  <EntrySelectedBy>
    <TypeName>System.Diagnostics.Process</TypeName>
  </EntrySelectedBy>
  <TableColumnItems>
    < TableColumnItem>
      <PropertyName> Property for first column</PropertyName>
    </ TableColumnItem>
  </TableColumnItems>
</TableRowEntry>

```

```
</TableColumnItem>
<TableColumnItem>
    <PropertyName> Property for second column</PropertyName>
</TableColumnItem>
</TableColumnItems>
</TableRowEntry>
```

EntrySelectedBy Element for TableRowEntry

Article • 09/17/2021

Defines the .NET types that use this definition of the table view or the condition that must exist for this definition to be used.

Schema

- Configuration Element
- ViewDefinitions Element
- View Element
- TableControl Element
- TableRowEntries Element
- TableRowEntry Element
- EntrySelectedBy Element

Syntax

XML

```
<EntrySelectedBy>
  <TypeName>Nameof.NetType</TypeName>
  <SelectionSetName>NameofSelectionSet</SelectionSetName>
  <SelectionCondition>...</SelectionCondition>
</EntrySelectedBy>
```

Attributes and Elements

The following sections describe attributes, child elements, and the parent element of the `EntrySelectedBy` element.

Attributes

None.

Child Elements

[+] Expand table

Element	Description
SelectionCondition Element for EntrySelectedBy for TableControl	Optional element. Defines the condition that must exist for this table view definition to be used.
SelectionSetName Element for EntrySelectedBy for TableControl	Optional element. Specifies a set of .NET types that use this table view definition.
TypeName Element for EntrySelectedBy for TableControl	Optional element. Specifies a .NET type that uses this table view definition.

Parent Elements

[+] Expand table

Element	Description
TableRowEntry Element for TableControl	Defines the data that is displayed in a row of the table.

Remarks

You must specify at least one type, selection set, or selection condition for a table view definition. There is no maximum limit to the number of child elements that you can use.

Selection conditions are used to define a condition that must exist for the definition to be used, such as when an object has a specific property or that a specific property value or script evaluates to `true`. For more information about selection conditions, see [Defining Conditions for when a View Entry or Item is Used](#).

For more information about the components of a table view, see [Creating a Table View](#).

Example

The following example shows a `TableRowEntry` element that is used to display the properties of the `System.Diagnostics.Process` object.

XML

```
<TableRowEntry>
  <EntrySelectedBy>
    <TypeName>System.Diagnostics.Process</TypeName>
  </EntrySelectedBy>
  <TableColumnItems>
    < TableColumnItem>
      <PropertyName>PropertyForFirstColumn</PropertyName>
    </ TableColumnItem>
    < TableColumnItem>
      <PropertyName>PropertyForSecondColumn</PropertyName>
    </ TableColumnItem>
  </TableColumnItems>
</TableRowEntry>
```

SelectionCondition Element for EntrySelectedBy for TableControl

Article • 09/17/2021

Defines the condition that must exist to use for this definition of the table view. There is no limit to the number of selection conditions that can be specified for a table definition.

Schema

- Configuration Element
- ViewDefinitions Element
- View Element
- TableControl Element
- TableRowEntries Element
- TableRowEntry Element
- EntrySelectedBy Element
- SelectionCondition Element

Syntax

XML

```
<SelectionCondition>
  <TypeName>Nameof.NetType</TypeName>
  <SelectionSetName>NameofSelectionSet</SelectionSetName>
  <PropertyName>.NetTypeProperty</PropertyName>
  <ScriptBlock>ScriptToEvaluate</ScriptBlock>
</SelectionCondition>
```

Attributes and Elements

The following sections describe attributes, child elements, and the parent element of the SelectionCondition element.

Attributes

None.

Child Elements

[Expand table](#)

Element	Description
PropertyName Element for SelectionCondition for EntrySelectedBy for TableRowEntry	Optional element. Specifies the .NET property that triggers the condition.
ScriptBlock Element for SelectionCondition for EntrySelectedBy for TableRowEntry	Optional element. Specifies the script that triggers the condition.
SelectionSetName Element for SelectionCondition for EntrySelectedBy for TableRowEntry	Optional element. Specifies the set of .NET types that trigger the condition.
TypeName Element for SelectionCondition for EntrySelectedBy for TableRowEntry	Optional element. Specifies a .NET type that triggers the condition.

Parent Elements

[Expand table](#)

Element	Description
EntrySelectedBy Element for TableRowEntry	Defines the .NET types that use this table entry or the condition that must exist for this entry to be used.

Remarks

Each list entry must have at least one type name, selection set, or selection condition defined.

When you are defining a selection condition, the following requirements apply:

- The selection condition must specify a least one property name or a script block, but cannot specify both.

- The selection condition can specify any number of .NET types or selection sets, but cannot specify both.

For more information about how to use selection conditions, see [Defining Conditions for when a View Entry or Item is Used](#).

For more information about the components of a table view, see [Creating a Table View](#).

PropertyName Element for SelectionCondition for EntrySelectedBy for TableRowEntry

Article • 09/17/2021

Specifies the .NET property that triggers the condition. When this property is present or when it evaluates to `true`, the condition is met, and the table entry is used.

Schema

- Configuration Element
- ViewDefinitions Element
- View Element
- TableControl Element
- TableRowEntries Element
- TableRowEntry Element
- EntrySelectedBy Element
- SelectionCondition Element
- PropertyName Element

Syntax

XML

```
<PropertyName>.NetTypeProperty</PropertyName>
```

Attributes and Elements

The following sections describe attributes, child elements, and the parent element of the `PropertyName` element.

Attributes

None.

Child Elements

None.

Parent Elements

 Expand table

Element	Description
SelectionCondition Element for EntrySelectedBy for TableRowEntry	Defines the condition that must exist for this table entry to be used.

Text Value

Specify the .NET property name.

Remarks

The selection condition must specify at least one property name or a script block, but cannot specify both. For more information about how selection conditions can be used, see [Defining Conditions for when a View Entry or Item is Used](#).

ScriptBlock Element for SelectionCondition for EntrySelectedBy for TableControl

Article • 09/17/2021

Specifies the script block that triggers the condition. When this script is evaluated to `true`, the condition is met, and the table entry is used.

Schema

- Configuration Element
- ViewDefinitions Element
- View Element
- TableControl Element
- TableRowEntries Element
- TableRowEntry Element
- EntrySelectedBy Element
- SelectionCondition Element
- ScriptBlock Element

Syntax

XML

```
<ScriptBlock>ScriptToEvaluate</ScriptBlock>
```

Attributes and Elements

The following sections describe attributes, child elements, and the parent element of the `ScriptBlock` element.

Attributes

None.

Child Elements

None.

Parent Elements

 Expand table

Element	Description
SelectionCondition Element for EntrySelectedBy for TableRowEntry	Defines the condition that must exist for this table entry to be used.

Text Value

Specify the script that is evaluated.

Remarks

The selection condition must specify at least one script block or property name, but cannot specify both. For more information about how to use selection conditions, see [Defining Conditions for when a View Entry or Item is Used](#).

For more information about the components of a table view, see [Creating a Table View](#).

SelectionSetName Element for SelectionCondition for EntrySelectedBy for TableControl

Article • 09/17/2021

Specifies the set of .NET types that trigger the condition. When any of the types in this set are present, the condition is met, and the object is displayed by using this definition of the table view.

Schema

- Configuration Element
- ViewDefinitions Element
- View Element
- TableControl Element
- TableRowEntries Element
- TableRowEntry Element
- EntrySelectedBy Element
- SelectionCondition Element
- SelectionSetName Element

Syntax

XML

```
<SelectionSetName>NameofSelectionSet</SelectionSetName>
```

Attributes and Elements

The following sections describe attributes, child elements, and the parent element of the `SelectionSetName` element.

Attributes

None.

Child Elements

None.

Parent Elements

 Expand table

Element	Description
SelectionCondition Element for EntrySelectedBy for TableRowEntry	Defines the condition that must exist to use for this definition of the table view.

Text Value

Specify the name of the selection set.

Remarks

The selection condition can specify a selection set or .NET type, but cannot specify both. For more information about how to use selection conditions, see [Defining Conditions for when Data is Displayed](#).

Selection sets are common groups of .NET objects that can be used by any view that the formatting file defines. For more information about creating and referencing selection sets, see [Defining Sets of Objects](#).

For more information about other components of a wide view, see [Creating a Table View](#).

TypeName Element for SelectionCondition for EntrySelectedBy for TableControl

Article • 09/17/2021

Specifies a .NET type that triggers the condition. When this type is present, the condition is met, and the table row is used.

Schema

- Configuration Element
- ViewDefinitions Element
- View Element
- TableControl Element
- TableRowEntries Element
- TableRowEntry Element
- EntrySelectedBy Element
- SelectionCondition Element
- TypeName Element

Syntax

XML

```
<TypeName>Nameof .NetType</TypeName>
```

Attributes and Elements

The following sections describe attributes, child elements, and the parent element of the `TypeName` element.

Attributes

None.

Child Elements

None.

Parent Elements

 Expand table

Element	Description
SelectionCondition Element for EntrySelectedBy for TableRowEntry	Defines the condition that must exist for this table row to be used.

Text Value

Specify the fully qualified name of the .NET type, such as `System.IO.DirectoryInfo`.

Remarks

The selection condition can specify any number of .NET types or selection sets, but cannot specify both. For more information about how to use selection conditions, see [Defining Conditions for when a View Entry or Item is Used](#).

For more information about the components of a table view, see [Creating a Table View](#).

SelectionSetName Element for EntrySelectedBy for TableControl

Article • 09/17/2021

Specifies a set of .NET types the use this entry of the table view. There is no limit to the number of selection sets that can be specified for an entry.

Schema

- Configuration Element
- ViewDefinitions Element
- View Element
- TableControl Element
- TableRowEntries Element
- TableRowEntry Element
- EntrySelectedBy Element
- SelectionSetName Element

Syntax

XML

```
<SelectionSetName>NameofSelectionSet</SelectionSetName>
```

Attributes and Elements

The following sections describe attributes, child elements, and parent elements.

Attributes

None.

Child Elements

None.

Parent Elements

Element	Description
EntrySelectedBy Element	Defines the .NET types that use this entry or the condition that must exist for this entry to be used.

Text Value

Specify the name of the selection set.

Remarks

Selection sets are typically used when you want to define a group of objects that are used in multiple views. For example, you might want to create a table view and a list view for the same set of objects. For more information about defining selection sets, see [Defining Sets of objects for a View](#).

If you specify a selection set for an entry, you cannot specify a type name. For more information about how to specify a .NET type, see [TypeName Element for EntrySelectedBy for TableRowEntry](#).

For more information about the components of a table view, see [Creating a Table View](#).

TypeName Element for EntrySelectedBy for TableControl

Article • 09/17/2021

Specifies a .NET type that uses this entry of the table view. There is no limit to the number of types that can be specified for a table entry.

Schema

- Configuration Element
- ViewDefinitions Element
- View Element
- TableControl Element
- TableRowEntries Element
- TableRowEntry Element
- EntrySelectedBy Element
- TypeName Element

Syntax

XML

```
<TypeName>Nameof .NetType</TypeName>
```

Attributes and Elements

The following sections describe attributes, child elements, and the parent element of the `TypeName` element.

Attributes

None.

Child Elements

None.

Parent Elements

 Expand table

Element	Description
EntrySelectedBy Element	Defines the .NET types that use this entry or the condition that must exist for this entry to be used.

Text Value

Specify the name of the .NET type.

Remarks

Each list entry must have at least one type name, selection set, or selection condition defined.

For more information about the components of a table view, see [Creating a Table View](#).

Wrap Element for TableRowEntry

Article • 09/17/2021

Specifies that text that exceeds the column width is displayed on the next line. By default, text that exceeds the column width is truncated.

Schema

- Configuration Element
- ViewDefinitions Element
- View Element
- TableControl Element
- TableRowEntries Element for TableControl
- TableRowEntry Element for TableRowEntries for TableControl
- Wrap Element for TableRowEntry for TableControl

Syntax

XML

```
<Wrap/>
```

Attributes and Elements

The following sections describe attributes, child elements, and parent elements of the `Wrap` element.

Attributes

None.

Child Elements

None.

Parent Elements

Element	Description
TableRowEntry Element for TableRowEntries for TableControl	Defines the data that is displayed in a row of the table.

Remarks

For more information about the components of a table view, see [Creating a Table View](#).

ViewSelectedBy Element

Article • 09/17/2021

Defines the .NET objects that are displayed by the view. Each view must specify at least one .NET object.

Schema

- ViewDefinitions Element
- View Element
- ViewSelectedBy Element

Syntax

XML

```
<ViewSelectedBy>
  <TypeName>Nameof.NetType</TypeName>
  <SelectionSetName>SelectionSet</SelectionSetName>
</ViewSelectedBy>
```

Attributes and Elements

The following sections describe the attributes, child elements, and parent element of the `ViewSelectedBy` element. This element must contain at least one `TypeName` or `SelectionSetName` child element. There is no limit to the number of child elements that can be specified nor is their order significant.

Attributes

None.

Child Elements

[+] Expand table

Element	Description
TypeName Element for ViewSelectedBy	Optional element. Specifies a .NET object that is displayed by the view.
SelectionSetName Element for ViewSelectedBy	Optional element. Specifies a set of .NET objects that are displayed by the view.

Parent Elements

[\[\] Expand table](#)

Element	Description
View Element	Defines a view that displays one or more .NET objects.

Remarks

For more information about how this element is used in different views, see [Table View Components](#), [List View Components](#), [Wide View Components](#), and [Custom Control Components](#).

The `SelectionSetName` element is used when the formatting file defines a set of objects that are displayed by multiple views. For more information about how selection sets are defined and referenced, see [Defining Sets of Objects](#).

Example

The following example shows how to specify the `System.ServiceProcess.ServiceController` object for a list view. The same schema is used for table, wide, and custom views.

XML

```
<View>
  <Name>System.ServiceProcess.ServiceController</Name>
  <ViewSelectedBy>
    <TypeName>System.ServiceProcess.ServiceController</TypeName>
  </ViewSelectedBy>
```

```
<ListControl>...</ListControl>  
</View>
```

SelectionSetName Element for ViewSelectedBy

Article • 09/17/2021

Specifies a set of .NET objects that are displayed by the view.

Schema

- Configuration Element
- ViewDefinitions Element
- View Element
- ViewSelectedBy Element
- SelectionSetName Element

Syntax

XML

```
<SelectionSetName>Name of selection set<SelectionSetName>
```

Attributes and Elements

The following sections describe the attributes, child elements, and the parent element of the `SelectionSetName` element.

Attributes

None.

Child Elements

None.

Parent Elements

[+] Expand table

Element	Description
ViewSelectedBy Element	Defines the .NET objects that are displayed by the view.

Text Value

Specify the name of the selection set that is defined by the `Name` element for the selection set.

Remarks

You can use selection sets when you have a set of related objects that you want to reference by using a single name, such as a set of objects that are related through inheritance. For more information about defining and referencing selection sets, see [Defining Sets of Objects](#).

Example

The following example shows how to specify a selection set for a list view. The same schema is used for table, wide, and custom views.

XML

```
<View>
  <Name>Name of View</Name>
  <ViewSelectedBy>
    <SelectionSetName>NameofSelectionSet</SelectionSetName>
  </ViewSelectedBy>
  <ListControl>...</ListControl>
</View>
```

TypeName Element for ViewSelectedBy

Article • 09/17/2021

Specifies a .NET object that is displayed by the view.

Schema

- Configuration Element
- ViewDefinitions Element
- View Element
- ViewSelectedBy Element
- TypeName Element

Syntax

XML

```
<TypeName>FullyQualifiedTypeName</TypeName>
```

Attributes and Elements

The following sections describe attributes, child elements, and the parent elements of the `TypeName` element.

Attributes

None.

Child Elements

None.

Parent Elements

[+] Expand table

Element	Description
ViewSelectedBy Element	Defines the .NET objects that are displayed by the view.

Text Value

Specify the fully qualified name of the .NET type, such as `System.IO.DirectoryInfo`.

Remarks

For more information about how this element is used in different views, see [Creating a Table View](#), [Creating a List View](#), [Creating a Wide View](#), and [Custom View Components](#).

Example

The following example shows how to specify the `System.ServiceProcess.ServiceController` object for a list view. The same schema is used for table, wide, and custom views.

```
XML
<View>
  <Name>System.ServiceProcess.ServiceController</Name>
  <ViewSelectedBy>
    <TypeName>System.ServiceProcess.ServiceController</TypeName>
  </ViewSelectedBy>
  <ListControl>...</ListControl>
</View>
```

[Writing a PowerShell Formatting File](#)

WideControl Element

Article • 09/17/2021

Defines a wide (single value) list format for the view. This view displays a single property value or script value for each object.

Schema

- Configuration Element
- ViewDefinitions Element
- View Element
- WideControl Element

Syntax

XML

```
<WideControl>
  <AutoSize/>
  <ColumnNumber>PositiveInteger</ColumnNumber>
  <WideEntries>...</WideEntries>
</WideControl>
```

Attributes and Elements

The following sections describe the attributes, child elements, and parent element of the `WideControl` element. You cannot specify the `AutoSize` and `ColumnNumber` elements at the same time.

Attributes

None.

Child Elements

[+] Expand table

Element	Description
AutoSize Element for WideControl	<p>Optional element.</p> <p>Specifies whether the column size and the number of columns are adjusted based on the size of the data.</p>
ColumnNumber Element for WideControl	<p>Optional element.</p> <p>Specifies the number of columns displayed in the wide view.</p>
WideEntries Element	<p>Required element.</p> <p>Provides the definitions of the wide view.</p>

Parent Elements

[\[+\] Expand table](#)

Element	Description
View Element	Defines a view that is used to display one or more .NET objects.

Remarks

When defining a wide view, you can add the `AutoSize` element or the `ColumnNumber` but you cannot add both.

In most cases, only one definition is required for each wide view, but it is possible to have multiple definitions if you want to use the same view to display different .NET objects. In those cases, you can provide a separate definition for each object or set of objects.

For more information about the components of a wide view, see [Wide View Components](#).

Example

The following example shows a `WideControl` element that is used to display a property of the `System.Diagnostics.Process` object.

XML

```
<View>
  <Name>process</Name>
  <ViewSelectedBy>
    <TypeName>System.Diagnostics.Process</TypeName>
  </ViewSelectedBy>
  <WideControl>
    <WideEntries>...</WideEntries>
  </WideControl>
</View>
```

For a complete example of a wide view, see [Wide View \(Basic\)](#).

WideEntries Element

Article • 09/17/2021

Provides the definitions of the wide view. The wide view must specify one or more definitions.

Schema

- Configuration Element
- ViewDefinitions Element
- View Element
- WideControl Element
- WideEntries Element

Syntax

XML

```
<WideEntries>
  <WideEntry>...</WideEntry>
</WideEntries>
```

Attributes and Elements

The following sections describe the attributes, child elements, and parent element of the `WideEntries` element. At least one child element must be specified.

Attributes

None.

Child Elements

[+] Expand table

Element	Description
WideEntry Element	Provides a definition of the wide view.

Parent Elements

[] [Expand table](#)

Element	Description
WideControl Element	Defines a wide (single value) list format for the view.

Remarks

A wide view is a list format that displays a single property value or script value for each object. For more information about the components of a wide view, see [Wide View Components](#).

Example

The following example shows a `WideEntries` element that defines a single `WideEntry` element. The `WideEntry` element contains a single `WideItem` element that defines what property or script value is displayed in the view.

XML

```
<WideControl>
  <WideEntries>
    <WideEntry>
      <WideItem>...</WideItem>
    <WideEntry>
  </WideEntries>
</WideControl>
```

WideEntry Element

Article • 09/17/2021

Provides a definition of the wide view.

Schema

- Configuration Element
- ViewDefinitions Element
- View Element
- WideControl Element
- WideEntries Element
- WideEntry Element

Syntax

XML

```
<WideEntry>
  <EntrySelectedBy>...</EntrySelectedBy>
  <WideItem>...</WideItem>
</WideEntry>
```

Attributes and Elements

The following sections describe the attributes, child elements, and the parent element of the `WideEntry` element. You must specify a single `WideItem` child element.

Attributes

None.

Child Elements

[+] Expand table

Element	Description
EntrySelectedBy Element for WideEntry	Optional element. Defines the .NET types that use this wide entry definition or the condition that must exist for this definition to be used.
WideItem Element	Required element. Defines the property or script whose value is displayed.

Parent Elements

[\[+\] Expand table](#)

Element	Description
WideEntries Element	Provides the definitions of the wide view.

Remarks

A wide view is a list format that displays a single property value or script value for each object. Unlike other types of views, you can specify only one item element for each view definition. For more information about the other components of a wide view, see [Creating a Wide View](#).

Example

The following example shows a `WideEntry` element that defines a single `WideItem` element. The `WideItem` element defines the property whose value is displayed in the view.

XML

```
<WideEntries>
  <WideEntry>
    <WideItem>
      <PropertyName>ProcessName</PropertyName>
    </WideItem>
  </WideEntry>
</WideEntries>
```

EntrySelectedBy Element for WideEntry

Article • 09/17/2021

Defines the .NET types that use this definition of the wide view or the condition that must exist for this definition to be used.

Schema

Configuration Element ViewDefinitions Element View Element WideControl Element
WideEntries Element WideEntry Element EntrySelectedBy Element

Syntax

XML

```
<EntrySelectedBy>
  <TypeName>Nameof.NetType</TypeName>
  <SelectionSetName>NameofSelectionSet</SelectionSetName>
  <SelectionCondition>...</SelectionCondition>
</EntrySelectedBy>
```

Attributes and Elements

The following sections describe attributes, child elements, and the parent element of the `EntrySelectedBy` element.

Attributes

None.

Child Elements

[] Expand table

Element	Description
SelectionCondition Element for EntrySelectedBy for WideEntry	Optional element. Defines the condition that must exist for this wide view definition to be used.

Element	Description
SelectionSetName Element for EntrySelectedBy for WideEntry	<p>Optional element.</p> <p>Specifies a set of .NET types that use this wide view definition.</p>
TypeName Element for EntrySelectedBy for WideEntry	<p>Optional element.</p> <p>Specifies a .NET type that uses this wide view definition.</p>

Parent Elements

[\[\] Expand table](#)

Element	Description
WideEntry Element	Provides a definition of the wide view.

Remarks

You must specify at least one type, selection set, or selection condition for a wide view definition. There is no maximum limit to the number of child elements that you can use.

Selection conditions are used to define a condition that must exist for the definition to be used, such as when an object has a specific property or that a specific property value or script value evaluates to `true`. For more information about selection conditions, see [Defining Conditions for Displaying Data](#).

For more information about other components of a wide view, see [Creating a Wide View](#).

SelectionCondition Element for EntrySelectedBy for WideControl

Article • 09/17/2021

Defines the condition that must exist for this definition to be used. There is no limit to the number of selection conditions that can be specified for a wide entry definition.

Schema

- Configuration Element
- ViewDefinitions Element
- View Element
- WideControl Element
- WideEntries Element
- WideEntry Element
- EntrySelectedBy Element
- SelectionCondition Element

Syntax

XML

```
<SelectionCondition>
  <TypeName>Nameof.NetType</TypeName>
  <SelectionSetName>NameofSelectionSet</SelectionSetName>
  <PropertyName>.NetTypeProperty</PropertyName>
  <ScriptBlock>ScriptToEvaluate</ScriptBlock>
</SelectionCondition>
```

Attributes and Elements

The following sections describe attributes, child elements, and the parent element of the `SelectionCondition` element. You must specify a single `PropertyName` or `ScriptBlock` element. The `SelectionSetName` and `TypeName` elements are optional. You can specify one of either element.

Attributes

None.

Child Elements

[Expand table](#)

Element	Description
PropertyName Element for SelectionCondition for EntrySelectedBy for WideEntry	Optional element. Specifies the .NET property that triggers the condition.
ScriptBlock Element for SelectionCondition for EntrySelectedBy for WideEntry	Optional element. Specifies the script block that triggers the condition.
SelectionSetName Element for SelectionCondition for EntrySelectedBy for WideEntry	Optional element. Specifies the set of .NET types that triggers the condition.
TypeName Element for SelectionCondition for EntrySelectedBy for WideEntry	Optional element. Specifies a .NET type that triggers the condition.

Parent Elements

[Expand table](#)

Element	Description
EntrySelectedBy Element for WideEntry	Defines the .NET types that use this wide entry or the condition that must exist for this entry to be used.

Remarks

Each wide entry must have at least one type name, selection set, or selection condition defined.

When you are defining a selection condition, the following requirements apply:

- The selection condition must specify at least one property name or a script block, but cannot specify both.
- The selection condition can specify any number of .NET types or selection sets, but cannot specify both.

For more information about how to use selection conditions, see [Defining Conditions for when a View Entry or Item is Used](#).

For more information about other components of a wide view, see [Creating a Wide View](#).

SelectionSetName Element for EntrySelectedBy for WideControl

Article • 09/17/2021

Specifies a set of .NET objects for the definition. The definition is used whenever one of these objects is displayed.

Schema

- Configuration Element
- ViewDefinitions Element
- View Element
- WideControl Element
- WideEntries Element
- WideEntry Element
- EntrySelectedBy Element
- SelectionSetName Element

Syntax

XML

```
<SelectionSetName>NameofSelectionSet</SelectionSetName>
```

Attributes and Elements

The following sections describe the attributes, child elements, and the parent element of the `SelectionSetName` element.

Attributes

None.

Child Elements

None.

Parent Elements

 Expand table

Element	Description
EntrySelectedBy Element for WideEntry	Defines the .NET types that use this wide entry or the condition that must exist for this entry to be used.

Text Value

Specify the name of the selection set.

Remarks

Each definition must specify one type name, selection set, or selection condition.

Selection sets are typically used when you want to define a group of objects that are used in multiple views. For example, you might want to create a table view and a list view for the same set of objects. For more information about defining selection sets, see [Defining Sets of Objects for a View](#).

WideItem Element for WideControl

Article • 09/17/2021

Defines the property or script whose value is displayed.

Schema

- Configuration Element
- ViewDefinitions Element
- View Element
- WideControl Element
- WideEntries Element
- WideEntry Element
- WideItem Element

Syntax

XML

```
<WideItem>
  <PropertyName>.NetTypeProperty</PropertyName>
  <ScriptBlock>ScriptToExecute</ScriptBlock>
  <FormatString>FormatPattern</FormatString>
</WideItem>
```

Attributes and Elements

The following sections describe the attributes, child elements, and the parent element of the `WideItem` element. The `FormatString` element is optional. However, you must specify a `PropertyName` or `ScriptBlock` element, but you cannot specify both.

Attributes

None.

Child Elements

[] Expand table

Element	Description
FormatString Element for <code>WideItem</code> for <code>WideControl</code>	<p>Optional element.</p> <p>Specifies a format pattern that defines how the property or script value is displayed in the view.</p>
PropertyName Element for <code>WideItem</code>	<p>Specifies the property of the object whose value is displayed in the wide view.</p>

FormatString Element for Wideltem

Article • 01/18/2022

Specifies a format pattern that defines how the property or script value is displayed in the view.

Schema

- Configuration Element
- ViewDefinitions Element
- View Element
- WideControl Element
- WideEntries Element
- WideEntry Element
- Wideltem Element
- FormatString Element

Syntax

XML

```
<FormatString>PropertyPattern</FormatString>
```

Attributes and Elements

The following sections describe the attributes, child elements, and the parent element of the `FormatString` element.

Attributes

None.

Child Elements

None.

Parent Elements

Element	Description
<code>WideItem</code> Element for <code>WideControl</code>	Defines the property or script whose value is displayed in a row of the list view.

Text Value

Specify the pattern that is used to format the data. For example, you can use this pattern to format the value of any property that is of type `System.TimeSpan`: {0:MMM}{0:dd}{0:HH}:{0:mm}.

Remarks

Format strings can be used when creating table views, list views, wide views, or custom views. For more information about formatting a value displayed in a view, see [Formatting Displayed Data](#).

For more information about using format strings in wide views, see [Creating a Wide View](#).

Example

The following example shows how to define a formatting string for the value of the `StartTime` property.

XML

```
<WideItem>
  <PropertyName>StartTime</PropertyName>
  <FormatString>{0:MMM} {0:DD} {0:HH}:{0:MM}</FormatString>
</WideItem>
```

Writing Help for PowerShell Scripts and Functions

Article • 07/10/2023

PowerShell scripts and functions should be fully documented whenever they're shared with others. The `Get-Help` cmdlet displays the script and function help topics in the same format as it displays help for cmdlets, and all the `Get-Help` parameters work on script and function help topics.

PowerShell scripts can include a help topic about the script and help topics about each functions in the script. Functions that are shared independently of scripts can include their own help topics.

This document explains the format and correct placement of the help topics, and it suggests guidelines for the content.

Types of Script and Function Help

Comment-Based Help

The help topic that describes a script or function can be implemented as a set of comments within the script or function. When writing comment-based help for a script and for functions in a script, pay careful attention to the rules for placing the comment-based help. The placement determines whether the `Get-Help` cmdlet associates the help topic with the script or a function. For more information about writing comment-based help topics, see [about_Comment_Based_Help](#).

XML-Based Command Help

The help topic that describes a script or function can be implemented in an XML file that uses the command help schema. To associate the script or function with the XML file, use the `.EXTERNALHELP` comment keyword followed by the path and name of the XML file.

When the `.EXTERNALHELP` comment keyword is present, it takes precedence over comment-based help, even when `Get-Help` can't find a help file that matches the value of the `.EXTERNALHELP` keyword.

Online Help

You can post your help topics on the internet and then direct `Get-Help` to open the topics. For more information about writing comment-based help topics, see [Supporting Online Help](#).

There is no established method for writing conceptual ("About") topics for scripts and functions. However, you can post conceptual topics on the internet list the topics and their URLs in the Related Links section of a command help topic.

Content Considerations for Script and Function Help

- If you are writing a very brief help topic with only a few of the available command help sections, be sure to include clear descriptions of the script or function parameters. Also include one or two sample commands in the examples section, even if you decide to omit example descriptions.
- In all descriptions, refer to the command as a script or function. This information helps the user to understand and manage the command.

For example, the following detailed description states that the `New-Topic` command is a script. This reminds users that they need to specify the path and full name when they run it.

"The `New-Topic` script creates a blank conceptual topic for each topic name in the input file..."

The following detailed description states that `Disable-PSRemoting` is a function. This information is particularly useful to users when the session includes multiple commands with the same name, some of which might be hidden by a command with higher precedence.

The `Disable-PSRemoting` function disables all session configurations on the local computer...

- In a script help topic, explain how to use the script as a whole. If you are also writing help topics for functions in the script, mention the functions in your script help topic and include references to the function help topics in the Related Links section of the script help topic. Conversely, when a function is part of a script, explain in the function help topic the role that the function plays in the script and

how it might be used independently. Then list the script help topic in the Related Links section of the function help topic.

- When writing examples for a script help topic, be sure to include the path to the script file in the example command. This reminds users that they must specify the path explicitly, even when the script is in the current directory.
- In a function help topic, remind users that the function exists only in the current session and, to use it in other sessions, they need to add it, or add it a PowerShell profile.
- `Get-Help` displays the help topic for a script or function only when the script file and help topic files are saved in the correct locations. Therefore, it's not useful to include instructions for installing PowerShell, or saving or installing the script or function in a script or function help topic. Instead, include any installation instructions in the document that you use to distribute the script or function.

[Writing Comment-Based Help Topics](#)

Writing Comment-Based Help Topics

Article • 07/10/2023

You can write comment-based Help topics for functions and scripts using special Help comment keywords.

The `Get-Help` cmdlet displays comment-based Help in the same format in which it displays the cmdlet Help topics that are generated from XML files. Users can use all of the parameters of `Get-Help`, such as Detailed, Full, Example, and Online, to display function and script Help.

You can also write XML-based Help topics for scripts and functions and use the Help comment keywords to redirect users to the XML-based topics or other topics.

In This Section

- [Syntax of Comment-Based Help](#) - Describes the syntax of comment-based help.
- [Comment-Based Help Keywords](#) - Lists the keywords in comment-based help.
- [Placing Comment-Based Help in Functions](#) - Shows where to place comment-based help for a function.
- [Placing Comment-Based Help in Scripts](#) - Shows where to place comment-based help for a script.

Syntax of Comment-Based Help

Article • 03/24/2025

This section describes the syntax of comment-based help.

Syntax Diagram

The syntax for comment-based Help is as follows:

```
# .< help keyword>
# <help content>
```

-or -

```
<#
.< help keyword>
< help content>
#>
```

Syntax Description

Comment-based Help is written as a series of comments. You can type a comment symbol (#) before each line of comments, or you can use the <# and #> symbols to create a comment block. All the lines within the comment block are interpreted as comments.

Each section of comment-based Help is defined by a keyword and each keyword is preceded by a dot (.). The keywords can appear in any order. The keyword names aren't case-sensitive.

A comment block must contain at least one help keyword. Some of the keywords, such as .EXAMPLE, can appear many times in the same comment block. The Help content for each keyword begins on the line after the keyword and can span multiple lines.

All the lines in a comment-based Help topic must be contiguous. If a comment-based Help topic follows a comment that isn't part of the Help topic, there must be at least

one blank line between the last non-Help comment line and the beginning of the comment-based Help.

For example, the following comment-based help topic contains the `.DESCRIPTION` keyword and its value, which is a description of a function or script.

PowerShell

```
<#
    .DESCRIPTION
        The Get-Function function displays the name and syntax of all functions
        in the session.
#>
```

Comment-Based Help Keywords

Article • 05/21/2025

This topic lists and describes the keywords in comment-based help.

Keywords in Comment-Based Help

The following are valid comment-based Help keywords. They're listed in the order in which they typically appear in a Help topic along with their intended use. These keywords can appear in any order in the comment-based Help, and they're not case-sensitive.

Note that the `.EXTERNALHELP` keyword takes precedence over all other comment-based help keywords. When `.EXTERNALHELP` is present, the [Get-Help](#) cmdlet doesn't display comment-based help, even when it can't find a help file that matches the value of the keyword.

.SYNOPSIS

A brief description of the function or script. This keyword can be used only once in each topic.

.DESCRIPTION

A detailed description of the function or script. This keyword can be used only once in each topic.

.PARAMETER <Parameter-Name>

The description of a parameter. You can include a `.PARAMETER` keyword for each parameter in the function or script.

The `.PARAMETER` keywords can appear in any order in the comment block, but the order in which the parameters appear in the `param` statement or function declaration determines the order in which the parameters appear in Help topic. To change the order of parameters in the Help topic, change the order of the parameters in the `param` statement or function declaration.

You can also specify a parameter description by placing a comment in the `param` statement immediately before the parameter variable name. If you use both a `param` statement comment and a `.PARAMETER` keyword, the description associated with the `.PARAMETER` keyword is used, and the `param` statement comment is ignored.

.EXAMPLE

A sample command that uses the function or script, optionally followed by sample output and a description. Repeat this keyword for each example.

.INPUTS

The .NET types of objects that can be piped to the function or script. You can also include a description of the input objects. Repeat this keyword for each input type.

.OUTPUTS

The .NET type of the objects that the cmdlet returns. You can also include a description of the returned objects. Repeat this keyword for each output type.

.NOTES

Additional information about the function or script.

.LINK

The name of a related topic. Repeat this keyword for each related topic. This content appears in the Related Links section of the Help topic.

The `.LINK` keyword content can also include a Uniform Resource Identifier (URI) to an online version of the same help topic. The online version opens when you use the **Online** parameter of `Get-Help`. The URI must begin with `http` or `https`.

.COMPONENT

The name of the technology or feature that the function or script uses, or to which it's related. The **Component** parameter of `Get-Help` uses this value to filter the search results returned by `Get-Help`.

.ROLE

The name of the user role for the help topic. The **Role** parameter of `Get-Help` uses this value to filter the search results returned by `Get-Help`.

.FUNCTIONALITY

The keywords that describe the intended use of the function. The **Functionality** parameter of `Get-Help` uses this value to filter the search results returned by `Get-Help`.

.FORWARDHELPTARGETNAME <Command-Name>

Redirects to the help topic for the specified command. You can redirect users to any help topic, including help content for a function, script, cmdlet, or provider.

PowerShell

```
# .FORWARDHELPTARGETNAME <Command-Name>
```

.FORWARDHELPCATEGORY

Specifies the help category of the item in `.FORWARDHELPTARGETNAME`. Valid values are `Alias`, `Cmdlet`, `HelpFile`, `Function`, `Provider`, `General`, `FAQ`, `Glossary`, `ScriptCommand`, `ExternalScript`, `Filter`, or `All`. Use this keyword to avoid conflicts when there are commands with the same name.

PowerShell

```
# .FORWARDHELPCATEGORY <Category>
```

.REMOTEHELPRUNSPACE <PSSession-variable>

Specifies a session that contains the help topic. Enter a variable that contains a `PSSession` object. This keyword is used by the `[Export-PSSession][09]` cmdlet to find the help content for the exported commands.

PowerShell

```
# .REMOTEHELPRUNSPACE <PSSession-variable>
```

.EXTERNALHELP

Specifies an XML-based help file for the script or function.

PowerShell

```
# .EXTERNALHELP <XML Help File>
```

The `.EXTERNALHELP` keyword is required when a function or script is documented in XML files. Without this keyword, `Get-Help` can't find the XML-based help file for the function or script.

The `.EXTERNALHELP` keyword takes precedence over other comment-based help keywords. If `.EXTERNALHELP` is present, `Get-Help` doesn't display comment-based help, even if it can't find a help topic that matches the value of the `.EXTERNALHELP` keyword.

If the function is exported by a module, set the value of the `.EXTERNALHELP` keyword to a filename without a path. `Get-Help` looks for the specified file name in a language-specific subdirectory of the module directory. There are no requirements for the name of the XML-based help file for a function, but a best practice is to use the following format:

Syntax

```
<ScriptModule.psm1>-help.xml
```

If the function isn't included in a module, include a path to the XML-based help file. If the value includes a path and the path contains UI-culture-specific subdirectories, `Get-Help` searches the subdirectories recursively for an XML file with the name of the script or function in accordance with the language fallback standards established for Windows, just as it does in a module directory.

For more information about the cmdlet help XML-based help file format, see [How to Write Cmdlet Help](#).

Placing Comment-Based Help in Functions

Article • 07/10/2023

This topic explains where to place comment-based help for a function so that the `Get-Help` cmdlet associates the comment-based help topic with the correct function.

Where to Place Comment-Based Help for a Function

- At the beginning of the function body.
- At the end of the function body.
- Before the `Function` keyword. When the function is in a script or script module, there can't be more than one blank line between the last line of the comment-based help and the `Function` keyword. Otherwise, `Get-Help` associates the help with the script, not with the function.

Examples of Help Placement in a Function

The following examples show each of the three placement options for comment-based help for a function.

Help at the Beginning of a Function Body

The following example shows comment-based at the beginning of a function body.

```
PowerShell

function MyProcess
{
    <#
        .DESCRIPTION
        The MyProcess function gets the Windows PowerShell process.
    #>

    Get-Process powershell
}
```

Help at the End of a Function Body

The following example shows comment-based help at the end of a function body.

PowerShell

```
function MyFunction
{
    Get-Process powershell

    <#
        .DESCRIPTION
        The MyProcess function gets the Windows PowerShell process.
    #>
}
```

Help Before the Function Keyword

The following examples shows comment-based help on the line before the function keyword.

PowerShell

```
<#
    .DESCRIPTION
    The MyProcess function gets the Windows PowerShell process.
#>
function MyFunction { Get-Process powershell}
```

Placing Comment-Based Help in Scripts

Article • 07/10/2023

This topic explains where to place comment-based help for a script so that the `Get-Help` cmdlet associates the comment-based help topic with scripts and not with any functions that might be in the script.

Where to Place Comment-Based Help for a Script

- At the beginning of the script file.

Script Help can be preceded in the script only by comments and blank lines.

- At the end of the script file.

If the first item in the script body (after the Help) is a function declaration, there must be at least two blank lines between the end of the script Help and the function declaration. Otherwise, the Help is interpreted as being Help for the function, not Help for the script.

Examples of Help Placement in a Script

The following examples show each of the placement options for comment-based help for a script.

Help at the Beginning of a Script

The following example shows comment-based at the beginning of a script.

```
PowerShell

<#
.DESCRIPTION
This script performs a series of network connection tests.
#>

param [string]$ComputerName
...
```

Help at the End of a Script

The following example shows comment-based at the end of a script.

PowerShell

```
...
function Ping { Test-Connection -ComputerName $ComputerName }

<#
.DESCRIPTION
This script performs a series of network connection tests.
#>
```

Autogenerated Elements of Comment-Based Help

Article • 03/24/2025

The `Get-Help` cmdlet automatically generates several elements of a comment-based topic. These autogenerated elements make comment-based help look very much like the help that's generated from XML files.

Autogenerated Elements

The `Get-Help` cmdlet automatically generates the following elements of a help topic. You can't edit these elements directly, but you can change the results by changing the source of the element.

Name

The Name section of a function Help topic is taken from the function name in the function definition. The Name of a script Help topic is taken from the script filename. To change the name or its capitalization, change the function definition or the script filename.

Syntax

The Syntax section of the Help topic is generated from the parameter list in the `param` statement of the function or script. To add detail to the Help topic syntax, such as the .NET type of a parameter, add the detail to the parameter list. If you don't specify a parameter type, the `Object` type is inserted as the default value.

Parameter List

The Parameters section of the Help topic is generated from the parameter list in the function or script and from the descriptions that you add using the `.PARAMETER` keyword or comments in the parameter list.

Parameters appear in the Parameters section in the same order that they appear in the parameter list. The spelling and capitalization of parameter names is also taken from the parameter list; it isn't affected by the parameter name specified by the `.PARAMETER` keyword.

Common Parameters

The common parameters are added to the syntax and parameter list of the Help topic, even if they have no effect. For more information about the common parameters, see [about_CommonParameters](#).

Parameter Attribute Table

`Get-Help` generates the table of parameter attributes that appears when you use the **Full** or **Parameter** parameter of `Get-Help`. The value of the **Required**, **Position**, and **Default** value attributes is taken from the function or script syntax.

Remarks

The Remarks section of the Help topic is automatically generated from the function or script name. You can't change or affect its content.

Examples of Comment-based Help

Article • 03/24/2025

This topic includes examples that demonstrate how to use comment-based help for scripts and functions.

Example 1: Comment-based Help for a Function

The following sample function includes comment-based Help.

PowerShell

```
function Add-Extension
{
    param ([string]$Name,[string]$Extension = "txt")
    $Name = $Name + "." + $Extension
    $Name

    <#
        .SYNOPSIS
        Adds a file name extension to a supplied name.

        .DESCRIPTION
        Adds a file name extension to a supplied name.
        Takes any strings for the file name or extension.

        .PARAMETER Name
        Specifies the file name.

        .PARAMETER Extension
        Specifies the extension. "Txt" is the default.

        .INPUTS
        None. You can't pipe objects to Add-Extension.

        .OUTPUTS
        System.String. Add-Extension returns a string with the extension or
        file name.

        .EXAMPLE
        PS> Add-Extension -Name "File"
        File.txt

        .EXAMPLE
        PS> Add-Extension -Name "File" -Extension "doc"
        File.doc

        .EXAMPLE
        PS> Add-Extension "File" "doc"
```

```
File.doc

.LINK
Online version: http://www.fabrikam.com/add-extension.html

.LINK
Set-Item
#>
}
```

The following output shows the results of a `Get-Help` command that displays the help for the `Add-Extension` function.

PowerShell

```
PS> Get-Help Add-Extension -Full
```

Output

NAME

Add-Extension

SYNOPSIS

Adds a file name extension to a supplied name.

SYNTAX

```
Add-Extension [[-Name] <String>] [[-Extension] <String>]
[<CommonParameters>]
```

DESCRIPTION

Adds a file name extension to a supplied name. Takes any strings for the file name or extension.

PARAMETERS

-Name

Specifies the file name.

Required? false

Position? 0

Default value

Accept pipeline input? false

Accept wildcard characters?

-Extension

Specifies the extension. "Txt" is the default.

Required? false

Position? 1

Default value

Accept pipeline input? false

Accept wildcard characters?

```
<CommonParameters>
    This cmdlet supports the common parameters: -Verbose, -Debug,
    -ErrorAction, -ErrorVariable, -WarningAction, -WarningVariable,
    -OutBuffer and -OutVariable. For more information, type
    "Get-Help about_CommonParameters".
```

INPUTS

None. You can't pipe objects to Add-Extension.

OUTPUTS

System.String. Add-Extension returns a string with the extension or file name.

----- EXAMPLE 1 -----

```
PS> Add-Extension -Name "File"
File.txt
```

----- EXAMPLE 2 -----

```
PS> Add-Extension -Name "File" -Extension "doc"
File.doc
```

----- EXAMPLE 3 -----

```
PS> Add-Extension "File" "doc"
File.doc
```

RELATED LINKS

Online version: <http://www.fabrikam.com/add-extension.html>
Set-Item

Example 2: Comment-based Help for a Script

The following sample function includes comment-based Help.

Notice the blank lines between the closing `#>` and the `param` statement. In a script that doesn't have a `param` statement, there must be at least two blank lines between the final comment in the Help topic and the first function declaration. Without these blank lines, `Get-Help` associates the Help topic with the function, instead of the script.

PowerShell

```
<#
.SYNOPSIS
Performs monthly data updates.

.DESCRIPTION
The Update-Month.ps1 script updates the registry with new data generated
```

```
 during the past month and generates a report.
```

```
.PARAMETER InputPath
```

```
Specifies the path to the CSV-based input file.
```

```
.PARAMETER OutputPath
```

```
Specifies the name and path for the CSV-based output file. By default,  
MonthlyUpdates.ps1 generates a name from the date and time it runs, and  
saves the output in the local directory.
```

```
.INPUTS
```

```
None. You can't pipe objects to Update-Month.ps1.
```

```
.OUTPUTS
```

```
None. Update-Month.ps1 doesn't generate any output.
```

```
.EXAMPLE
```

```
PS> .\Update-Month.ps1
```

```
.EXAMPLE
```

```
PS> .\Update-Month.ps1 -InputPath C:\Data\January.csv
```

```
.EXAMPLE
```

```
PS> .\Update-Month.ps1 -InputPath C:\Data\January.csv -OutputPath  
C:\Reports\2009\January.csv
```

```
#>
```

```
param ([string]$InputPath, [string]$OutputPath)
```

```
function Get-Data { }
```

The following command gets the script Help. Because the script isn't in a directory that's listed in the PATH environment variable, the `Get-Help` command that gets the script Help must specify the script path.

PowerShell

```
PS> Get-Help C:\ps-test\update-month.ps1 -Full
```

Output

NAME

```
C:\ps-test\Update-Month.ps1
```

SYNOPSIS

```
Performs monthly data updates.
```

SYNTAX

```
C:\ps-test\Update-Month.ps1 [-InputPath] <String> [[-OutputPath]  
<String>] [<CommonParameters>]
```

DESCRIPTION

The Update-Month.ps1 script updates the registry with new data generated during the past month and generates a report.

PARAMETERS

-InputPath

Specifies the path to the CSV-based input file.

Required?	true
Position?	0
Default value	
Accept pipeline input?	false
Accept wildcard characters?	

-OutputPath

Specifies the name and path for the CSV-based output file. By default, MonthlyUpdates.ps1 generates a name from the date and time it runs, and saves the output in the local directory.

Required?	false
Position?	1
Default value	
Accept pipeline input?	false
Accept wildcard characters?	

<CommonParameters>

This cmdlet supports the common parameters: -Verbose, -Debug, -ErrorAction, -ErrorVariable, -WarningAction, -WarningVariable, -OutBuffer and -OutVariable. For more information, type, "Get-Help about_CommonParameters".

INPUTS

None. You can't pipe objects to Update-Month.ps1.

OUTPUTS

None. Update-Month.ps1 doesn't generate any output.

----- EXAMPLE 1 -----

PS> .\Update-Month.ps1

----- EXAMPLE 2 -----

PS> .\Update-Month.ps1 -InputPath C:\Data\January.csv

----- EXAMPLE 3 -----

PS> .\Update-Month.ps1 -InputPath C:\Data\January.csv -OutputPath C:\Reports\2009\January.csv

RELATED LINKS

Example 3: Parameter Descriptions in a `param` Statement

This example shows how to insert parameter descriptions in the `param` statement of a function or script. This format is most useful when the parameter descriptions are brief.

PowerShell

```
function Add-Extension
{
    param
    (
        [string]
        # Specifies the file name.
        $Name,
        [string]
        # Specifies the file name extension. "Txt" is the default.
        $Extension = "txt"
    )
    $Name = $Name + "." + $Extension
    $Name

    <#
    .SYNOPSIS
    Adds a file name extension to a supplied name.
    ...
    #>
}
```

The results are the same as the results for Example 1. `Get-Help` interprets the parameter descriptions as though they were accompanied by the `.PARAMETER` keyword.

Example 4: Redirecting to an XML File

You can write XML-based Help topics for functions and scripts. Although comment-based Help is easier to implement, XML-based Help is required if you want more precise control over Help content or if you are translating Help topics into multiple languages. The following example shows the first few lines of the `Update-Month.ps1` script. The script uses the `.EXTERNALHELP` keyword to specify the path to an XML-based Help topic for the script.

PowerShell

```
# .EXTERNALHELP C:\MyScripts\Update-Month-Help.xml
```

```
param ([string]$InputPath, [string]$OutputPath)

function Get-Data { }
```

The following example shows the use of the `.EXTERNALHELP` keyword in a function.

```
PowerShell

function Add-Extension
{
    param ([string]$Name, [string]$Extension = "txt")
    $Name = $Name + "." + $Extension
    $Name

    # .EXTERNALHELP C:\ps-test\Add-Extension.xml
}
```

Example 5: Redirecting to a Different Help Topic

The following code is an excerpt from the beginning of the built-in `help` function in PowerShell, which displays one screen of Help text at a time. Because the Help topic for the `Get-Help` cmdlet describes the `Help` function, the `Help` function uses the `.FORWARDHELPTARGETNAME` and `.FORWARDHELPCATEGORY` keywords to redirect the user to the `Get-Help` cmdlet Help topic.

```
PowerShell

function help
{
    <#
        .FORWARDHELPTARGETNAME Get-Help
        .FORWARDHELPCATEGORY Cmdlet
    #>
    [CmdletBinding(DefaultParameterSetName='AllUsersView')]
    param(
        [Parameter(Position=0, ValueFromPipelineByPropertyName=$true)]
        [System.String]
        ${Name},
        ...
    }
```

The following command uses this feature. When a user types a `Get-Help` command for the `help` function, `Get-Help` displays the Help topic for the `Get-Help` cmdlet.

PowerShell

```
PS> Get-Help help
```

Output

NAME

Get-Help

SYNOPSIS

Displays information about Windows PowerShell cmdlets and concepts.

...

Writing Help for PowerShell Cmdlets

Article • 07/10/2023

PowerShell cmdlets can be useful, but unless your Help topics clearly explain what the cmdlet does and how to use it, the cmdlet may not get used or, even worse, it might frustrate users. The XML-based cmdlet Help file format enhances consistency, but great help requires much more.

If you have never written cmdlet Help, review the following guidelines. The XML schema required to author the cmdlet Help topic is described in the following section. Start with [Creating the Cmdlet Help File](#). That topic includes a description of the top-level XML nodes.

Writing Guidelines for Cmdlet Help

Write well

Nothing replaces a well-written topic. If you aren't a professional writer, find a writer or editor to help you. Another alternative is to copy your Help text into Microsoft Word and use the grammar and spelling checks to improve your work.

Write simply

Use simple words and phrases. Avoid jargon. Consider that many readers are equipped only with a foreign-language dictionary and your Help topic.

Write consistently

Help for related cmdlets should be similar (for example, `Get-Content` and `Set-Content`). Use the standard descriptions for standard parameters, like **Force** and **InputObject**. (Copy them from Help for the core cmdlets.) Use standard terms. For example, use "parameter", not "argument", and use "cmdlet" not "command" or "command-let."

Start the synopsis with a verb

The synopsis field informs the user what the cmdlet does, not what it's or how it works. Verbs create a task-based statement that informs users if this cmdlet meets their requirements. Use simple verbs like "get", "create", and "change." Avoid "set", which can be vague and fancy words like "modify".

Focus on objects

Most "get" cmdlets display something, but their primary function is to get an object. In your Help, focus on the object, so that users understand that the default display is one of many, and that they can use the methods and properties of the object that you retrieved for them in different ways.

Write detailed descriptions

Briefly list everything that the cmdlet can do in the detailed description. If the main function is to change one property, but the cmdlet can change all properties, list this in the detailed description.

Use conventional syntax

Use the standard Backus-Naur format which is common for Windows and Unix command-line Help.

Use Microsoft .NET types for parameter values

The placeholders for parameter values (in the syntax and parameter descriptions) show the .NET Framework types of the objects that the parameter will accept. The PowerShell team developed this convention to help teach users about the .NET Framework.

Write complete parameter descriptions

Parameter descriptions must inform users of two things: what the parameter does (its effect) and what they must type for the parameter values.

Write practical examples

The examples should show how to use all of the parameters, but the most important thing is to show how to use the cmdlet in real-world tasks. Start with a simple example and write increasingly complex examples. In the final example, show how to use the cmdlet in a pipeline.

Use the Notes field

Use the Notes field to explain concepts that users need to understand the cmdlet. You can also use notes to help users avoid common errors. Avoid URLs as they change.

Instead, provide users terms to search for.

Test your Help

Test the Help just like you test your code. Have friends and colleagues read your Help content and provide feedback. You can also solicit feedback from newsgroups.

How to create the cmdlet help file

Article • 07/10/2023

ⓘ Note

Manual authoring of XML-based help is very difficult. The **PlatyPS** module allows you to write help in Markdown and then convert it to XML-based help. This makes it much easier to write and maintain help. **PlatyPS** can also create the Updateable Help packages for you. For more information, see [Create XML-based help using PlatyPS](#).

This section describes how to create a valid XML file that contains content for Windows PowerShell cmdlet Help topics. This section discusses how to name the Help file, how to add the appropriate XML headers, and how to add nodes that will contain the different sections of the cmdlet Help content.

ⓘ Note

For a complete view of a Help file, open one of the `dll-Help.xml` files located in the Windows PowerShell installation directory. For example, the `Microsoft.PowerShell.Commands.Management.dll-Help.xml` file contains content for several of the PowerShell cmdlets.

How to create a cmdlet help file

1. Create a text file and save it using UTF8 encoding. The filename must have the following format so that Windows PowerShell can detect it as a cmdlet Help file.

```
<PSSnapInAssemblyName>.dll-Help.xml
```

2. Add the following XML headers to the text file. Be aware that the file will be validated against the Microsoft Assistance Markup Language (MAML) schema. Currently, PowerShell doesn't provide any tools to validate the file.

```
<?xml version="1.0" encoding="utf-8" ?> <helpItems xmlns="http://msh"  
schema="maml">
```

3. Add a **Command** node to the cmdlet Help file for each cmdlet in the assembly. Each node within the **Command** node relates to the different sections of the

cmdlet Help topic.

The following table lists the XML element for each node, followed by a descriptions of each node.

 Expand table

Node	Description
<details>	Adds content for the NAME and SYNOPSIS sections of the cmdlet Help topic. For more information, see How to Add the Cmdlet Name and Synopsis .
<maml:description>	Adds content for the DESCRIPTION section of the cmdlet Help topic. For more information, see How to Add the Detailed Description to a Cmdlet Help Topic .
<command:syntax>	Adds content for the SYNTAX section of the cmdlet Help topic. For more information, see How to Add Syntax to a Cmdlet Help Topic .
<command:parameters>	Adds content for the PARAMETERS section of the cmdlet Help topic. For more information, see How to Add Parameters to a Cmdlet Help Topic .
<command:inputTypes>	Adds content for the INPUTS section of the cmdlet Help topic. For more information, see How to Add Input Types to a Cmdlet Help Topic .
<command:returnValues>	Adds content for the OUTPUTS section of the cmdlet Help topic. For more information, see How to Add Return Values to a Cmdlet Help Topic .
<maml:alertset>	Adds content for the NOTES section of the cmdlet Help topic. For more information, see How to add Notes to a Cmdlet Help Topic .
<command:examples>	Adds content for the EXAMPLES section of the cmdlet Help topic. For more information, see How to Add Examples to a Cmdlet Help Topic .
<maml:relatedLinks>	Adds content for the RELATED LINKS section of the cmdlet Help topic. For more information, see How to Add Related Links to a Cmdlet Help Topic .

Example

Here is an example of a **Command** node that includes the nodes for the various sections of the cmdlet Help topic.

XML

```
<command:command
    xmlns:maml="http://schemas.microsoft.com/maml/2004/10"
    xmlns:command="http://schemas.microsoft.com/maml/dev/command/2004/10"
    xmlns:dev="http://schemas.microsoft.com/maml/dev/2004/10">
    <command:details>
        <!--Add name and synopsis here-->
    </command:details>
    <maml:description>
        <!--Add detailed description here-->
    </maml:description>
    <command:syntax>
        <!--Add syntax information here-->
    </command:syntax>
    <command:parameters>
        <!--Add parameter information here-->
    </command:parameters>
    <command:inputTypes>
        <!--Add input type information here-->
    </command:inputTypes>
    <command:returnValues>
        <!--Add return value information here-->
    </command:returnValues>
    <maml:alertSet>
        <!--Add Note information here-->
    </maml:alertSet>
    <command:examples>
        <!--Add cmdlet examples here-->
    </command:examples>
    <maml:relatedLinks>
        <!--Add links to related content here-->
    </maml:relatedLinks>
</command:command>
```

How to add the cmdlet name and synopsis to a cmdlet help topic

Article • 07/10/2023

ⓘ Note

Manual authoring of XML-based help is very difficult. The **PlatyPS** module allows you to write help in Markdown and then convert it to XML-based help. This makes it much easier to write and maintain help. **PlatyPS** can also create the Updateable Help packages for you. For more information, see [Create XML-based help using PlatyPS](#).

This section describes how to add content that's displayed in the **NAME** and **SYNOPSIS** sections of the cmdlet help. In the Help file, this content is added to the Command node for each cmdlet.

ⓘ Note

For a complete view of a Help file, open one of the `dll-Help.xml` files located in the PowerShell installation directory. For example, the `Microsoft.PowerShell.Commands.Management.dll-Help.xml` file contains content for several of the PowerShell cmdlets.

To add the cmdlet name and a synopsis

- The cmdlet Help can display two descriptions for the cmdlet. The first description is a short description that's referred to as the synopsis. The second description is a more detailed description that's discussed in [Adding the Detailed Description to a Cmdlet Help Topic](#). Both these descriptions should be written as a single paragraph.
- In the synopsis don't repeat the cmdlet name. Informing the user that the `Get-Server` cmdlet gets a server is brief, but not informative. Instead, use synonyms and add details to the description.

Example: "Gets an object that represents a local or remote computer."

- Use simple verbs like "get", "create", and "change" in the synopsis. Avoid using "set" because it is vague, and fancy words such as "modify."

Example: "Gets information about the Authenticode signature in a file."

- Write in active voice. For example, "Use the TimeSpan object..." is much clearer than "the TimeSpan object can be used to..."
- Avoid the verb "display" when describing cmdlets that get objects. Although Windows PowerShell displays cmdlet data, it's important to introduce users to the concept that the cmdlet returns .NET Framework objects whose data may not be displayed. If you emphasize the display, the user might not realize that the cmdlet may have returned many other useful properties and methods that aren't displayed.

How to Add a Cmdlet Description

Article • 07/10/2023

ⓘ Note

Manual authoring of XML-based help is very difficult. The **PlatyPS** module allows you to write help in Markdown and then convert it to XML-based help. This makes it much easier to write and maintain help. **PlatyPS** can also create the Updateable Help packages for you. For more information, see [Create XML-based help using PlatyPS](#).

This section describes how to add content that's displayed in the **DESCRIPTION** section of the cmdlet Help. In the Help file, this content is added to the **Command** node for each cmdlet.

ⓘ Note

For a complete view of a Help file, open one of the `dll-Help.xml` files located in the PowerShell installation directory. For example, the `Microsoft.PowerShell.Commands.Management.dll-Help.xml` file contains content for several of the PowerShell cmdlets.

To Add a Description

- Begin by explaining the basic features of the cmdlet in more detail. In many cases, you can explain the terms used in the cmdlet name and illustrate unfamiliar concepts with an example. For example, if the cmdlet appends data to a file, explain that it adds data to the end of an existing file.
- To find all of the features of the cmdlet, review the parameter list. Describe the primary function of the cmdlet, and then include other functions and features. For example, if the main function of the cmdlet is to change one property, but the cmdlet can change all of the properties, say so in the detailed description. If the cmdlet parameters let the users solicit information in different ways, explain it.
- Include information on ways that users can use the cmdlet, in addition to the obvious uses. For example, you can use the object that the `Get-Host` cmdlet retrieves to change the color of text in the Windows PowerShell command window.

Example: "The `Get-Acl` cmdlet gets objects that represent the security descriptor of a file or resource. The security descriptor contains the access control lists (ACLs) of the resource. The ACL specifies the permissions that users and user groups have to access the resource."

- The detailed description should describe the cmdlet, but it shouldn't describe concepts that the cmdlet uses. Place concept definitions in Additional Notes.

How to add syntax to a cmdlet help topic

Article • 07/10/2023

ⓘ Note

Manual authoring of XML-based help is very difficult. The **PlatyPS** module allows you to write help in Markdown and then convert it to XML-based help. This makes it much easier to write and maintain help. **PlatyPS** can also create the Updateable Help packages for you. For more information, see [Create XML-based help using PlatyPS](#).

Before you start to code the XML for the syntax diagram in the cmdlet Help file, read this section to get a clear picture of the kind of data you need to provide, such as the parameter attributes, and how that data is displayed in the syntax diagram..

Parameter attributes

- Required
 - If true, the parameter must appear in all commands that use the parameter set.
 - If false, the parameter is optional in all commands that use the parameter set.
- Position
 - If named, the parameter name is required.
 - If positional, the parameter name is optional. When it's omitted, the parameter value must be in the specified position in the command. For example, if the value is position="1", the parameter value must be the first or only unnamed parameter value in the command.
- Pipeline Input
 - If true (ByValue), you can pipe input to the parameter. The input is associated with ("bound to") the parameter even if the property name and the object type don't match the expected type. The PowerShell parameter binding components try to convert the input to the correct type and fail the command only when the type can't be converted. Only one parameter in a parameter set can be associated by value.
 - If true (ByPropertyName), you can pipe input to the parameter. However, the input is associated with the parameter only when the parameter name matches the name of a property of the input object. For example, if the parameter name

is `Path`, objects piped to the cmdlet are associated with that parameter only when the object has a property named path.

- If true (ByValue, ByPropertyName), you can pipe input to the parameter either by property name or by value. Only one parameter in a parameter set can be associated by value.
- If false, you can't pipe input to this parameter.
- Globbing
 - If true, the text that the user types for the parameter value can include wildcard characters.
 - If false, the text that the user types for the parameter value can't include wildcard characters.

Parameter value attributes

- Required
 - If true, the specified value must be used whenever using the parameter in a command.
 - If false, the parameter value is optional. Typically, a value is optional only when it's one of several valid values for a parameter, such as in an enumerated type.

The **Required** attribute of a parameter value is different from the **Required** attribute of a parameter.

The required attribute of a parameter indicates whether the parameter (and its value) must be included when invoking the cmdlet. In contrast, the required attribute of a parameter value is used only when the parameter is included in the command. It indicates whether that particular value must be used with the parameter.

Typically, parameter values that are placeholders are required and parameter values that are literal aren't required, because they're one of several values that might be used with the parameter.

Gathering syntax information

1. Start with the cmdlet name.

SYNTAX
Get-Tech

2. List all the parameters of the cmdlet. Type a hyphen (-) before each parameter name. Separate the parameters into parameter sets (some cmdlets may have only one parameter set). In this example the Get-Tech cmdlet has two parameter sets.

SYNTAX

```
Get-Tech -Name -Type  
Get-Tech -Id -List -Type
```

Start each parameter set with the cmdlet name.

List the default parameter set first. The default parameter is specified by the cmdlet class.

For each parameter set, list its unique parameter first, unless there are positional parameters that must appear first. In the previous example, the Name and Id parameters are unique parameters for the two parameter sets (each parameter set must have one parameter that's unique to that parameter set). This makes it easier for users to identify what parameter they need to supply for the parameter set.

List the parameters in the order that they should appear in the command. If the order doesn't matter, list related parameters together, or list the most frequently used parameters first.

Be sure to list the WhatIf and Confirm parameters if the cmdlet supports ShouldProcess.

Don't list the common parameters (such as Verbose, Debug, and ErrorAction) in your syntax diagram. The `Get-Help` cmdlet adds that information for you when it displays the Help topic.

3. Add the parameter values. In PowerShell, parameter values are represented by their .NET type. However, the type name can be abbreviated, such as "string" for `System.String`.

SYNTAX

```
Get-Tech -Name string -Type Basic Advanced  
Get-Tech -Id int -List -Type Basic Advanced
```

Abbreviate types as long as their meaning is clear, such as `string` for `System.String` and `int` for `System.Int32`.

List all values of enumerations, such as the `-Type` parameter in the previous example, which can be set to **basic** or **advanced**.

Switch parameters, such as `-List` in the previous example, don't have values.

4. Add angle brackets to parameters values that are placeholder, as compared to parameter values that are literals.

SYNTAX

```
Get-Tech -Name <string> -Type Basic Advanced  
Get-Tech -Id <int> -List -Type Basic Advanced
```

5. Enclose optional parameters and their values in square brackets.

SYNTAX

```
Get-Tech -Name <string> [-Type Basic Advanced]  
Get-Tech -Id <int> [-List] [-Type Basic Advanced]
```

6. Enclose optional parameters names (for positional parameters) in square brackets.
The name for parameters that are positional, such as the `Name` parameter in the following example, don't have to be included in the command.

SYNTAX

```
Get-Tech [-Name] <string> [-Type Basic Advanced]  
Get-Tech -Id <int> [-List] [-Type Basic Advanced]
```

7. If a parameter value can contain multiple values, such as a list of names in the `Name` parameter, add a pair of square brackets directly following the parameter value.

SYNTAX

```
Get-Tech [-Name] <string[]> [-Type Basic Advanced]  
Get-Tech -Id <int[]> [-List] [-Type Basic Advanced]
```

8. If the user can choose from parameters or parameter values, such as the `Type` parameter, enclose the choices in curly brackets and separate them with the exclusive OR symbol();.

SYNTAX

```
Get-Tech [-Name] <string[]> [-Type {Basic | Advanced}]  
Get-Tech -Id <int[]> [-List] [-Type {Basic | Advanced}]
```

9. If the parameter value must use specific formatting, such as quotation marks or parentheses, show the format in the syntax.

SYNTAX

```
Get-Tech [-Name] <"string[]"> [-Type {Basic | Advanced}]  
Get-Tech -Id <int[]> [-List] [-Type {Basic | Advanced}]
```

Coding the syntax diagram XML

The syntax node of the XML begins immediately after the description node, which ends with the `</maml:description>` tag. For information about gathering the data used in the syntax diagram, see [Gathering Syntax Information](#).

Adding a syntax node

The syntax diagram displayed in the cmdlet Help topic is generated from the data in the syntax node of the XML. The syntax node is enclosed in a pair of `<command:syntax>` tags. With each parameter set of the cmdlet enclosed in a pair of `<command:syntaxitem>` tags. There is no limit to the number of `<command:syntaxitem>` tags that you can add.

The following example shows a syntax node that has syntax item nodes for two parameter sets.

XML

```
<command:syntax>  
  <command:syntaxItem>  
    ...  
    <!--Parameter Set 1 (default parameter set) parameters go here-->  
    ...  
  </command:syntaxItem>  
  <command:syntaxItem>  
    ...  
    <!--Parameter Set 2 parameters go here-->  
    ...
```

```
</command:syntaxItem>  
</command:syntax>
```

Adding the cmdlet name to the parameter set data

Each parameter set of the cmdlet is specified in a syntax item node. Each syntax item node begins with a pair of `<maml:name>` tags that include the name of the cmdlet.

The following example includes a syntax node that has syntax item nodes for two parameter sets.

XML

```
<command:syntax>  
  <command:syntaxItem>  
    <maml:name>Cmdlet-Name</maml:name>  
  </command:syntaxItem>  
  <command:syntaxItem>  
    <maml:name>Cmdlet-Name</maml:name>  
  </command:syntaxItem>  
</command:syntax>
```

Adding parameters

Each parameter added to the syntax item node is specified within a pair of `<command:parameter>` tags. You need a pair of `<command:parameter>` tags for each parameter included in the parameter set, with the exception of the common parameters that are provided by PowerShell.

The attributes of the opening `<command:parameter>` tag determine how the parameter appears in the syntax diagram. For information on parameter attributes, see [Parameter Attributes](#).

① Note

The `<command:parameter>` tag supports a child element `<maml:description>` whose content is never displayed. The parameter descriptions are specified in the parameter node of the XML. To avoid inconsistencies between the information in the syntax item nodes and the parameter node, omit the (`<maml:description>` or leave it empty.

The following example includes a syntax item node for a parameter set with two parameters.

XML

```
<command:syntaxItem>
  <maml:name>Cmdlet-Name</maml:name>
  <command:parameter required="true" globbing="true"
    pipelineInput="true (ByValue)" position="1">
    <maml:name>ParameterName1</maml:name>
    <command:parameterValue required="true">
      string[]
    </command:parameterValue>
  </command:parameter>
  <command:parameter required="true" globbing="true"
    pipelineInput="true (ByPropertyName)">
    <maml:name>ParameterName2</maml:name>
    <command:parameterValue required="true">
      int32[]
    </command:parameterValue>
  </command:parameter>
</command:syntaxItem>
```

How to add parameter information

Article • 07/10/2023

ⓘ Note

Manual authoring of XML-based help is very difficult. The **PlatyPS** module allows you to write help in Markdown and then convert it to XML-based help. This makes it much easier to write and maintain help. **PlatyPS** can also create the Updateable Help packages for you. For more information, see [Create XML-based help using PlatyPS](#).

This section describes how to add content that's displayed in the **PARAMETERS** section of the cmdlet Help topic. The **PARAMETERS** section of the Help topic lists each of the parameters of the cmdlet and provides a detailed description of each parameter.

The content of the **PARAMETERS** section should be consistent with the content of the **SYNTAX** section of the Help topic. It's the responsibility of the Help author to make sure that both the **Syntax** and **Parameters** node contain similar XML elements.

ⓘ Note

For a complete view of a Help file, open one of the `dll-Help.xml` files located in the PowerShell installation directory. For example, the `Microsoft.PowerShell.Commands.Management.dll-Help.xml` file contains content for several of the PowerShell cmdlets.

To add parameters

1. Open the cmdlet Help file and locate the **Command** node for the cmdlet you are documenting. If you are adding a new cmdlet you will need to create a new **Command** node. Your Help file will contain a **Command** node for each cmdlet that you are providing Help content for. Here is an example of a blank **Command** node.

XML

```
<command:command>
</command:command>
```

2. Within the **Command** node, locate the **Description** node and add a **Parameters** node as shown below. Only one **Parameters** node is allowed, and it should immediately follow the **Syntax** node.

XML

```
<command:command>
  <command:details></command:details>
  <maml:description></maml:description>
  <command:syntax></command:syntax>
  <command:parameters>
    </command:parameters>
</command:command>
```

3. Within the **Parameters** node, add a **Parameter** node for each parameter of the cmdlet as shown below.

In this example, a **Parameter** node is added for three parameters.

XML

```
<command:parameters>
  <command:parameter></command:parameter>
  <command:parameter></command:parameter>
  <command:parameter></command:parameter>
</command:parameters>
```

Because these are the same XML tags that are used in the **Syntax** node, and because the parameters specified here must match the parameters specified by the **Syntax** node, you can copy the **Parameter** nodes from the **Syntax** node and paste them into the **Parameters** node. However, be sure to copy only one instance of a **Parameter** node, even if the parameter is specified in multiple parameter sets in the syntax.

4. For each **Parameter** node, set the attribute values that define the characteristics of each parameter. These attributes include the following: **required**, **globbing**, **pipelineInput**, and **position**.

XML

```
<command:parameters>
  <command:parameter required="true" globbing="true"
    pipelineInput="false" position="named">
  </command:parameter>
  <command:parameter required="false" globbing="false"
    pipelineInput="false" position="named">
  </command:parameter>
```

```
<command:parameter required="false" globbing="false"
    pipelineInput="false" position="named" ></command:parameter>
</command:parameters>
```

5. For each **Parameter** node, add the name of the parameter. Here is an example of the parameter name added to the **Parameter** node.

XML

```
<command:parameters>
    <command:parameter required="true" globbing="true"
        pipelineInput="false" position="named">
        <maml:name> Add parameter name... </maml:name>
    </command:parameter>
</command:parameters>
```

6. For each **Parameter** node, add the description of the parameter. Here is an example of the parameter description added to the **Parameter** node.

XML

```
<command:parameters>
    <command:parameter required="true" globbing="true"
        pipelineInput="false" position="named">
        <maml:name> Add parameter name... </maml:name>
        <maml:description>
            <maml:para> Add parameter description... </maml:para>
        </maml:description>
    </command:parameter>
</command:parameters>
```

7. For each **Parameter** node, add the .NET type of the parameter. The parameter type is displayed along with the parameter name.

Here is an example of the parameter .NET type added to the **Parameter** node.

XML

```
<command:parameters>
    <command:parameter required="true" globbing="true"
        pipelineInput="false" position="named">
        <maml:name> Add parameter name... </maml:name>
        <maml:description>
            <maml:para> Add parameter description... </maml:para>
        </maml:description>
        <dev:type> Add .NET Framework type... </dev:type>
    </command:parameter>
</command:parameters>
```

8. For each **Parameter** node, add the default value of the parameter. The following sentence is added to the parameter description when the content is displayed: **DefaultValue** is the default.

Here is an example of the parameter default value is added to the **Parameter** node.

XML

```
<command:parameters>
  <command:parameter required="true" globbing="true"
    pipelineInput="false" position="named">
    <maml:name> Add parameter name... </maml:name>
    <maml:description>
      <maml:para> Add parameter description... </maml:para>
    </maml:description>
    <dev:type> Add .NET Framework type... </dev:type>
    <dev:defaultValue> Add default value...</dev:defaultValue>
  </command:parameter>
</command:parameters>
```

9. For each Parameter that has multiple values, add a **possibleValues** node.

Here is an example of the of a **possibleValues** node that defines two possible values for the parameter

XML

```
<dev:possibleValues>
  <dev:possibleValue>
    <dev:value>Unknown</dev:value>
    <maml:description>
      <maml:para></maml:para>
    </maml:description>
  </dev:possibleValue>
  <dev:possibleValue>
    <dev:value>String</dev:value>
    <maml:description>
      <maml:para></maml:para>
    </maml:description>
  </dev:possibleValue>
</dev:possibleValues>
```

Here are some things to remember when adding parameters.

- The attributes of the parameter aren't displayed in all views of the cmdlet Help topic. However, they're displayed in a table following the parameter description when the user asks for the **Full** (`Get-Help <cmdletname> -Full`) or **Parameter** (`Get-Help <cmdletname> -Parameter`) view of the topic.

- The parameter description is one of the most important parts of a cmdlet Help topic. The description should be brief, as well as thorough. Also, remember that if the parameter description becomes too long, such as when two parameters interact with each other, you can add more content in the **NOTES** section of the cmdlet Help topic.

The parameter description provides two types of information.

- What the cmdlet does when the parameter is used.
- What a legal value is for the parameter.
- Because the parameter values are expressed as .NET objects, users need more information about these values than they would in a traditional command-line Help. Tell the user what type of data the parameter is designed to accept, and include examples.

The default value of the parameter is the value that's used if the parameter isn't specified on the command line. Note that the default value is optional, and isn't needed for some parameters, such as required parameters. However, you should specify a default value for most optional parameters.

The default value helps the user to understand the effect of not using the parameter. Describe the default value very specifically, such as the "Current directory" or the "PowerShell installation directory (`$PSHOME`)" for an optional path. You can also write a sentence that describes the default, such as the following sentence used for the **PassThru** parameter: "If **PassThru** isn't specified, the cmdlet doesn't pass objects down the pipeline." Also, because the value is displayed opposite the field name **Default value**, you don't need to include the term "default value" in the entry.

The default value of the parameter isn't displayed in all views of the cmdlet Help topic. However, it's displayed in a table (along with the parameter attributes) following the parameter description when the user asks for the **Full** (`Get-Help <cmdletname> -Full`) or **Parameter** (`Get-Help <cmdletname> -Parameter`) view of the topic.

The following XML shows a pair of `<dev:defaultValue>` tags added to the `<command:parameter>` node. Notice that the default value follows immediately after the closing `</command:parameterValue>` tag (when the parameter value is specified) or the closing `</maml:description>` tag of the parameter description. name.

XML

```
<command:parameters>
  <command:parameter required="true" globbing="true">
```

```

    pipelineInput="false" position="named">
<maml:name> Parameter name </maml:name>
<maml:description>
    <maml:para> Parameter Description </maml:para>
</maml:description>
<command:parameterValue required="true">
    Value
</command:parameterValue>
<dev:defaultValue> Default parameter value </dev:defaultValue>
</command:parameter>
</command:parameters>

```

Add Values for Enumerated Types

If the parameter has multiple values or values of an enumerated type, you can use an optional `<dev:possibleValues>` node. This node allows you to specify a name and description for multiple values.

Be aware that the descriptions of the enumerated values don't appear in any of the default Help views displayed by the `Get-Help` cmdlet, but other Help viewers may display this content in their views.

The following XML shows a `<dev:possibleValues>` node with two values specified.

XML

```

<command:parameters>
<command:parameter required="true" globbing="true"
    pipelineInput="false" position="named">
<maml:name> Parameter name </maml:name>
<maml:description>
    <maml:para> Parameter Description </maml:para>
</maml:description>
<command:parameterValue required="true">
    Value
</command:parameterValue>
<dev:defaultValue> Default parameter value </dev:defaultValue>
<dev:possibleValues>
    <dev:possibleValue>
        <dev:value> Value 1 </dev:value>
        <maml:description>
            <maml:para> Description 1 </maml:para>
        </maml:description>
    <dev:possibleValue>
        <dev:value> Value 2 </dev:value>
        <maml:description>
            <maml:para> Description 2 </maml:para>
        </maml:description>
    <dev:possibleValue>
</dev:possibleValues>

```

```
</command:parameter>  
</command:parameters>
```

How to add input types to a cmdlet help topic

Article • 07/10/2023

ⓘ Note

Manual authoring of XML-based help is very difficult. The **PlatyPS** module allows you to write help in Markdown and then convert it to XML-based help. This makes it much easier to write and maintain help. **PlatyPS** can also create the Updateable Help packages for you. For more information, see [Create XML-based help using PlatyPS](#).

This section describes how to add an **INPUTS** section to a PowerShell cmdlet Help topic. The **INPUTS** section lists the .NET classes of objects that the cmdlet accepts as input from the pipeline, either by value or by property name.

There is no limit to the number of classes that you can add to an **INPUTS** section. The input types are enclosed in a `<command:inputTypes>` node, with each class enclosed in a `<command:inputType>` element.

The schema includes two `<maml:description>` elements in each `<command:inputType>` element. However, the `Get-Help` cmdlet displays only the content of the `<command:inputType>/<maml:description>` element.

Beginning in PowerShell 3.0, the `Get-Help` cmdlet displays the content of the `<maml:uri>` element. This element lets you direct users to topics that describe the .NET class.

The following XML shows the `<maml:inputTypes>` node.

XML

```
<command:inputTypes>
  <command:inputType>
    <dev:type>
      <maml:name> Class name </maml:name>
      <maml:uri> URI of a topic that describes the class </maml:uri>
      <maml:description/>
    </dev:type>
    <maml:description>
      <maml:para> Brief description </maml:para>
    </maml:description>
  </command:inputType>
</command:inputTypes>
```

```
</command:inputType>  
</command:inputTypes>
```

The following XML shows an example of using the `<maml:inputTypes>` node to document an input type.

XML

```
<command:inputTypes>  
  <command:inputType>  
    <dev:type>  
      <maml:name>System.DateTime</maml:name>  
  
      <maml:uri>https://learn.microsoft.com/dotnet/api/system.datetime</maml:uri>  
        <maml:description/>  
      </dev:type>  
      <maml:description>  
        <maml:para> You can pipe a date to the Set-Date cmdlet. <maml:para>  
        <maml:description>  
      </command:inputType>  
</command:inputTypes>
```

How to add return values to a cmdlet help topic

Article • 07/10/2023

This section describes how to add an **OUTPUTS** section to a PowerShell cmdlet Help topic. The **OUTPUTS** section lists the .NET classes of objects that the cmdlet returns or passes down the pipeline.

There is no limit to the number of classes that you can add to the **OUTPUTS** section. The return types of a cmdlet are enclosed in a `<command:returnValues>` node, with each class enclosed in a `<command:returnValue>` element.

If a cmdlet doesn't generate any output, use this section to indicate that there is no output. For example, in place of the class name, write **None** and provide a brief explanation. If the cmdlet generates output conditionally, use this node to explain the conditions and describe the conditional output.

The schema includes two `<maml:description>` elements in each `<command:returnValue>` element. However, the `Get-Help` cmdlet displays only the content of the `<command:returnValue>/<maml:description>` element.

Beginning in PowerShell 3.0, the `Get-Help` cmdlet displays the content of the `<maml:uri>` element. This element lets you direct users to topics that describe the .NET class.

The following XML shows the `<maml:returnValues>` node.

XML

```
<command:returnValues>
  <command:returnValue>
    <dev:type>
      <maml:name> Class Name </maml:name>
      <maml:uri> URI of a topic that describes the class </maml:uri>
      <maml:description/>
    </dev:type>
    <maml:description>
      <maml:para> Brief description <maml:para>
    </maml:description>
  </command:returnValue>
</command:returnValues>
```

The following XML shows an example of using the `<maml:returnValues>` node to document an output type.

XML

```
<command:returnValues>
  <command:returnValue>
    <dev:type>
      <maml:name> System.DateTime </maml:name>
      <maml:uri> https://learn.microsoft.com/dotnet/api/system.datetime
    </maml:uri>
    <maml:description/>
  </dev:type>
  <maml:description>
    <maml:para> Get-Date returns a DateTime object. <maml:para>
  </maml:description>
</command: returnValue>
</command: returnValues>
```

How to add notes to a cmdlet help topic

Article • 07/10/2023

ⓘ Note

Manual authoring of XML-based help is very difficult. The **PlatyPS** module allows you to write help in Markdown and then convert it to XML-based help. This makes it much easier to write and maintain help. **PlatyPS** can also create the Updateable Help packages for you. For more information, see [Create XML-based help using PlatyPS](#).

This section describes how to add a **NOTES** section to a PowerShell cmdlet Help topic. The **NOTES** section is used to explain details that don't fit easily into the other structured sections, such as a more detailed explanation of a parameter. This content could include comments on how the cmdlet works with a specific provider, some unique, yet important, uses of the cmdlet, or ways to avoid possible error conditions.

The **NOTES** section is defined using a single `<maml:alertset>` node. There are no limits to the number of notes that you can add to a Notes section. For each note, add a pair of `<maml:alert>` tags to the `<maml:alertset>` node. The content of each note is added within a set of `<maml:para>` tags. Use blank `<maml:para>` tags for spacing.

XML

```
<maml:alertSet>
  <maml:title>Optional title for Note</maml:title>
  <maml:alert>
    <maml:para>Note 1</maml:para>
    <maml:para>Note a</maml:para>
  </maml:alert>
  <maml:alert>
    <maml:para>Note 2</maml:para>
  </maml:alert>
</maml:alertSet>
```

How to add examples to a cmdlet help topic

Article • 07/10/2023

ⓘ Note

Manual authoring of XML-based help is very difficult. The **PlatyPS** module allows you to write help in Markdown and then convert it to XML-based help. This makes it much easier to write and maintain help. **PlatyPS** can also create the Updateable Help packages for you. For more information, see [Create XML-based help using PlatyPS](#).

Things to know about examples in cmdlet help

- List all of the parameter names in the command, even when the parameter names are optional. This helps the user to interpret the command easily.
- Avoid aliases and partial parameter names, even though they work in PowerShell.
- In the example description, explain the rational for the construction of the command. Explain why you chose particular parameters and values, and how you use variables.
- If the command uses expressions, explain them in detail.
- If the command uses properties and methods of objects, especially properties that don't appear in the default display, use the example as an opportunity tell the user about the object.

Help Views that Display Examples

Examples appear only in the Detailed and Full views of cmdlet Help.

Adding an examples node

The following XML shows how to add an **Examples** node that contains a single **Example** node. Add additional example nodes for each examples you want to include in the topic.

XML

```
<command:examples>
  <command:example>
    </command:example>
</command:examples>
```

Adding an example title

The following XML shows how to add a **title** for the example. The **title** is used to set the example apart from other examples. PowerShell uses a standard header that includes a sequential example number.

XML

```
<command:examples>
  <command:example>
    <maml:title>----- EXAMPLE 1 -----</maml:title>
  </command:example>
</command:examples>
```

Adding preceding characters

The following XML shows how to add characters, such as the Windows PowerShell prompt, that are displayed immediately before the example command (without any intervening spaces). PowerShell uses the Windows PowerShell prompt: `C:\PS>`.

XML

```
<command:examples>
  <command:example>
    <maml:title>----- EXAMPLE 1 -----</maml:title>
    <maml:introduction>
      <maml:para>C:\PS></maml:para>
    </maml:introduction>
  </command:example>
</command:examples>
```

Adding the command

The following XML shows how to add the actual command of the example. When adding the command, type the entire name (do not use alias) of cmdlets and parameters. Also, use lowercase characters whenever possible.

XML

```
<command:examples>
  <command:example>
    <maml:title>----- EXAMPLE 1 -----</maml:title>
    <maml:introduction>
      <maml:para>C:\PS</maml:para>
    </maml:introduction>
    <dev:code> command </dev:code>
  </command:example>
</command:examples>
```

Adding a Description

The following XML shows how to add a description for the example. PowerShell uses a single set of `<maml:para>` tags for the description, even though multiple `<maml:para>` tags can be used.

XML

```
<command:examples>
  <command:example>
    <maml:title>----- EXAMPLE 1 -----</maml:title>
    <maml:introduction>
      <maml:para>C:\PS</maml:para>
    </maml:introduction>
    <dev:code> command </dev:code>
    <dev:remarks>
      <maml:para> command description </maml:para>
    </dev:remarks>
  </command:example>
</command:examples>
```

Adding example output

The following XML shows how to add the output of the command. The command results information is optional, but in some cases it's helpful to demonstrate the effect of using specific parameters. PowerShell uses two sets of blank `<maml:para>` tags to separate the command output from the command.

XML

```
<command:examples>
  <command:example>
    <maml:title>----- EXAMPLE 1 -----</maml:title>
    <maml:introduction>
```

```
<maml:para>C:\PS></maml:para>
</maml:introduction>
<dev:code> command </dev:code>
<dev:remarks>
  <maml:para> command description </maml:para>
  <maml:para></maml:para>
  <maml:para></maml:para>
  <maml:para> command output </maml:para>
</dev:remarks>
</command:example>
</command:examples>
```

How to add related links to a cmdlet help topic

Article • 07/10/2023

ⓘ Note

Manual authoring of XML-based help is very difficult. The **PlatyPS** module allows you to write help in Markdown and then convert it to XML-based help. This makes it much easier to write and maintain help. **PlatyPS** can also create the Updateable Help packages for you. For more information, see [Create XML-based help using PlatyPS](#).

This section describes how to add references to other content that's related to a PowerShell cmdlet Help topic. Because these references appear in a command window, they don't link directly to the referenced content.

In the cmdlet Help topics that are included in PowerShell, these links reference other cmdlets, conceptual content (`about_`), and other documents and Help files that aren't related to PowerShell.

The following XML shows how to add a **RelatedLinks** node that contains two references to related topics.

XML

```
<maml:relatedLinks>
  <maml:navigationLink>
    <maml:linkText>Topic-name</maml:linkText>
  </maml:navigationLink>
  <maml:navigationLink>
    <maml:linkText>Topic-name</maml:linkText>
  </maml:navigationLink>
</ maml:relatedLinks >
```

Writing Help for PowerShell Modules

Article • 07/10/2023

PowerShell modules can include Help topics about the module and about the module members, such as cmdlets, providers, functions and scripts. The `Get-Help` cmdlet displays the module Help topics in the same format as it displays Help for other PowerShell items, and users use standard `Get-Help` commands to get the Help topics.

This document explains the format and correct placement of module Help topics, and it suggests guidelines for module Help content.

Types of Module Help

A module can include the following types of Help.

- **Cmdlet Help.** The Help topics that describe cmdlets in a module are XML files that use the command help schema
- **Provider Help.** The Help topics that describe providers in a module are XML files that use the provider help schema.
- **Function Help.** The Help topics that describe functions in a module can be XML files that use the command help schema or comment-based Help topics within the function, or the script or script module
- **Script Help.** The Help topics that describe scripts in a module can be XML files that use the command help schema or comment-based Help topics in the script or script module.
- **Conceptual ("About") Help.** You can use a conceptual ("about") Help topic to describe the module and its members and to explain how the members can be used together to perform tasks. Conceptual Help topics are text files with Unicode (UTF-8) encoding. The filename must use the `about_<name>.help.txt` format, such as `about_MyModule.help.txt`. By default, PowerShell includes over 100 of these conceptual About Help topics, and they're formatted like the following example.

Output

TOPIC

`about_<subject or module name>`

SHORT DESCRIPTION

A short, one-line description of the topic contents.

LONG DESCRIPTION

A detailed, full description of the subject or purpose of the module.

EXAMPLES

Examples of how to use the module or how the subject feature works in practice.

KEYWORDS

Terms or titles on which you might expect your users to search for the information in this topic.

SEE ALSO

Text-only references for further reading. Hyperlinks can't work in the PowerShell console.

All the schema files can be found in the `$PSHOME\Scripts\PSMaml` folder.

Placement of Module Help

The `Get-Help` cmdlet looks for module Help topic files in language-specific subdirectories of the module directory.

For example, the following directory structure diagram shows the location of the Help topics for the `SampleModule` module.

```
<ModulePath>
  \SampleModule
    \<en-US>
      \about_SampleModule.help.txt
      \SampleModule.dll-help.xml
      \SampleNestedModule.dll-help.xml
    \<fr-FR>
      \about_SampleModule.help.txt
      \SampleModule.dll-help.xml
      \SampleNestedModule.dll-help.xml
```

ⓘ Note

In the example, the `<ModulePath>` placeholder represents one of the paths in the `PSModulePath` environment variable, such as `$HOME\Documents\Modules`, `$PSHOME\Modules`, or a custom path that the user specifies.

Getting Module Help

When a user imports a module into a session, the Help topics for that module are imported into the session along with the module. You can list the Help topic files in the value of the `FileList` key in the module manifest, but Help topics aren't affected by the `Export-ModuleMember` cmdlet.

You can provide module Help topics in different languages. The `Get-Help` cmdlet automatically displays module Help topics in the language that's specified for the current user in the Regional and Language Options item in Control Panel. In Windows Vista and later versions of Windows, `Get-Help` searches for the Help topics in language-specific subdirectories of the module directory in accordance with the language fallback standards established for Windows.

Beginning in PowerShell 3.0, running a `Get-Help` command for a cmdlet or function triggers automatic importing of the module. The `Get-Help` cmdlet immediately displays the contents of the help topics in the module.

If the module doesn't contain help topics and there are no help topics for the commands in the module on the user's computer, `Get-Help` displays auto-generated help. The auto-generated help includes the command syntax, parameters, and input and output types, but doesn't include any descriptions. The auto-generated help includes text that directs the user to try to use the `Update-Help` cmdlet to download help for the command from the internet or a file share. It also recommends using the `Online` parameter of the `Get-Help` cmdlet to get the online version of the help topic.

Supporting Updatable Help

Users of PowerShell 3.0 and later versions of PowerShell can download and install updated help files for a module from the internet or from a local file share. The `Update-Help` and `Save-Help` cmdlets hide the management details from the user. Users run the `Update-Help` cmdlet and then use the `Get-Help` cmdlet to read the newest help files for the module at the PowerShell command prompt. Users don't need to restart Windows or PowerShell.

Users behind firewalls and those without internet access can use Updatable Help, as well. Administrators with internet access use the `Save-Help` cmdlet to download and install the newest help files to a file share. Then, users use the `Path` parameter of the `Update-Help` cmdlet to get the newest help files from the file share.

Module authors can include help files in the module and use Updatable Help to update the help files, or omit help files from the module and use Updatable Help both to install and to update them.

For more information about Updatable Help, see [Supporting Updatable Help](#).

Supporting Online Help

Users who can't or don't install updated help files on their computers often rely on the online version of module help topics. The **Online** parameter of the `Get-Help` cmdlet opens the online version of a cmdlet or advanced function help topic for the user in their default internet browser.

The `Get-Help` cmdlet uses the value of the **HelpUri** property of the cmdlet or function to find the online version of the help topic.

Beginning in PowerShell 3.0, you can help users find the online version of cmdlet and function help topics by defining the **HelpUri** attribute on the cmdlet class or the **HelpUri** property of the **CmdletBinding** attribute. The value of the attribute is the value of the **HelpUri** property of the cmdlet or function.

For more information, see [Supporting Online Help](#).

Naming Help files

Article • 03/24/2025

ⓘ Note

Manual authoring of XML-based help is very difficult. The **PlatyPS** module allows you to write help in Markdown and then convert it to XML-based help. This makes it much easier to write and maintain help. **PlatyPS** can also create the Updateable Help packages for you. For more information, see [Create XML-based help using PlatyPS](#).

This topic explains how to name an XML-based help file so that the [Get-Help](#) cmdlet can find it. The name requirements differ for each command type.

Cmdlet Help files

The help file for a C# cmdlet must be named for the assembly in which the cmdlet is defined. Use the following filename format:

```
<AssemblyName>.dll-help.xml
```

The assembly name format is required even when the assembly is a nested module.

For example, the [Get-WinEvent](#) cmdlet is defined in the `Microsoft.PowerShell.Diagnostics.dll` assembly. The [Get-Help](#) cmdlet looks for a help topic for the `Get-WinEvent` cmdlet only in the `Microsoft.PowerShell.Diagnostics.dll-help.xml` file in the module directory.

Provider Help files

The help file for a PowerShell provider must be named for the assembly in which the provider is defined. Use the following filename format:

```
<AssemblyName>.dll-help.xml
```

The assembly name format is required even when the assembly is a nested module.

For example, the Certificate provider is defined in the `Microsoft.PowerShell.Security.dll` assembly. The `Get-Help` cmdlet looks for a help topic for the Certificate provider only in the `Microsoft.PowerShell.Security.dll-help.xml` file in the module directory.

Function Help files

Functions can be documented using [comment-based help](#) or documented in an XML help file. When the function is documented in an XML file, the function must have an `.EXTERNALHELP` comment keyword that associates the function with the XML file.

Otherwise, the `Get-Help` cmdlet can't find the help file.

There are no technical requirements for the name of a function help file. However, a best practice is to name the help file for the script module in which the function is defined. For example, the following function is defined in the `MyModule.psm1` file.

```
C#  
  
#.EXTERNALHELP MyModule.psm1-help.xml  
function Test-Function { ... }
```

CIM Command Help files

The help file for a CIM command must be named for the CDXML file in which the CIM command is defined. Use the following filename format:

```
<FileName>.cdxml-help.xml
```

CIM commands are defined in CDXML files that can be included in modules as nested modules. When the CIM command is imported into the session as a function, PowerShell adds an `.EXTERNALHELP` comment keyword to the function definition that associates the function with an XML help file that is named for the CDXML file in which the CIM command is defined.

Script Workflow Help files

Script workflows that are included in modules can be documented in XML-based help files. There are no technical requirements for the name of the help file. However, a best practice is to name the help file for the script module in which the script workflow is defined. For example:

<ScriptModule>.psm1-help.xml

Unlike other scripted commands, script workflows don't require an `.EXTERNALHELP` comment keyword to associate them with a help file. Instead, PowerShell searches the UI-Culture-specific subdirectories of the module directory for XML-based help files and looks for help for the script workflow in all the files. `.EXTERNALHELP` comment keyword are ignored.

Because the `.EXTERNALHELP` comment keyword is ignored, the `Get-Help` cmdlet can find help for script workflows only when they're included in modules.

Supporting Updatable Help

Article • 07/10/2023

The *Windows PowerShell Updatable Help System*, introduced in Windows PowerShell 3.0, is designed to ensure that users always have the newest help topics at the command prompt on their local computer. Along with Windows PowerShell online help, Updatable Help provides a complete help solution for users. This section describes the Updatable Help System and explains how module authors can support Updatable Help for their modules.

This section includes the following topics.

- [Updatable Help Overview](#)
- [Updatable Help Authoring: Step-by-Step](#)
- [How Updatable Help Works](#)
- [How to Create a HelpInfo XML File](#)
- [How to Prepare Updatable Help CAB Files](#)
- [How to Update Help Files](#)
- [How to Test Updatable Help](#)

Updatable Help Overview

Article • 07/10/2023

This document provides a basic introduction to the design and operation of the PowerShell Updatable Help feature. It's designed for module authors and others who deliver Windows PowerShell help topics to users.

Introduction

PowerShell help topics are an integral part of the PowerShell experience. Like PowerShell modules, help topics are continually updated and improved by the authors and by the contributions of the community of PowerShell users.

The *Updatable Help* feature, introduced in Windows PowerShell 3.0, ensures that users have the newest versions of help topics at the command prompt, even for built-in PowerShell commands, without downloading new modules or running Windows Update. Updatable Help makes updating simple by providing cmdlets that download the newest versions of help topics from the internet and install them in the correct subdirectories on the user's local computer. Even users who are behind firewalls can use the new cmdlets to get updated help from an internal file share.

Updatable Help is fully supported by all Windows PowerShell modules in Windows 8 and Windows Server 2012, and its features are available to all Windows PowerShell module authors. Updatable Help supports only XML-based help files. It doesn't support comment-based help.

Updatable Help includes the following features.

- The [Update-Help](#) cmdlet, which determines whether users have the newest help files for a module and, if not, downloads the newest help files from the internet, unpacks them, and installs them in the correct module subdirectories on the user's computer. Users can use the [Get-Help](#) cmdlet to view the newly-installed help topics immediately. They don't need to restart PowerShell.
- The [Save-Help](#) cmdlet, which downloads the newest help files from the internet and saves them in a file system directory. Users can use the [Update-Help](#) cmdlet to get help files from the file system directory, and unpack and install them in the module subdirectories on the user's computer. The [Save-Help](#) cmdlet is designed for users who have limited or no internet access and for enterprises who prefer to limit internet access.

- **Help for a Module.** Help files for a module are managed and delivered as a unit, so users can get all of the help files for the modules they use. Updatable help is supported only for modules, not for Windows PowerShell snap-ins.
- **Version support.** Updatable Help uses standard four-position (N1.N2.N3.N4) version numbers. Updatable Help downloads help files when the version number of the help files on the user's computer (or in the `Save-Help` directory) is lower than the version number of the help files at the internet location.
- **Multi-language support.** Updatable Help supports module help files in multiple UI cultures. Updatable Help filenames include standard language codes, such as "en-US" and "ja-JP", and the `Update-Help` and `Save-Help` cmdlets place the help files into language-specific subdirectories of the module directory.
- **Auto-generated help.** The `Get-Help` cmdlet displays basic help for commands that don't have help files. The auto-generated help includes the command syntax and aliases, and instructions for using online help and Updatable Help.
- **Enhanced Online help.** Easy access to online help no longer requires help files. The `Online` parameter of the `Get-Help` cmdlet now gets the URL of an online help topic from the value of the `HelpUri` property of any command, if it can't find the online help URL in a help file. You can populate the `HelpUri` property by adding a `HelpUri` attribute to the code of cmdlets, functions, and CIM commands, or using the `.LINK` comment-based help keyword in workflows and scripts.

To make our help files updatable, the Windows PowerShell modules in Windows don't come with help files. Users can use Updatable Help to install help files and update them. Authors of other modules can include help files in modules or omit them. Support for Updatable Help is optional, but recommended.

Updatable Help Authoring: Step-by-Step

Article • 07/10/2023

This article documents the steps required to publish Updatable Help.

Authoring Updatable Help: Step-by-Step

Updatable Help is designed for end-users, but it also provides significant benefits to module authors and help writers, including the ability to add content, fix errors, deliver in multiple UI cultures, and respond to user comments and requests, long after the module has shipped. This topic explains how you package and upload help files so that users can download and install them using the [Update-Help](#) and [Save-Help](#) cmdlets.

The following steps provide an overview of the process of supporting Updatable Help.

Step 1: Find an internet site for your help files

The first step in creating updatable help is to find an internet location for your module's help files. Actually, you can use two different locations. You can keep your module's help information file (HelpInfo XML - described below) at one internet location and the help content files (CAB and ZIP) at another internet location. All help content files for a module must be in the same location. You can place help content files for different modules in the same location.

Step 2: Add a HelpInfoURI key to your module manifest

Add a **HelpInfoURI** key to your module manifest. The value of the key is the Uniform Resource Identifier (URI) of the location of the HelpInfo XML information file for your module. For security, the address must begin with `http:` or `https:`. The URI should specify an internet location for the HelpInfo XML file. Don't include the HelpInfo XML filename.

For example:

PowerShell

```
@{
    RootModule = TestModule.psm1
    ModuleVersion = '2.0'
```

```
    HelpInfoURI = 'https://go.microsoft.com/fwlink/?LinkID=0123'  
}
```

ⓘ Note

The **HelpInfoURI** must end with a forward slash (/) character or redirect to a location that ends with a forward slash (/).

Step 3: Create a HelpInfo XML file

The HelpInfo XML information file contains the URI of the internet location of your help files and the version numbers of the newest help files for your module in each supported UI culture. Every PowerShell module has one HelpInfo XML file. When you update your help files, you must update the HelpInfo XML file. For more information, see [How to Create a HelpInfo XML File](#).

Step 4: Create CAB and ZIP files

PowerShell on Windows expects the help content files a module to be stored in a CAB file. PowerShell on Linux or macOS expects the help content files a module to be stored in a ZIP file. If your module runs across multiple platforms you must create both formats.

Use a tool, such as `MakeCab.exe`, to create a CAB file that contains the help files for your module. Create a separate CAB file for the help files in each supported UI culture. For more information, see [How to Prepare Updatable Help CAB Files](#).

You can use the [Compress-Archive cmdlet](#) to create a ZIP file.

Step 5: Upload your files

To publish new or updated help files, upload the help content files to the internet location specified by the **HelpContentUri** element in the HelpInfo XML file. Then, upload the HelpInfo XML file to the internet location specified by the value of the **HelpInfoUri** key in the module manifest.

Using PlatyPS to create help content

PlatyPS is a PowerShell module designed to help you create Help content for your modules. You author the help content in Markdown files. PlatyPS can create Markdown

templates for your cmdlet, convert the Markdown files to the XML help format (MAML), create HelpInfo XML files, and package the MAML help content into CAB and ZIP files.

For more information, see [Create XML-based help using PlatyPS](#).

How Updatable Help Works

Article • 07/10/2023

This topic explains how Updatable Help processes the HelpInfo XML file and CAB files for each module, and installs updated help for users.

The Update-Help Process

The following list describes the actions of the [Update-Help](#) cmdlet when a user runs a command to update the help files for a module in a particular UI culture.

1. `Update-Help` gets the remote HelpInfo XML file from the location specified by the value of the **HelpInfoURI** key in the module manifest and validates the file against the schema. (To view the schema, see [HelpInfo XML Schema](#).) Then `Update-Help` looks for a local HelpInfo XML file for the module in the module directory on the user's computer.
2. `Update-Help` compares the version number of the help files for the specified UI culture in the remote and local HelpInfo XML files for the module. If the version number on the remote file is greater than version number on the local file, or if there is no local HelpInfo XML file for the module, `Update-Help` prepares to download new help files.
3. `Update-Help` selects the CAB file for the module from the location specified by the **HelpContentUri** element in the remote HelpInfo XML file. It uses the module name, module GUID, and UI culture to identify the CAB file.
4. `Update-Help` downloads the CAB file, unpacks it, validates the help content files, and saves the help content files in the language-specific subdirectory of the module directory on the user's computer.
5. `Update-Help` creates a local HelpInfo XML file by copying the remote HelpInfo XML file. It edits the local HelpInfo XML file so that it includes elements only for the CAB file that it installed. Then it saves the local HelpInfo XML file in the module directory and concludes the update.

The Save-Help Process

The following list describes the actions of the [Save-Help](#) and [Update-Help](#) cmdlets when a user runs commands to update the help files in a file share, and then use those files to

update the help files on the user's computer.

The `Save-Help` cmdlet performs the following actions in response to a command to save the help files for a module in a file share that's specified by the **DestinationPath** parameter.

1. `Save-Help` gets the remote HelpInfo XML file from the location specified by the value of the **HelpInfoURI** key in the module manifest and validates the file against the schema. (To view the schema, see [HelpInfo XML Schema](#).) Then `Save-Help` looks for a local HelpInfo XML file in the directory that's specified by the **DestinationPath** parameter in the `Save-Help` command.
2. `Save-Help` compares the version number of the help files for the specified UI culture in the remote and local HelpInfo XML files for the module. If the version number on the remote file is greater than version number on the local file, or if there is no local HelpInfo XML file for the module in the **DestinationPath** directory, `Save-Help` prepares to download new help files.
3. `Save-Help` selects the CAB file for the module from the location specified by the **HelpContentUri** element in the remote HelpInfo XML file. It uses the module name, module GUID, and UI culture to identify the CAB file.
4. `Save-Help` downloads the CAB file and saves it in the **DestinationPath** directory. (It does not create any language-specific subdirectories.)
5. `Save-Help` creates a local HelpInfo XML file by copying the remote HelpInfo XML file. It edits the local HelpInfo XML file so that it includes elements only for the CAB file that it saved. Then it saves the local HelpInfo XML file in the **DestinationPath** directory and concludes the update.

The `Update-Help` cmdlet performs the following actions in response to a command to update the help files on a user's computer from the files in a file share that's specified by the **SourcePath** parameter.

6. `Update-Help` gets the remote HelpInfo XML file from the **SourcePath** directory. Then it looks for a local HelpInfo XML file in the module directory on the user's computer.
7. `Update-Help` compares the version number of the help files for the specified UI culture in the remote and local HelpInfo XML files for the module. If the version number on the remote file is greater than version number on the local file, or if there is no local HelpInfo XML file, `Update-Help` prepares to install new help files.

8. `Update-Help` selects the CAB file for the module from **SourcePath** directory. It uses the module name, module GUID, and UI culture to identify the CAB file.
9. `Update-Help` unpacks the CAB file, validates the help content files, and saves the help content files in the language-specific subdirectory of the module directory on the user's computer.
10. `Update-Help` creates a local HelpInfo XML file by copying the remote HelpInfo XML file. It edits the local HelpInfo XML file so that it includes elements only for the CAB file that it installed. Then it saves the local HelpInfo XML file in the module directory and concludes the update.

How to create a HelpInfo XML file

Article • 07/10/2023

ⓘ Note

Manual authoring of XML-based help is very difficult. The **PlatyPS** module allows you to write help in Markdown and then convert it to XML-based help. This makes it much easier to write and maintain help. **PlatyPS** can also create the Updateable Help packages for you. For more information, see [Create XML-based help using PlatyPS](#).

This topics in this section explains how to create and populate a help information file, commonly known as a "HelpInfo XML file," for the PowerShell Updatable Help feature.

HelpInfo XML file overview

The HelpInfo XML file is the primary source of information about Updatable Help for the module. It includes the location of the help files for the modules, the supported UI cultures, and the version numbers that Updatable Help uses to determine whether the user has the newest help files.

Each module has just one HelpInfo XML file, even if the module includes multiple help files for multiple UI cultures. The module author creates the HelpInfo XML file and places it in the internet location that's specified by the **HelpInfoUri** key in the module manifest. When the module help files are updated and uploaded, the module author updates the HelpInfo XML file and replaces the original HelpInfo XML file with the new version.

It's critical that the HelpInfo XML file is carefully maintained. If you upload new files, but forget to increment the version numbers, Updatable Help will not download the new files to users' computers. If you add help files for a new UI culture, but don't update the HelpInfo XML file or place it in the correct location, Updatable Help will not download the new files.

In this section

This section includes the following topics.

- [HelpInfo XML Schema](#)

- [HelpInfo XML Sample File](#)
- [How to Name a HelpInfo XML File](#)
- [How to Set HelpInfo XML Version Numbers](#)

HelpInfo XML Schema

Article • 07/10/2023

This topic contains the XML schema for Updatable Help Information files, commonly known as "HelpInfo XML files."

HelpInfo XML Schema

HelpInfo XML files are based on the following XML schema.

XML

```
<?xml version="1.0" encoding="utf-8"?>
<schema elementFormDefault="qualified"
targetNamespace="http://schemas.microsoft.com/powershell/help/2010/05"
xmlns="http://www.w3.org/2001/XMLSchema">
<element name="HelpInfo">
<complexType>
<sequence>
<element name="HelpContentURI" type="anyURI" minOccurs="1"
maxOccurs="1" />
<element name="SupportedUICultures" minOccurs="1" maxOccurs="1">
<complexType>
<sequence>
<element name="UICulture" minOccurs="1" maxOccurs="unbounded">
<complexType>
<sequence>
<element name="UICultureName" type="language"
minOccurs="1" maxOccurs="1" />
<element name="UICultureVersion" type="string"
minOccurs="1" maxOccurs="1" />
</sequence>
</complexType>
</element>
</sequence>
</complexType>
</element>
</sequence>
</complexType>
</element>
</schema>
```

HelpInfo XML Elements

The HelpInfo XML file includes the following elements.

- **HelpContentURI** - Contains the URI of the location of the help CAB files for the module. The URI must begin with "http" or "https". The URI should specify an internet location, but must not include the CAB filename. The **HelpContentURI** value can be the same or different from the **HelpInfoURI** value.
- **SupportedUICultures** - Represents the module help files in all UI cultures. Contains **UICulture** elements, each of which represents a set of help files for the module in a specified UI culture.
- **UICulture** - Represents a set of help files for the module in a specified UI culture. Add a **UICulture** element for each UI culture in which the help files are written.
- **UICultureName** - Contains the language code for the UI culture in which the help files are written.
- **UICultureVersion** - Contains a 4-part version number in "N1.N2.N3.N4" format that represents the version of the help CAB file in the UI culture. Increment this version number whenever you upload new help CAB files in the UI culture that's specified by **UICultureName**. For more information about this value, see [Version Class](#).

Note

Manual authoring of XML-based help is very difficult. The **PlatyPS** module allows you to write help in Markdown and then convert it to XML-based help. This makes it much easier to write and maintain help. **PlatyPS** can also create the Updateable Help packages for you. For more information, see [Create XML-based help using PlatyPS](#).

HelpInfo XML Sample File

Article • 07/10/2023

This topic displays a sample of a well-formed Updatable Help Information file, commonly known as "HelpInfo XML file." In this sample file, the UI culture elements are arranged in alphabetical order by UI culture name. Alphabetical ordering is a best practice, but it's not required.

HelpInfo XML Sample File

XML

```
<?xml version="1.0" encoding="utf-8"?>
<HelpInfo xmlns="http://schemas.microsoft.com/powershell/help/2010/05">
    <HelpContentURI>https://go.microsoft.com/fwlink/?LinkID=141553</HelpContentURI>
    <SupportedUICultures>
        <UICulture>
            <UICultureName>de-DE</UICultureName>
            <UICultureVersion>2.15.0.10</UICultureVersion>
        </UICulture>
        <UICulture>
            <UICultureName>en-US</UICultureName>
            <UICultureVersion>3.2.0.7</UICultureVersion>
        </UICulture>
        <UICulture>
            <UICultureName>it-IT</UICultureName>
            <UICultureVersion>1.1.0.5</UICultureVersion>
        </UICulture>
        <UICulture>
            <UICultureName>ja-JP</UICultureName>
            <UICultureVersion>3.2.0.4</UICultureVersion>
        </UICulture>
    </SupportedUICultures>
</HelpInfo>
```

How to name a HelpInfo XML file

Article • 07/10/2023

Note

Manual authoring of XML-based help is very difficult. The **PlatyPS** module allows you to write help in Markdown and then convert it to XML-based help. This makes it much easier to write and maintain help. **PlatyPS** can also create the Updateable Help packages for you. For more information, see [Create XML-based help using PlatyPS](#).

This topic explains the required name format for the Updatable Help Information files, commonly known as HelpInfo XML files. A HelpInfo XML file must have a name with the following format.

```
<ModuleName>_<ModuleGUID>_HelpInfo.xml
```

The elements of the name are as follows.

- `<ModuleName>` - The value of the **Name** property of the **ModuleInfo** object that the [Get-Module](#) cmdlet returns.
- `<ModuleGUID>` - The value of the **GUID** key in the module manifest.

For example, if the module name is "TestModule" and the module GUID is 9cabb9ad-f2ac-4914-a46b-bfc1bebf07f9, the name of the HelpInfo XML file for the module would be:

```
TestModule_9cabb9ad-f2ac-4914-a46b-bfc1bebf07f9_HelpInfo.xml
```

How to set HelpInfo XML version numbers

Article • 07/10/2023

ⓘ Note

Manual authoring of XML-based help is very difficult. The **PlatyPS** module allows you to write help in Markdown and then convert it to XML-based help. This makes it much easier to write and maintain help. **PlatyPS** can also create the Updateable Help packages for you. For more information, see [Create XML-based help using PlatyPS](#).

The version numbers in a HelpInfo XML file are critical to the operation of Updatable Help. The [Update-Help](#) and [Save-Help](#) cmdlets download new help files only when the version number for a UI culture in the remote HelpInfo XML file is greater than the version number for that UI culture in the local HelpInfo XML, or there is no local HelpInfo XML file.

The HelpInfo XML file uses the 4-part version number that's defined in the **System.Version** class of the Microsoft .NET Framework. The format is `N1.N2.N3.N4`. Module authors can use any version numbering scheme that's permitted by the **System.Version** class. Updatable Help requires only that the version number for a UI culture increase when a new version of the CAB file for that UI culture is uploaded to the location that's specified by the **HelpContentURI** element in the HelpInfo XML file.

The following example shows the elements of the HelpInfo XML file for the German (de-DE) UI culture when the version is 2.15.0.10.

XML

```
<UICulture>
  <UICultureName>de-DE</UICultureName>
  <UICultureVersion>2.15.0.10</UICultureVersion>
</UICulture>
```

The version number for a UI culture reflects the version of the CAB file for that UI culture. The version number applies to the entire CAB file. You can't set different version numbers for different files in the CAB file. The version number for each UI culture is evaluated independently and need not be related to the version numbers for other UI cultures that the module supports.

How to create and upload CAB files

Article • 07/10/2023

ⓘ Note

Manual authoring of XML-based help is very difficult. The **PlatyPS** module allows you to write help in Markdown and then convert it to XML-based help. This makes it much easier to write and maintain help. **PlatyPS** can also create the Updatable Help packages for you. For more information, see [Create XML-based help using PlatyPS](#).

This topic explains how to create Updatable Help CAB files and upload them to the location where the Updatable Help cmdlets can find them.

How to create and upload updatable help CAB files

You can use the Updatable Help feature to deliver new or updated help files for a module in multiple languages and cultures. An Updatable Help package for a module consists of one HelpInfo XML file and one or more cabinet (.CAB) files. Each CAB file contains help files for the module in one UI culture. Use the following procedure to create CAB files for Updatable Help.

1. Organize the help files for the module by UI culture. Each Updatable Help CAB file contains the help files for one module in one UI culture. You can deliver multiple help CAB files for the module, each for a different UI culture.
2. Verify that help files include only the file types permitted for Updatable Help and validate them against a help file schema. If the `Update-Help` cmdlet encounters a file that's invalid or is not a permitted type, it doesn't install the invalid file and stops installing files from the CAB. For a list of permitted file types, see [File Types Permitted in an Updatable Help CAB File](#).
3. Include all the help files for the module in the UI culture, not only files that are new or have changed. If the CAB file is incomplete, users who download help files for the first time or do not download every update, won't have all the help files.
4. Use a utility that creates cabinet files, such as `MakeCab.exe`. PowerShell doesn't include cmdlets that create CAB files.

5. Name the CAB files. For more information, see [How to Name an Updatable Help CAB File](#).

6. Upload the CAB files for the module to the location that's specified by the **HelpContentUri** element in the HelpInfo XML file for the module. Then upload the HelpInfo XML file to the location that's specified by the **HelpInfoUri** key of the module manifest. The **HelpContentUri** and **HelpInfoUri** can point to the same location.

 **Caution**

The value of the **HelpInfoUri** key and the **HelpContentUri** element must begin with `http` or `https`. The value must a URL path pointing to the location (folder) containing the updateable help. The URL must end with `/`. The URL must not include a filename.

 **Collaborate with us on GitHub**

The source for this content can be found on GitHub, where you can also create and review issues and pull requests. For more information, see [our contributor guide](#).

How to name an Updatable Help CAB file

Article • 07/10/2023

ⓘ Note

Manual authoring of XML-based help is very difficult. The **PlatyPS** module allows you to write help in Markdown and then convert it to XML-based help. This makes it much easier to write and maintain help. **PlatyPS** can also create the Updateable Help packages for you. For more information, see [Create XML-based help using PlatyPS](#).

An updatable cabinet (.CAB) file must have a name with the following format.

```
<ModuleName>_<ModuleGUID>_<UICulture>_HelpContent.cab
```

The elements of the name are as follows.

- `<ModuleName>` -The value of the **Name** property of the **ModuleInfo** object that the [Get-Module](#) cmdlet returns.
- `<ModuleGUID>` - The value of the **GUID** key in the module manifest.
- `<UICulture>` - The UI culture of the help files in the CAB file. This value must match the value of one of the **UICulture** elements in the HelpInfo XML file for the module.

For example, if the module name is "TestModule," the module GUID is 9cabb9ad-f2ac-4914-a46b-bfc1bebf07f9, and the UI culture is `en-US`, the name of the CAB file would be:

```
TestModule_9cabb9ad-f2ac-4914-a46b-bfc1bebf07f9_en-US_HelpContent.cab
```

File Types Permitted in an Updatable Help CAB File

Article • 07/10/2023

Uncompressed CAB file content is limited to 1 GB by default. To bypass this limit, users have to use the **Force** parameter of the [Update-Help](#) and [Save-Help](#) cmdlets.

To assure the security of help files that are downloaded from the internet, an Updatable Help CAB file can include only the file types listed below. The [Update-Help](#) cmdlet validates all files against the help topic schemas. If the [Update-Help](#) cmdlet encounters a file that's invalid or is not a permitted type, it doesn't install the invalid file and stops installing files from the CAB on the user's computer.

- XML-based help topics for cmdlets.
- XML-based help topics for scripts and functions.
- XML-based help topics for PowerShell providers.
- Text-based help topics, such as About topics.

The [Update-Help](#) verifies the CAB contents when it unpacks the CAB. If [Update-Help](#) finds non-compliant file types in an Updatable Help CAB file, it generates a terminating error and stops the operation. It doesn't install any help files from the CAB, even those of compliant file types.

ⓘ Note

How to update help files

Article • 07/10/2023

Note

Manual authoring of XML-based help is very difficult. The **PlatyPS** module allows you to write help in Markdown and then convert it to XML-based help. This makes it much easier to write and maintain help. **PlatyPS** can also create the Updateable Help packages for you. For more information, see [Create XML-based help using PlatyPS](#).

There are many reasons to update help files, such as correcting errors, clarifying a concept, answering a frequently asked question, adding new files, or adding new and better examples.

To update a help file:

1. Change the files.
2. Translate the files into other UI cultures.
3. Collect all help files (new, changed, and unchanged) for the module in each UI culture.
4. Validate the files against the XML schema.
5. Rebuild the CAB files for each UI culture.
6. In the HelpInfo XML file, increment the version numbers of the CAB file for each UI culture.
7. Upload the new CAB files to the location that's specified by the value of the **HelpContentUri** element in the HelpInfo XML file. Replace the older CAB files with the new CAB files.
8. Upload the updated HelpInfo XML file to the location that's specified by the **HelpInfoUri** key in the module manifest. Replace the older HelpInfo XML file with the new file.

How to test Updatable Help

Article • 07/10/2023

Note

Manual authoring of XML-based help is very difficult. The **PlatyPS** module allows you to write help in Markdown and then convert it to XML-based help. This makes it much easier to write and maintain help. **PlatyPS** can also create the Updatable Help packages for you. For more information, see [Create XML-based help using PlatyPS](#).

This topic describes approaches to testing Updatable Help for a module.

Using verbose to detect errors

After uploading the HelpInfo XML file and CAB files for your module, test the files by running an [Update-Help](#) command with the **Verbose** parameter. The **Verbose** parameter directs [Update-Help](#) to report the critical steps in its actions, from reading the **HelpInfoUri** key in the module manifest to validating the file types in the unpacked CAB file and placing the files in the language-specific module directory.

When all verbose messages are resolved, run an [Update-Help](#) command with the **Debug** parameter. This parameter should detect any remaining problems with the Updatable Help files.

Supporting Online Help

Article • 07/10/2023

ⓘ Note

Manual authoring of XML-based help is very difficult. The **PlatyPS** module allows you to write help in Markdown and then convert it to XML-based help. This makes it much easier to write and maintain help. **PlatyPS** can also create the Updateable Help packages for you. For more information, see [Create XML-based help using PlatyPS](#).

Beginning in PowerShell 3.0, there are two ways to support the `Get-Help` Online feature for PowerShell commands. This topic explains how to implement this feature for different command types.

About Online Help

Online help has always been a vital part of PowerShell. Although the `Get-Help` cmdlet displays help topics at the command prompt, many users prefer the experience of reading online, including color-coding, hyperlinks, and sharing ideas in Community Content and wiki-based documents. Most importantly, before the advent of Updatable Help, online help provided the most up-to-date version of the help files.

With the advent of Updatable Help in PowerShell 3.0, online help still plays a vital role. In addition to the flexible user experience, online help provides help to users who don't or can't use Updatable Help to download help topics.

How Get-Help -Online Works

To help users find the online help topics for commands, the `Get-Help` command has an `Online` parameter that opens the online version of help topic for a command in the user's default internet browser.

For example, the following command opens the online help topic for the `Invoke-Command` cmdlet.

PowerShell

```
Get-Help Invoke-Command -Online
```

To implement `Get-Help -Online`, the `Get-Help` cmdlet looks for a Uniform Resource Identifier (URI) for the online version help topic in the following locations.

- The first link in the **Related Links** section of the help topic for the command. The help topic must be installed on the user's computer. This feature was introduced in PowerShell 2.0.
- The **HelpUri** property of any command. The **HelpUri** property is accessible even when the help topic for the command isn't installed on the user's computer. This feature was introduced in PowerShell 3.0.

`Get-Help` looks for a URI in the first entry in the **Related Links** section before getting the **HelpUri** property value. If the property value is incorrect or has changed, you can override it by entering a different value in the first related link. However, the first related link works only when the help topics are installed on the user's computer.

Adding a URI to the first related link of a command help topic

You can support `Get-Help -Online` for any command by adding a valid URI to the first entry in the **Related Links** section of the XML-based help topic for the command. This option is valid only in XML-based help topics and works only when the help topic is installed on the user's computer. When the help topic is installed and the URI is populated, this value takes precedence over the **HelpUri** property of the command.

To support this feature, the URI must appear in the `maml:uri` element under the first `maml:relatedLinks/maml:navigationLink` element in the `maml:relatedLinks` element.

The following XML shows the correct placement of the URI. The `Online version:` text in the `maml:linkText` element is a best practice, but it's not required.

XML

```
<maml:relatedLinks>
  <maml:navigationLink>
    <maml:linkText>Online version:</maml:linkText>
    <maml:uri>https://go.microsoft.com/fwlink/?LinkID=113279</maml:uri>
  </maml:navigationLink>
  <maml:navigationLink>
    <maml:linkText>about_History</maml:linkText>
    <maml:uri/>
```

```
</maml:navigationLink>  
</maml:relatedLinks>
```

Adding the HelpUri property to a command

This section shows how to add the **HelpUri** property to commands of different types.

Adding a HelpUri Property to a Cmdlet

For cmdlets written in C#, add a **HelpUri** attribute to the **Cmdlet** class. The value of the attribute must be a URI that begins with `http` or `https`.

The following code shows the **HelpUri** attribute of the `Get-History` cmdlet class.

```
C#
```

```
[Cmdlet(VerbsCommon.Get, "History", HelpUri =  
"https://go.microsoft.com/fwlink/?LinkID=001122")]
```

Adding a HelpUri property to an advanced function

For advanced functions, add a **HelpUri** property to the **CmdletBinding** attribute. The value of the property must be a URI that begins with "http" or "https".

The following code shows the **HelpUri** attribute of the `New-Calendar` function

```
PowerShell
```

```
function New-Calendar {  
    [CmdletBinding(SupportsShouldProcess=$true,  
    HelpUri="https://go.microsoft.com/fwlink/?LinkID=01122")]
```

Adding a HelpUri attribute to a cim command

For CIM commands, add a **HelpUri** attribute to the **CmdletMetadata** element in the CDXML file. The value of the attribute must be a URI that begins with `http` or `https`.

The following code shows the **HelpUri** attribute of the `Start-Debug` CIM command

```
XML
```

```
<CmdletMetadata Verb="Debug" HelpUri="https://go.microsoft.com/fwlink/?LinkID=001122"/>
```

Adding a HelpUri attribute to a workflow

For workflows that are written in the PowerShell language, add an `.EXTERNALHELP` comment keyword to the workflow code. The value of the keyword must be a URI that begins with `http` or `https`.

ⓘ Note

The `HelpUri` property isn't supported for XAML-based workflows in PowerShell.

The following code shows the `.EXTERNALHELP` keyword in a workflow file.

PowerShell

```
# .EXTERNALHELP "https://go.microsoft.com/fwlink/?LinkID=138338"
```

How to add dynamic parameters to a provider help topic

Article • 07/10/2023

ⓘ Note

Manual authoring of XML-based help is very difficult. The **PlatyPS** module allows you to write help in Markdown and then convert it to XML-based help. This makes it much easier to write and maintain help. **PlatyPS** can also create the Updateable Help packages for you. For more information, see [Create XML-based help using PlatyPS](#).

This section explains how to populate the **DYNAMIC PARAMETERS** section of a provider help topic.

Dynamic parameters are parameters of a cmdlet or function that are available only under specified conditions.

The dynamic parameters that are documented in a provider help topic are the dynamic parameters that the provider adds to the cmdlet or function when the cmdlet or function is used in the provider drive.

Dynamic parameters can also be documented in custom cmdlet help for a provider. When writing both provider help and custom cmdlet help for a provider, include the dynamic parameter documentation in both documents.

If a provider doesn't implement any dynamic parameters, the provider help topic contains an empty `DynamicParameters` element.

To add dynamic parameters

1. In the `<AssemblyName>.dll-help.xml` file, within the `providerHelp` element, add a `DynamicParameters` element. The `DynamicParameters` element should appear after the `Tasks` element and before the `RelatedLinks` element.

For example:

XML

```
<providerHelp>
  <Tasks>
```

```
</Tasks>
<DynamicParameters>
</DynamicParameters>
<RelatedLinks>
</RelatedLinks>
</providerHelp>
```

If the provider doesn't implement any dynamic parameters, the `DynamicParameters` element can be empty.

2. Within the `DynamicParameters` element, for each dynamic parameter, add a `DynamicParameter` element.

For example:

XML

```
<DynamicParameters>
  <DynamicParameter>
  </DynamicParameter>
</DynamicParameters>
```

3. In each `DynamicParameter` element, add a `Name` and `CmdletSupported` element.

- Name - Specifies the parameter name
- CmdletSupported - Specifies the cmdlets in which the parameter is valid.
Type a comma-separated list of cmdlet names.

For example, the following XML documents the `Encoding` dynamic parameter that the Windows PowerShell FileSystem provider adds to the `Add-Content`, `Get-Content`, `Set-Content` cmdlets.

XML

```
<DynamicParameters>
  <DynamicParameter>
    <Name> Encoding </Name>
    <CmdletSupported> Add-Content, Get-Content, Set-Content
  </CmdletSupported>
</DynamicParameters>
```

4. In each `DynamicParameter` element, add a `Type` element. The `Type` element is a container for the `Name` element which contains the .NET type of the value of the dynamic parameter.

For example, the following XML shows that the .NET type of the `Encoding` dynamic parameter is the [FileSystemCmdletProviderEncoding](#) enumeration.

```
XML

<DynamicParameters/>
  <DynamicParameter>
    <Name> Encoding </Name>
    <CmdletSupported> Add-Content, Get-Content, Set-Content
  </CmdletSupported>
  <Type>
    <Name>
      Microsoft.PowerShell.Commands.FileSystemCmdletProviderEncoding </Name>
    <Type>
    ...
  </DynamicParameters>
```

5. Add the `Description` element, which contains a brief description of the dynamic parameter. When composing the description, use the guidelines prescribed for all cmdlet parameters in [How to Add Parameter Information](#).

For example, the following XML includes the description of the `Encoding` dynamic parameter.

```
XML

<DynamicParameters/>
  <DynamicParameter>
    <Name> Encoding </Name>
    <CmdletSupported> Add-Content, Get-Content, Set-Content
  </CmdletSupported>
  <Type>
    <Name>
      Microsoft.PowerShell.Commands.FileSystemCmdletProviderEncoding </Name>
    <Type>
      <Description> Specifies the encoding of the output file that
      contains the content. </Description>
    ...
  </DynamicParameters>
```

6. Add the `PossibleValues` element and its child elements. Together, these elements describe the values of the dynamic parameter. This element is designed for enumerated values. If the dynamic parameter doesn't take a value, such as is the case with a switch parameter, or the values can't be enumerated, add an empty `PossibleValues` element.

The following table lists and describes the `PossibleValues` element and its child elements.

- `PossibleValues` - This element is a container. Its child elements are described below. Add one `PossibleValues` element to each provider help topic. The element can be empty.
- `PossibleValue` - This element is a container. Its child elements are described below. Add one `PossibleValue` element for each value of the dynamic parameter.
- `Value` - Specifies the value name.
- `Description` - This element contains a `Para` element. The text in the `Para` element describes the value that's named in the `Value` element.

For example, the following XML shows one `PossibleValue` element of the `Encoding` dynamic parameter.

XML

```
<DynamicParameters/>
  <DynamicParameter>
    ...
      <Description> Specifies the encoding of the output file that
contains the content. </Description>
      <PossibleValues>
        <PossibleValue>
          <Value> ASCII </Value>
          <Description>
            <para> Uses the encoding for the ASCII (7-bit)
character set. </para>
            </Description>
          </PossibleValue>
        ...
      </PossibleValues>
  </DynamicParameter>
```

Example

The following example shows the `DynamicParameters` element of the `Encoding` dynamic parameter.

XML

```
<DynamicParameters/>
  <DynamicParameter>
    <Name> Encoding </Name>
    <CmdletSupported> Add-Content, Get-Content, Set-Content
```

```
</CmdletSupported>
<Type>
  <Name>
Microsoft.PowerShell.Commands.FileSystemCmdletProviderEncoding </Name>
  <Type>
    <Description> Specifies the encoding of the output file that
contains the content. </Description>
    <PossibleValues>
      <PossibleValue>
        <Value> ASCII </Value>
        <Description>
          <para> Uses the encoding for the ASCII (7-bit) character
set. </para>
        </Description>
      </PossibleValue>
      <PossibleValue>
        <Value> Unicode </Value>
        <Description>
          <para> Encodes in UTF-16 format using the little-endian
byte order. </para>
        </Description>
      </PossibleValue>
    </PossibleValues>
  </Type>
</DynamicParameters>
```

How to Add a See Also Section to a Provider Help Topic

Article • 07/10/2023

ⓘ Note

Manual authoring of XML-based help is very difficult. The **PlatyPS** module allows you to write help in Markdown and then convert it to XML-based help. This makes it much easier to write and maintain help. **PlatyPS** can also create the Updateable Help packages for you. For more information, see [Create XML-based help using PlatyPS](#).

This section explains how to populate the **SEE ALSO** section of a provider help topic.

The **SEE ALSO** section consists of a list of topics that are related to the provider or might help the user better understand and use the provider. The topic list can include cmdlet help, provider help and conceptual ("about") help topics in Windows PowerShell. It can also include references to books, paper, and online topics, including an online version of the current provider help topic.

When you refer to online topics, provide the URI or a search term in plain text. The `Get-Help` cmdlet doesn't link or redirect to any of the topics in the list. Also, the `Online` parameter of the `Get-Help` cmdlet doesn't work with provider help.

The **See Also** section is created from the `RelatedLinks` element and the tags that it contains. The following XML shows how to add the tags.

To Add SEE ALSO Topics

1. In the `<AssemblyName>.dll-help.xml` file, within the `providerHelp` element, add a `RelatedLinks` element. The `RelatedLinks` element should be the last element in the `providerHelp` element. Only one `RelatedLinks` element is permitted in each provider help topic.

For example:

XML

```
<providerHelp>
  <RelatedLinks>
```

```
</RelatedLinks>  
</providerHelp>
```

2. For each topic in the SEE ALSO section, within the `RelatedLinks` element, add a `navigationLink` element. Then, within each `navigationLink` element, add one `linkText` element and one `uri` element. If you aren't using the `uri` element, you can add it as an empty element (`<uri/>`).

For example:

XML

```
<providerHelp>  
  <RelatedLinks>  
    <navigationLink>  
      <linkText> </linkText>  
      <uri> </uri>  
    </navigationLink>  
  </RelatedLinks>  
</providerHelp>
```

3. Type the topic name between the `linkText` tags. If you are providing a URI, type it between the `uri` tags. To indicate the online version of the current provider help topic, between the `linkText` tags, type "Online version:" instead of the topic name. Typically, the "Online version:" link is the first topic in the SEE ALSO topic list.

The following example include three SEE ALSO topics. The first refer to the online version of the current topic. The second refers to a Windows PowerShell cmdlet help topic. The third refers to another online topic.

XML

```
<providerHelp>  
  <RelatedLinks>  
    <navigationLink>  
      <linkText> Online version: </linkText>  
      <uri>http://www.fabrikam.com/help/myFunction.htm</uri>  
    </navigationLink>  
    <navigationLink>  
      <linkText> about_functions </linkText>  
      <uri/>  
    </navigationLink>  
    <navigationLink>  
      <linkText> Windows PowerShell Getting Started Guide  
</linkText>  
      <uri>https://go.microsoft.com/fwlink/?LinkID=89597</uri>  
    </navigationLink>
```

```
</RelatedLinks>  
</providerHelp>
```

Extended Type System Overview

Article • 12/18/2023

PowerShell uses its **PSObject** object to extend the types of objects in two ways. First, the **PSObject** object provides a way to show different views of specific object types. This is referred to as showing an adapted view of an object. Second, the **PSObject** object provides a way to add members to existing object. Together, by wrapping an existing object, referred to as the base object, the **PSObject** object provides an extended type system (ETS) that script and cmdlet developers can use to manipulate .NET objects within the shell.

Cmdlet and Script Development Issues

ETS resolves two fundamental issues:

First, some .NET Objects do not have the necessary default behavior for acting as the data between cmdlets.

- Some .NET objects are "meta" objects (for example: WMI Objects, ADO objects, and XML objects) whose members describe the data they contain. However, in a scripting environment it is the contained data that is most interesting, not the description of the contained data. ETS resolves this issue by introducing the notion of Adapters that adapt the underlying .NET object to have the expected default semantics.
- Some .NET Object members are inconsistently named, provide an insufficient set of public members, or provide insufficient capability. ETS resolves this issue by introducing the ability to extend the .NET object with additional members.

Second, the PowerShell scripting language is *typeless* in that a variable does not need to be declared of a particular type. That is, the variables a script developer creates are by nature *typeless*. However, the PowerShell system is "type-driven" in that it depends on having a type name to operate against for basic operations such as outputting results or sorting.

Therefore a script developer must have the ability to state the type of one of their variables and build up their own set of dynamically typed "objects" that contain properties and methods and can participate in the type-driven system. ETS solves this problem by providing a common object for the scripting language that has the ability to state its type dynamically and to add members dynamically.

Fundamentally, ETS resolves the issue mentioned previously by providing the **PSObject** object, which acts as the basis of all object access from the scripting language and provides a standard abstraction for the cmdlet developer.

Cmdlet Developers

For the cmdlet developers, ETS provides the following support:

- The abstractions to work against objects in a generic way using the **PSObject** object. ETS also provides the ability to drill past these abstractions if required.
- The mechanisms to create a default behavior for formatting, sorting, serialization, and other system manipulations of their object type using a well-known set of extended members.
- The means to operate against any object using the same semantics as the script language using a **LanguagePrimitives** object.
- The means to dynamically "type" a hash table so that the rest of the system can operate against it effectively.

Script Developers

For the script developers, ETS provides the following support:

- The ability to reference any underlying object type using the same syntax (`$a.x`).
- The ability to access beyond the abstraction provided by the **PSObject** object (such as accessing only adapted members, or accessing the base object itself).
- The ability to define well-known members that control the formatting, sorting, serialization, and other manipulations of an object instance or type.
- The means to name an object as a specific type and thus control the inheritance of its type-based members.
- The ability to add, remove, and modify extended members.
- The ability to manipulate the **PSObject** object itself if required.

The **PSObject** class

The **PSObject** object is the basis of all object access from the scripting language and provides a standard abstraction for the cmdlet developer. It contains a base-object (a .NET object) and any instance members (members, specifically extended members, that are present on a particular object instance while not necessarily on other objects of the same type). Depending on the type of the base-object, the **PSObject** object might also provide implicit and explicit access to adapted members as well as any type-based extended members.

The **PSObject** object provides the following mechanisms:

- The ability to construct a **PSObject** with or without a base-object.
- The ability to access of all members of each constructed **PSObject** object through a common lookup algorithm and the ability to override that algorithm when required.
- The ability to get and set the type-names of the constructed **PSObject** objects so that scripts and cmdlets can reference similar **PSObject** objects by the same type-name, regardless of the type of their base-object.

How to Construct a PSObject

The following list describes ways to create a **PSObject** object:

- Calling the **PSObject** `#ctor` constructor creates a new **PSObject** object with a base-object of **PSCustomObject**. A base-object of this type indicates that the **PSObject** object has no meaningful base-object. However, a **PSObject** object with this type of base-object does provide a property bag that cmdlet developers can find helpful by adding extended-members.

Developers can also specify the object type-name, which allows this object to share its extended-members with other **PSObject** objects of the same type-name.

- Calling the **PSObject** `#ctor(System.Object)` constructor creates a new **PSObject** object with a base-object of type **System.Object**.

In this case, the type-name for the created object is a collection of the derivation hierarchy of the base-object. For example, the type-name for the **PSObject** that contains a **ProcessInfo** base-object would include the following names:

- **System.Diagnostics.Process**
- **System.ComponentModel.Component**
- **System.MarshalByRefObject**
- **System.Object**

- Calling the **PSObject** `.AsPSObject(System.Object)` method creates a new **PSObject** object based on a supplied object.

If the supplied object is of type **System.Object**, the supplied object is used as the base-object for the new **PSObject** object. If the supplied object is already a **PSObject** object, the supplied object is returned as is.

Base, adapted, and extended members

Conceptually, ETS uses the following terms to show the relationship between the original members of the base-object and those members added by PowerShell. For more information about the specific types of members that are used by the **PSObject** object, see [PSObject class](#).

Base-object members

If the base-object is specified when constructing the **PSObject** objects, then the members of the base-object are made available through the Members property.

Adapted members

When a base-object is a meta-object, one that contains data in a generic fashion whose properties "describe" their contained data, ETS adapts those objects to a view that allows for direct access to the data through adapted members of the **PSObject** object. Adapted members and base-object members are accessed through the Members property.

Extended members

In addition to the members made available from the base-object or those adapted members created by PowerShell, a **PSObject** may also define extended members that extend the original base-object with additional information that is useful in the scripting environment.

For example, all the core cmdlets provided by PowerShell, such as the Get-Content and Set-Content cmdlets, take a Path parameter. To ensure that these cmdlets, and others, can work against objects of different types, a Path member can be added to those objects so that they all state their information in a common way. This extended Path member ensures that the cmdlets can work against all those types even though their base class might not have a Path member.

Extended members, adapted members, and base-object members are all accessed through the Members property.

Extended Type System class members

Article • 09/17/2021

ETS refers to a number of different kinds of members whose types are defined by the **PSMemberTypes** enumeration. These member types include properties, methods, members, and member sets that are each defined by their own CLR type. For example, a **NoteProperty** is defined by its own **PSNoteProperty** type. These individual CLR types have both their own unique properties and common properties that are inherited from the [PSMemberInfo class](#).

The PSMemberInfo class

The **PSMemberInfo** class serves as a base class for all ETS member types. This class provides the following base properties to all member CLR types.

- **Name** property: The name of the member. This name can be defined by the base-object or defined by PowerShell when adapted members or extended members are exposed.
- **Value** property: The value returned from the particular member. Each member type defines how it handles its member value.
- **TypeNameOfValue** property: This is the name of the CLR type of the value that is returned by the Value property.

Accessing members

Collections of members can be accessed through the **Members**, **Methods**, and **Properties** properties of the **PSObject** object.

ETS properties

ETS properties are members that can be treated as a property. Essentially, they can appear on the left-hand side of an expression. They include alias properties, code properties, PowerShell properties, note properties, and script properties. For more information about these types of properties, see [ETS properties](#).

ETS methods

ETS methods are members that can take arguments, may return results, and cannot appear on the left-hand side of an expression. They include code methods, PowerShell

methods, and script methods. For more information about these types of methods, see [ETS methods](#).

ETS member sets

Article • 12/18/2023

Member sets allow you to partition the members of the **PSObject** object into two subsets so that the members of the subsets can be referenced together by their subset name. The two types of subsets include property sets and member sets. For example of how PowerShell uses member sets, there is a specific property set named **DefaultDisplayPropertySet** that is used to determine, at runtime, which properties to display for a given **PSObject** object.

Property Sets

Property sets can include any number of properties of a **PSObject** type. In general, a property set can be used whenever a collection of properties (of the same type) is needed. The property set is created by calling the

`PSPropertySet(System.String, System.Collections.Generic.IEnumerable{System.String})`

constructor with the name of the property set and the names of the referenced properties. The created **PSPropertySet** object can then be used as an alias that points to the properties in the set. The **PSPropertySet** class has the following properties and methods.

- **IsInstance** property: Gets a **Boolean** value that indicates the source of the property.
- **MemberType** property: Gets the type of properties in the property set.
- **Name** property: Gets the name of the property set.
- **ReferencedPropertyNames** property: Gets the names of the properties in the property set.
- **TypeNameOfValue** property: Gets a **PropertySet** enumeration constant that defines this set as a property set.
- **Value** property: Gets or sets the **PSPropertySet** object.
- `PSPropertySet.Copy` method: Makes an exact copy of the **PSPropertySet** object.
- `PSMemberSet.ToString` method: Converts the **PSPropertySet** object to a string.

Member Sets

Member sets can include any number of extended members of any type. The member set is created by calling the

`PSMemberSet(System.String, System.Collections.Generic.IEnumerable{System.Management.Automation.PSMemberInfo})`

constructor with the name of the member set and the names

of the referenced members. The created **PSPropertySet** object can then be used as an alias that points to the members in the set. The **PSMemberSet** class has the following properties and methods.

- **IsInstance** property: Gets a **Boolean** value that indicates the source of the member.
- **Members** property: Gets all the members of the member set.
- **MemberType** property: Gets a **MemberSet** enumeration constant that defines this set as a member set.
- **Methods** property: Gets the methods included in the member set.
- **Properties** property: Gets the properties included in the member set.
- **TypeNameOfValue** property: Gets a **MemberSet** enumeration constant that defines this set as a member set.
- **Value** property: Gets the **PSMemberSet** object.
- **PSMemberSet.Copy** method: Makes an exact copy of the **PSMemberSet** object.
- **PSMemberSet.ToString** method: Converts the **PSMemberSet** object to a string.

ETS properties

Article • 09/17/2021

Properties are members that can be treated as a property. Essentially, they can appear on the left-hand side of an expression. The properties that are available include alias, code, note, and script properties.

Alias Property

An alias property is a property that references another property that the **PSObject** object contains. It is used primarily to rename the referenced property. However, it may also be used to convert the referenced property's value to another type. With respect to ETS, this type of property is always an extended-member and is defined by the [PSAliasProperty](#) class. The class includes the following properties.

- **ConversionType** property: The CLR type used to convert the referenced member's value.
- **IsGettable** property: Indicates whether the value of the referenced property can be retrieved. This property is dynamically determined by examining the **IsGettable** property of the referenced property.
- **IsSettable** property: Indicates whether the value of the referenced property can be set. This property is dynamically determined by examining the **IsSettable** property of the referenced property.
- **MemberType** property: An **AliasProperty** enumeration constant that defines this property as an alias property.
- **ReferencedMemberName** property: The name of the referenced property that this alias refers to.
- **TypeNameOfValue** property: The full name of the CLR type of the referenced property's value.
- **Value** property: The value of the referenced property.

Code Property

A code property is a property that is a getter and setter that is defined in a CLR language. In order for a code property to become available, a developer must write the property in some CLR language, compile, and ship the resultant assembly. This assembly must be available in the runspace where the code property is desired. With respect to ETS, this type of property is always an extended-member and is defined by the [PSCodeProperty](#) class. The class includes the following properties.

- **GetterCodeReference** property: The method used to get the value of the code property.
- **IsGettable** property: Indicates whether the value of the code property can be retrieved, that the **SetterCodeReference** property: The method used to set the value of the code property.
- **IsSettable** property: Indicates whether the value of the code property can be set, that the **SetterCodeReference** property is not null.
- **MemberType** property: A **CodeProperty** enumeration constant that defines this property as a code property.
- **SetterCodeReference** property: The method used to get the value of the code property.
- **TypeNameOfValue** property: The CLR type of the code property value that is returned by the properties get operation.
- **Value** property: The value of the code property. When this property is retrieved, the getter code in the **GetterCodeReference** property is invoked, passing the current **PSObject** object and returning the value returned by the invocation. When this property is set, the setter code in the **SetterCodeReference** property is invoked, passing the current **PSObject** object as the first argument and the object used to set the value as the second argument.

Note Property

A Note property is a property that has a name/value pairing. With respect to ETS, this type of property is always an extended-member and is defined by the [PSNoteProperty](#) class. The class includes the following properties.

- **IsGettable** property: Indicates whether the value of the note property can be retrieved.
- **IsSettable** property: Indicates whether the value of the note property can be set.
- **MemberType** property: A **NoteProperty** enumeration constant that defines this property as a note property.
- **TypeNameOfValue** property: The fully-qualified type name of the object returned by the note property's get operation.
- **Value**: The value of the note property.

PowerShell property

A PowerShell property is a property defined on the base object or a property that is made available through an adapter. It can refer to both CLR fields as well as CLR properties. With respect to ETS, this type of property can be either a base-member or an

adapter-member and is defined by the [PSProperty](#) class. The class includes the following properties.

- **IsGettable** property: Indicates whether the value of the base or adapted property can be retrieved.
- **IsSettable** property: Indicates whether the value of the base or adapted property can be set.
- **MemberType** property: A Property enumeration constant that defines this property as a PowerShell property.
- **TypeNameOfValue** property: The fully-qualified name of the property value type. For example, for a property whose value is a string, its property value type is `System.String`.
- **Value** property: The value of the property. If the get or set operation is called on a property that does not support that operation, a `GetValueException` or `SetValueException` exception is thrown

PowerShell Script property

A Script property is a property that has getter and setter scripts. With respect to ETS, this type of property is always an extended-member and is defined by the [PSScriptProperty](#) class. The class includes the following properties.

- **GetterScript** property: The script used to retrieve the script property value.
- **IsGettable** property: Indicates whether the **GetterScript** property exposes a script block.
- **IsSettable** property: Indicates whether the **SetterScript** property exposes a script block.
- **MemberType** property: A ScriptProperty enumeration constant that identifies this property as a script property.
- **SetterScript** property: The script used to set the script property value.
- **TypeNameOfValue** property: The fully-qualified type name of the object returned by the getter script. In this case `System.Object` is always returned.
- **Value** property: The value of the script property. A get invokes the getter script and returns the value provided. A set invokes the setter script.

ETS class methods

Article • 09/17/2021

ETS methods are members that can take arguments, may return results, and cannot appear on the left-hand side of an expression. The methods that are available within ETS include code, Windows PowerShell, and script methods.

ⓘ Note

From scripts, methods are accessed using the same syntax as other members with the addition of parenthesis at the end of the method name.

Code Methods

A code method is an extended member that is defined in a CLR language. It provides similar functionality to a method defined on a base object; however, a code method may be added dynamically to an **PSObject** object. In order for a code method to become available, a developer must write the property in some CLR language, compile, and ship the resultant assembly. This assembly must be available in the runspace where the code method is desired. Be aware that a code method implementation must be thread safe. Access to these methods is done through **PSCodemethod** objects that provides the following public methods and properties.

- **PSCodemethod.Copy** method: Makes an exact copy of the **PSCodemethod** object.
- **PSCodemethod.Invoke(System.Object[])** method: Invokes the underlying code method.
- **PSCodemethod.ToString** method: Converts the **PSCodemethod** object to a string.
- **PSCodemethod.CodeReference** property: Gets the underlying method that the code method is based on.
- **PSMemberInfo.Isinstance** property: Gets a **Boolean** value that indicates the source of the member.
- **PSCodemethod.MemberType** property: Gets an **PSMemberTypes.CodeMethod** enumeration constant that identifies this method as a code method.
- **PSMemberInfo.Name** property: Gets the name of the underlying code method.
- **PSCodemethod.OverloadDefinitions** property: Gets a definition of all the overloads of the underlying code method.
- **PSCodemethod.TypeNameOfValue** property: Gets the full name of the code method.
- **PSMemberInfo.Value** property: Gets the **PSCodemethod** object.

Windows PowerShell Methods

A PowerShell method is a CLR method defined on the base object or is made accessible through an adapter. Access to these methods is done through **PSMethod** objects that provides the following public methods and properties.

- **PSMethod.Copy** method: Makes an exact copy of the **PSMethod** object.
- **PSMethod.Invoke(System.Object[])** method: Invokes the underlying method.
- **PSMethod.ToString** method: Converts the **PSMethod** object to a string.
- **PSMethodInfo.IsInstance** property: Gets a **Boolean** value that indicates the source of the member.
- **PSMethod.MemberType** property: Gets an **PSMemberTypes.Method** enumeration constant that identifies this method as a PowerShell method.
- **PSMethodInfo.Name** property: Gets the name of the underlying method.
- **PSMethod.OverloadDefinitions** property: Gets the definitions of all the overloads of the underlying method.
- **PSMethod.TypeNameOfValue** property: Gets the ETS type of this method.
- **PSMethodInfo.Value** property: Gets the **PSMethod** object.

Script Methods

A script method is an extended member that is defined in the PowerShell language. It provides similar functionality to a method defined on a base object; however, a script method may be added dynamically to an **PSObject** object. Access to these methods is done through **PSScriptMethod** objects that provides the following public methods and properties.

- **PSScriptMethod.Copy** method: Makes an exact copy of the **PSScriptMethod** object.
- **PSScriptMethod.Invoke(System.Object[])** method: Invokes the underlying script method.
- **PSScriptMethod.ToString** method: Converts the **PSScriptMethod** object to a string.
- **PSMethodInfo.IsInstance** property: Gets a **Boolean** value that indicates the source of the member.
- **PSScriptMethod.MemberType** property: Gets a **PSMemberTypes.ScriptMethod** enumeration constant that identifies this method as a script method.
- **PSMethodInfo.Name** property: Gets the name of the underlying code method.
- **PSScriptMethod.OverloadDefinitions** property: Gets the definitions of all the overloads of the underlying script method.
- **PSScriptMethod.TypeNameOfValue** property: Gets the ETS type of this method.
- **PSScriptMethod.Script** property: Gets the script used to invoke the method.

- **PSMemberInfo.Value** property: Gets the **PSScriptMethod** object.

ETS type converters

Article • 09/17/2021

ETS uses two basic types of type converters when a call is made to the `LanguagePrimitives.ConvertTo(System.Object, System.Type)` method. When this method is called, PowerShell attempts to perform the type conversion using its standard PowerShell language converters or a custom converter. If PowerShell cannot perform the conversion, it throws an `PSInvalidCastException` exception.

Standard Windows PowerShell Language Converters

These standard conversions are checked before any custom conversions and cannot be overridden. The following table lists the type conversions performed by PowerShell when the `ConvertTo(System.Object, System.Type)` method is called. Be aware that references to the `valueToConvert` and `resultType` parameters refer to parameters of the `ConvertTo(System.Object, System.Type)` method.

 Expand table

From (<code>valueToConvert</code>)	To (<code>resultType</code>)	Returns
Null	String	""
Null	Char	'\0'
Null	Numeric	0 of the type specified in the <code>resultType</code> parameter.
Null	Boolean	Results of call to the <code>IsTrue(System.Object)(Null)</code> method.
Null	PSObject	New object of type <code>PSObject</code> .
Null	Non-value-type	Null.
Null	Nullable<T>	Null.
Derived Class	Base class	<code>valueToConvert</code>
Anything	Void	<code>AutomationNull.Value</code>
Anything	String	Calls <code>ToString</code> mechanism.
Anything	Boolean	<code>IsTrue(System.Object) (valueToConvert)</code>

From Anything (valueToConvert)	To PSObject (resultType)	Returns Results of call to the <code>AsPSObject(System.Object)(valueToConvert)</code> method.
Anything	Xml Document	Converts valueToConvert to string, then calls XMLDocument constructor.
Array	Array	Attempts to convert each element of the array.
Singleton	Array	<code>Array[0]</code> equals valueToConvert that is converted to the element type of the array.
IDictionary	Hash table	Results of call to <code>Hashtable(valueToConvert)</code> .
String	Char[]	<code>valueToConvert.ToCharArray</code>
String	RegEx	Results of call to <code>Regx(valueToConvert)</code> .
String	Type	Returns the appropriate type using the valueToConvert parameter to search RunspaceConfiguration.Assemblies .
String	Numeric	If valueToConvert is "", returns <code>0</code> of the resultType . Otherwise the culture "culture invariant" is used to produce a numeric value.
Integer	System.Enum	Converts the integer to the constant if the integer is defined by the enumeration. If the integer is not defined an PSInvalidCastException exception is thrown.

Custom conversions

If PowerShell cannot convert the type using a standard PowerShell language converter, it then checks for custom converters. PowerShell looks for several types of custom converters in the order described in this section. Be aware that references to the **valueToConvert** and **resultType** parameters refer to parameters of the `ConvertTo(System.Object, System.Type)` method. If a custom converter throws an exception, then no further attempt is made to convert the object and that exception is wrapped in a **PSInvalidCastException** exception which is then thrown.

PowerShell type converter

PowerShell type converters are used to convert a single type or a family of types, such as all types that derive from the **System.Enum** class. To create a PowerShell type converter you must implement an **PSTypeConverter** class and associate that implementation with the target class. There are two ways of associating the PowerShell type converter with its target class.

- Through the type configuration file
- By applying the **TypeConverterAttribute** attribute to the target class

PowerShell type converters, derived from the [PSTypeConverter](#) abstract class, provide methods for converting an object to a specific type or from a specific type. If the **valueToConvert** parameter contains an object that has a PowerShell Type converter associated with it, PowerShell calls the `PSTypeConverter.ConvertTo(System.Object, System.Type, System.IFormatProvider, System.Boolean)` method of the associated converter to convert the object to the type specified by the **resultType** parameter. If the **resultType** parameter references a type that has a PowerShell type converter associated with it, PowerShell calls the `PSTypeConverter.ConvertFrom(System.Object, System.Type, System.IFormatProvider, System.Boolean)` method of the associated converter to convert the object from the type specified by the **resultType** parameter.

System type converter

System type converters are used to convert a specific target class. This type of converter cannot be used to convert a family of classes. To create an system type converter you must implement an [TypeConverter](#) class and associate that implementation with the target class. There are two ways of associating the system type converter with its target class.

- Through the type configuration file
- By applying the **TypeConverterAttribute** attribute to the target class

Parse converter

If the **valueToConvert** parameter is a string, and the object type of the **resultType** parameter has a `Parse` method, then the `Parse` method is called to convert the string.

Constructor converter

If the object type of the **resultType** parameter has a constructor that has a single parameter that is the same type as the object of the **valueToConvert** parameter, then this constructor is called.

Implicit cast operator converter

If the `valueToConvert` parameter has an implicit cast operator that converts to `resultType`, then its cast operator is called. If the `resultType` parameter has an implicit cast operator that converts from `valueToConvert`, then its cast operator is called.

Explicit cast operator converter

If the `valueToConvert` parameter has an explicit cast operator that converts to `resultType`, then its cast operator is called. If the `resultType` parameter has an explicit cast operator that converts from `valueToConvert`, then its cast operator is called.

Errors and exceptions in the Extended Type System

Article • 09/17/2021

Errors can occur in ETS during the initialization of type data and when accessing a member of an **PSObject** object or using one of the utility classes such as **LanguagePrimitives**.

Runtime errors

With one exception, when casting, all exceptions thrown from ETS during runtime are either an **ExtendedTypeSystemException** exception or an exception derived from the **ExtendedTypeSystemException** class. This allows script developers to trap these exceptions using the `trap` statement in their script.

Errors getting member values

All errors that occur when getting the value of an ETS member (property, method, or parameterized property) cause a **GetValueException** or **GetValueInvocationException** exception to be thrown. When ETS recognizes that an error occurred a **GetValueException** exception is thrown. When the underlying getter of a referenced member recognizes that an error occurred, a **GetValueInvocationException** exception is thrown that may or may not include the inner exception that caused the get invocation error.

Errors setting member values

All errors that occur when setting the value of an ETS property cause a **SetValueException** or **SetValueInvocationException** exception to be thrown. When ETS recognizes that an error occurred a **SetValueException** exception is thrown. When the underlying setter of a referenced property recognizes that an error occurred, a **SetValueInvocationException** exception is thrown that may or may not include the inner exception that caused the set invocation error.

Errors invoking a method

All errors that occur when invoking an ETS method cause a **MethodException** or **MethodInvocationException** exception to be thrown. When ETS recognizes that an error occurred a **MethodException** exception is thrown. When the referenced method recognizes that an error occurred, a **MethodInvocationException** exception is thrown that may or may not include the inner exception that caused the invocation error.

Casting errors

When an invalid cast is attempted, an **PSInvalidCastException** is thrown. Because this exception derives from **System.InvalidCastException**, it is not able to be directly trapped from script. Be aware that the entity attempting the cast would need to wrap **PSInvalidCastException** in an **PSRuntimeException** for this to be trappable by scripts. If an attempt is made to set the value of an **PSPropertySet**, **PSMemberSet**, **PSMethodInfo**, or a member of the **ReadOnlyPSMemberInfoCollection`1**, a **NotSupportedException** is thrown.

Common runtime errors

Any other common runtime errors that occur are of type **ExtendedTypeSystemException** exception with no additional specific exception types.

Initialization errors

Errors may occur when initializing `types.ps1xml`. Typically, these errors are displayed when the PowerShell runtime starts. However, they can also be displayed when a module is loaded.

Windows PowerShell Programmer's Guide

Article • 09/17/2021

This programmer's guide is targeted at developers who are interested in providing a command-line management environment for system administrators. Windows PowerShell provides a simple way for you to build management commands that expose .NET objects, while allowing Windows PowerShell to do most of the work for you.

In traditional command development, you are required to write a parameter parser, a parameter binder, filters, and all other functionality exposed by each command. Windows PowerShell provides the following to make it easy for you to write commands:

- A powerful Windows PowerShell runtime (execution engine) with its own parser and a mechanism for automatically binding command parameters.
- Utilities for formatting and displaying command results using a command line interpreter (CLI).
- Support for high levels of functionality (through Windows PowerShell providers) that make it easy to access stored data.

At little cost, you can represent a .NET object by a rich command or set of commands that will offer a complete command-line experience to the administrator.

The next section covers the key Windows PowerShell concepts and terms. Familiarize yourself with these concepts and terms before starting development.

About Windows PowerShell

Windows PowerShell defines several types of commands that you can use in development. These commands include: functions, filters, scripts, aliases, and executables (applications). The main command type discussed in this guide is a simple, small command called a "cmdlet". Windows PowerShell furnishes a set of cmdlets and fully supports cmdlet customization to suit your environment. The Windows PowerShell runtime processes all command types just as it does cmdlets, using pipelines.

In addition to commands, Windows PowerShell supports various customizable Windows PowerShell providers that make available specific sets of cmdlets. The shell operates within the Windows PowerShell-provided host application (`powershell.exe`), but it is equally accessible from a custom host application that you can develop to meet specific requirements. For more information, see [How Windows PowerShell Works](#).

Windows PowerShell Cmdlets

A cmdlet is a lightweight command that is used in the Windows PowerShell environment. The Windows PowerShell runtime invokes these cmdlets within the context of automation scripts that are provided at the command line, and the Windows PowerShell runtime also invokes them programmatically through Windows PowerShell APIs.

For more information about cmdlets, see [Writing a Windows PowerShell Cmdlet](#).

Windows PowerShell Providers

In performing administrative tasks, the user may need to examine data stored in a data store (for example, the file system, the Windows Registry, or a certificate store). To make these operations easier, Windows PowerShell defines a module called a Windows PowerShell provider that can be used to access a specific data store, such as the Windows Registry. Each provider supports a set of related cmdlets to give the user a symmetrical view of the data in the store.

Windows PowerShell provides several default Windows PowerShell providers. For example, the Registry provider supports navigation and manipulation of the Windows Registry. Registry keys are represented as items, and registry values are treated as properties.

If you expose a data store that the user will need to access, you might need to write your own Windows PowerShell provider, as described in [Creating Windows PowerShell Providers](#). For more information about Windows PowerShell providers, see [How Windows PowerShell Works](#).

Host Application

Windows PowerShell includes the default host application powershell.exe, which is a console application that interacts with the user and hosts the Windows PowerShell runtime using a console window.

Only rarely will you need to write your own host application for Windows PowerShell, although customization is supported. One case in which you might need your own application is when you have a requirement for a GUI interface that is richer than the interface provided by the default host application. You might also want a custom application when you are basing your GUI on the command line. For more information, see [How to Create a Windows PowerShell Host Application](#).

Windows PowerShell Runtime

The Windows PowerShell runtime is the execution engine that implements command processing. It includes the classes that provide the interface between the host application and Windows PowerShell commands and providers. The Windows PowerShell runtime is implemented as a runspace object for the current Windows PowerShell session, which is the operational environment in which the shell and the commands execute. For operational details, see [How Windows PowerShell Works](#).

Windows PowerShell Language

The Windows PowerShell language provides scripting functions and mechanisms to invoke commands. For complete scripting information, see the Windows PowerShell Language Reference shipped with Windows PowerShell.

Extended Type System (ETS)

Windows PowerShell provides access to a variety of different objects, such as .NET and XML objects. As a consequence, to present a common abstraction for all object types the shell uses its extended type system (ETS). Most ETS functionality is transparent to the user, but the script or .NET developer uses it for the following purposes:

- Viewing a subset of the members of specific objects. Windows PowerShell provides an "adapted" view of several specific object types.
- Adding members to existing objects.
- Access to serialized objects.
- Writing customized objects.

Using ETS, you can create flexible new "types" that are compatible with the Windows PowerShell language. If you are a .NET developer, you are able to work with objects using the same semantics as the Windows PowerShell language applies to scripting, for example, to determine if an object evaluates to `true`.

For more information about ETS and how Windows PowerShell uses objects, see [Windows PowerShell Object Concepts](#).

Programming for Windows PowerShell

Windows PowerShell defines its code for commands, providers, and other program modules using the .NET Framework. You are not confined to the use of Microsoft Visual Studio in creating customized modules for Windows PowerShell, although the samples provided in this

guide are known to run in this tool. You can use any .NET language that supports class inheritance and the use of attributes. In some cases, Windows PowerShell APIs require the programming language to be able to access generic types.

Programmer's Reference

For reference when developing for Windows PowerShell, see the [Windows PowerShell SDK](#).

Getting Started Using Windows PowerShell

For more information about starting to use the Windows PowerShell shell, see the [Getting Started with Windows PowerShell](#) shipped with Windows PowerShell. A Quick Reference tri-fold document is also supplied as a primer for cmdlet use.

Contents of This Guide

How to Create a Windows PowerShell Provider

Article • 09/17/2021

This section describes how to build a Windows PowerShell provider. A Windows PowerShell provider can be considered in two ways. To the user, the provider represents a set of stored data. For example, the stored data can be the Internet Information Services (IIS) Metabase, the Microsoft Windows Registry, the Windows file system, Active Directory, and the variable and alias data stored by Windows PowerShell.

To the developer, the Windows PowerShell provider is the interface between the user and the data that the user needs to access. From this perspective, each type of provider described in this section supports a set of specific base classes and interfaces that allow the Windows PowerShell runtime to expose certain cmdlets to the user in a common way.

Providers Provided by Windows PowerShell

Windows PowerShell provides several providers (such as the FileSystem provider, Registry provider, and Alias provider) that are used to access known data stores. For more information about the providers supplied by Windows PowerShell, use the following command to access online Help:

```
PS>Get-Help about_Providers
```

Accessing the Stored Data Using Windows PowerShell Paths

Windows PowerShell providers are accessible to the Windows PowerShell runtime and to commands programmatically through the use of Windows PowerShell paths. Most of the time, these paths are used to directly access the data through the provider. However, some paths can be resolved to provider-internal paths that allow a cmdlet to use non-Windows PowerShell application programming interfaces (APIs) to access the data. For more information about how Windows PowerShell providers operate within Windows PowerShell, see [How Windows PowerShell Works](#).

Exposing Provider Cmdlets Using Windows PowerShell Drives

A Windows PowerShell provider exposes its supported cmdlets using virtual Windows PowerShell drives. Windows PowerShell applies the following rules for a Windows PowerShell drive:

- The name of a drive can be any alphanumeric sequence.
- A drive can be specified at any valid point on a path, called a "root".
- A drive can be implemented for any stored data, not just the file system.
- Each drive keeps its own current working location, allowing the user to retain context when shifting between drives.

In This Section

The following table lists topics that include code examples that build on each other. Starting with the second topic, the basic Windows PowerShell provider can be initialized and uninitialized by the Windows PowerShell runtime, the next topic adds functionality for accessing the data, the next topic adds functionality for manipulating the data (the items in the stored data), and so on.

[] Expand table

Topic	Definition
Designing Your Windows PowerShell Provider	This topic discusses things you should consider before implementing a Windows PowerShell provider. It summarizes the Windows PowerShell provider base classes and interfaces that are used.
Creating a Basic Windows PowerShell Provider	This topic shows how to create a Windows PowerShell provider that allows the Windows PowerShell runtime to initialize and uninitialized the provider.
Creating a Windows PowerShell Drive Provider	This topic shows how to create a Windows PowerShell provider that allows the user to access a data store through a Windows PowerShell drive.
Creating a Windows PowerShell Item Provider	This topic shows how to create a Windows PowerShell provider that allows the user to manipulate the items in a data store.
Creating a Windows PowerShell Container Provider	This topic shows how to create a Windows PowerShell provider that allows the user to work on multilayer data stores.

Topic	Definition
Creating a Windows PowerShell Navigation Provider	This topic shows how to create a Windows PowerShell provider that allows the user to navigate the items of a data store in a hierarchical manner.
Creating a Windows PowerShell Content Provider	This topic shows how to create a Windows PowerShell provider that allows the user to manipulate the content of items in a data store.
Creating a Windows PowerShell Property Provider	This topic shows how to create a Windows PowerShell provider that allows the user to manipulate the properties of items in a data store.

Designing Your Windows PowerShell Provider

Article • 03/24/2025

You should implement a Windows PowerShell provider if your product or configuration exposes a set of stored data, such as a database that the user will want to navigate or browse. Additionally, if your product provides a container, even if it is not a multilevel container, it makes sense to implement a Windows PowerShell provider. For example, you might want to implement a Windows PowerShell container provider if the cmdlet verb Copy, Move, Rename, New, or Remove makes sense as an operation on your product or configuration data.

Windows PowerShell Paths Identify Your Provider

The Windows PowerShell runtime uses Windows PowerShell paths to access the appropriate Windows PowerShell provider. When a cmdlet specifies one of these paths, the runtime knows which provider to use to access the associated data store. These paths include drive-qualified paths, provider-qualified paths, provider-direct paths, and provider-internal paths. Each Windows PowerShell provider must support one or more of these paths.

For more information about Windows PowerShell paths, see [How Windows PowerShell Works](#).

Defining a Drive-Qualified Path

To allow the user to access data located at a physical drive, your Windows PowerShell provider must support a drive-qualified path. This path starts with the drive name followed by a colon (:), for example, mydrive:\abc\bar.

Defining a Provider-Qualified Path

To allow the Windows PowerShell runtime to initialize and uninitialized the provider, your Windows PowerShell provider must support a provider-qualified path. For example, FileSystem::\\uncshare\abc\bar is the provider-qualified path for the FileSystem provider furnished by Windows PowerShell.

Defining a Provider-Direct Path

To allow remote access to your Windows PowerShell provider, it should support a provider-direct path to pass directly to the Windows PowerShell provider for the current location. For example, the registry Windows PowerShell provider can use \\server\regkeypath as a provider-direct path.

Defining a Provider-Internal Path

To allow the provider cmdlet to access data using non-Windows PowerShell application programming interfaces (APIs), your Windows PowerShell provider should support a provider-internal path. This path is indicated after the ":" in the provider-qualified path. For example, the provider-internal path for the FileSystem Windows PowerShell provider is \\uncshare\abc\bar.

Changing Stored Data

When overriding methods that modify the underlying data store, always call the [System.Management.Automation.Provider.CmdletProvider.WriteItemObject*](#) method with the most up-to-date version of the item changed by that method. The provider infrastructure determines if the item object needs to be passed to the pipeline, such as when the user specifies the -PassThru parameter. If retrieving the most up-to-date item is a costly operation (performance-wise,) you can test the Context.PassThru property to determine if you actually need to write the resulting item.

Choose a Base Class for Your Provider

Windows PowerShell provides a number of base classes that you can use to implement your own Windows PowerShell provider. When designing a provider, choose the base class, described in this section, that is most suited to your requirements.

Each Windows PowerShell provider base class makes available a set of cmdlets. This section describes the cmdlets, but it does not describe their parameters.

Using the session state, the Windows PowerShell runtime makes several location cmdlets available to certain Windows PowerShell providers, such as the `Get-Location`, `Set-Location`, `Pop-Location`, and `Push-Location` cmdlets. You can use the `Get-Help` cmdlet to obtain information about these location cmdlets.

CmdletProvider Base Class

The [System.Management.Automation.Provider.CmdletProvider](#) class defines a basic Windows PowerShell provider. This class supports the provider declaration and supplies a number of properties and methods that are available to all Windows PowerShell providers. The class is invoked by the `Get-PSProvider` cmdlet to list all available providers for a session. The implementation of this cmdlet is furnished by the session state.

 **Note**

Windows PowerShell providers are available to all Windows PowerShell language scopes.

DriveCmdletProvider Base Class

The [System.Management.Automation.Provider.DriveCmdletProvider](#) class defines a Windows PowerShell drive provider that supports operations for adding new drives, removing existing drives, and initializing default drives. For example, the [FileSystem](#) provider provided by Windows PowerShell initializes drives for all volumes that are mounted, such as hard drives and CD/DVD device drives.

This class derives from the [System.Management.Automation.Provider.CmdletProvider](#) base class. The following table lists the cmdlets exposed by this class. In addition to those listed, the `Get-PSDrive` cmdlet (exposed by session state) is a related cmdlet that is used to retrieve available drives.

 [Expand table](#)

Cmdlet	Definition
<code>New-PSDrive</code>	Creates a new drive for the session, and streams drive information.
<code>Remove-PSDrive</code>	Removes a drive from the session.

ItemCmdletProvider Base Class

The [System.Management.Automation.Provider.ItemCmdletProvider](#) class defines a Windows PowerShell item provider that performs operations on the individual items of the data store, and it does not assume any container or navigation capabilities. This class derives from the [System.Management.Automation.Provider.DriveCmdletProvider](#) base class. The following table lists the cmdlets exposed by this class.

[+] Expand table

Cmdlet	Definition
Clear-Item	Clears the current content of items at the specified location, and replaces it with the "clear" value specified by the provider. This cmdlet does not pass an output object through the pipeline unless its <code>PassThru</code> parameter is specified.
Get-Item	Retrieves items from the specified location, and streams the resultant objects.
Invoke-Item	Invokes the default action for the item at the specified path.
Set-Item	Sets an item at the specified location with the indicated value. This cmdlet does not pass an output object through the pipeline unless its <code>PassThru</code> parameter is specified.
Resolve-Path	Resolves the wildcards for a Windows PowerShell path, and streams path information.
Test-Path	Tests for the specified path, and returns <code>true</code> if it exists and <code>false</code> otherwise. This cmdlet is implemented to support the <code>IsContainer</code> parameter for the System.Management.Automation.Provider.CmdletProvider.WriteLineObject * method.

ContainerCmdletProvider Base Class

The [System.Management.Automation.Provider.ContainerCmdletProvider](#) class defines a Windows PowerShell container provider that exposes a container, for data store items, to the user. Be aware that a Windows PowerShell container provider can be used only when there is one container (no nested containers) with items in it. If there are nested containers, then you must implement a Windows PowerShell navigation provider .

This class derives from the

[System.Management.Automation.Provider.ItemCmdletProvider](#) base class. The following table defines the cmdlets implemented by this class.

[+] Expand table

Cmdlet	Definition
Copy-Item	Copies items from one location to another. This cmdlet does not pass an output object through the pipeline unless its <code>PassThru</code> parameter is specified.
Get-ChildItem	Retrieves the child items at the specified location, and streams them as objects.
New-Item	Creates new items at the specified location, and streams the resultant object.

Cmdlet	Definition
Remove-Item	Removes items from the specified location.
Rename-Item	Renames an item at the specified location. This cmdlet does not pass an output object through the pipeline unless its <code>PassThru</code> parameter is specified.

NavigationCmdletProvider Base Class

The [System.Management.Automation.Provider.NavigationCmdletProvider](#) class defines a Windows PowerShell navigation provider that performs operations for items that use more than one container. This class derives from the [System.Management.Automation.Provider.ContainerCmdletProvider](#) base class. The following table lists the cmdlets exposed by this class.

[] [Expand table](#)

Cmdlet	Definition
Combine-Path	Combines two paths into a single path, using a provider-specific delimiter between paths. This cmdlet streams strings.
Move-Item	Moves items to the specified location. This cmdlet does not pass an output object through the pipeline unless its <code>PassThru</code> parameter is specified.

A related cmdlet is the basic `Parse-Path` cmdlet furnished by Windows PowerShell. This cmdlet can be used to parse a Windows PowerShell path to support the `Parent` parameter. It streams the parent path string.

Select Provider Interfaces to Support

In addition to deriving from one of the Windows PowerShell base classes, your Windows PowerShell provider can support other functionality by deriving from one or more of the following provider interfaces. This section defines those interfaces and the cmdlets supported by each. It does not describe the parameters for the interface-supported cmdlets. Cmdlet parameter information is available online using the `Get-Command` and `Get-Help` cmdlets.

IContentCmdletProvider

The [System.Management.Automation.Provider.IContentCmdletProvider](#) interface defines a content provider that performs operations on the content of a data item. The following table lists the cmdlets exposed by this interface.

[+] [Expand table](#)

Cmdlet	Definition
Add-Content	Appends the indicated value lengths to the contents of the specified item. This cmdlet does not pass an output object through the pipeline unless its <code>PassThru</code> parameter is specified.
Clear-Content	Sets the content of the specified item to the "clear" value. This cmdlet does not pass an output object through the pipeline unless its <code>PassThru</code> parameter is specified.
Get-Content	Retrieves the contents of the specified items and streams the resultant objects.
Set-Content	Replaces the existing content for the specified items. This cmdlet does not pass an output object through the pipeline unless its <code>PassThru</code> parameter is specified.

IPropertyCmdletProvider

The [System.Management.Automation.Provider.IPropertyCmdletProvider](#) interface defines a property Windows PowerShell provider that performs operations on the properties of items in the data store. The following table lists the cmdlets exposed by this interface.

ⓘ Note

The `Path` parameter on these cmdlets indicates a path to an item instead of identifying a property.

[+] [Expand table](#)

Cmdlet	Definition
Clear-ItemProperty	Sets properties of the specified items to the "clear" value. This cmdlet does not pass an output object through the pipeline unless its <code>PassThru</code> parameter is specified.
Get-ItemProperty	Retrieves properties from the specified items and streams the resultant objects.

Cmdlet	Definition
Set- ItemProperty	Sets properties of the specified items with the indicated values. This cmdlet does not pass an output object through the pipeline unless its <code>PassThru</code> parameter is specified.

IDynamicPropertyCmdletProvider

The [System.Management.Automation.Provider.IDynamicPropertyCmdletProvider](#) interface, derived from [System.Management.Automation.Provider.IPropertyCmdletProvider](#), defines a provider that specifies dynamic parameters for its supported cmdlets. This type of provider handles operations for which properties can be defined at run time, for example, a new property operation. Such operations are not possible on items having statically defined properties. The following table lists the cmdlets exposed by this interface.

[+] [Expand table](#)

Cmdlet	Definition
Copy- ItemProperty	Copies a property from the specified item to another item. This cmdlet does not pass an output object through the pipeline unless its <code>PassThru</code> parameter is specified.
Move- ItemProperty	Moves a property from the specified item to another item. This cmdlet does not pass an output object through the pipeline unless its <code>PassThru</code> parameter is specified.
New- ItemProperty	Creates a property on the specified items and streams the resultant objects.
Remove- ItemProperty	Removes a property for the specified items.
Rename- ItemProperty	Renames a property of the specified items. This cmdlet does not pass an output object through the pipeline unless its <code>PassThru</code> parameter is specified.

ISecurityDescriptorCmdletProvider

The [System.Management.Automation.Provider.ISecurityDescriptorCmdletProvider](#) interface adds security descriptor functionality to a provider. This interface allows the user to get and set security descriptor information for an item in the data store. The following table lists the cmdlets exposed by this interface.

Cmdlet	Definition
Get-Acl	Retrieves the information contained in an access control list (ACL), which is part of a security descriptor used to guard operating system resources, for example, a file or an object.
Set-Acl	Sets the information for an ACL. It is in the form of an instance of System.Security.AccessControl.ObjectSecurity on the item(s) designated for the specified path. This cmdlet can set information about files, keys, and subkeys in the registry, or any other provider item, if the Windows PowerShell provider supports the setting of security information.

Creating a Basic Windows PowerShell Provider

Article • 09/17/2021

This topic is the starting point for learning how to create a Windows PowerShell provider. The basic provider described here provides methods for starting and stopping the provider, and although this provider does not provide a means to access a data store or to get or set the data in the data store, it does provide the basic functionality that is required by all providers.

As mentioned previously, the basic provider described here implements methods for starting and stopping the provider. The Windows PowerShell runtime calls these methods to initialize and uninitialized the provider.

ⓘ Note

You can find a sample of this provider in the `AccessDBSampleProvider01.cs` file provided by Windows PowerShell.

Defining the Windows PowerShell Provider Class

The first step in creating a Windows PowerShell provider is to define its .NET class. This basic provider defines a class called `AccessDBProvider` that derives from the [System.Management.Automation.Provider.CmdletProvider](#) base class.

It is recommended that you place your provider classes in a `Providers` namespace of your API namespace, for example, `xxx.PowerShell.Providers`. This provider uses the `Microsoft.Samples.PowerShell.Provider` namespace, in which all Windows PowerShell provider samples run.

ⓘ Note

The class for a Windows PowerShell provider must be explicitly marked as public. Classes not marked as public will default to internal and will not be found by the Windows PowerShell runtime.

Here is the class definition for this basic provider:

C#

```
[CmdletProvider("AccessDB", ProviderCapabilities.None)]
public class AccessDBProvider : CmdletProvider
```

Right before the class definition, you must declare the [System.Management.Automation.Provider.CmdletProviderAttribute](#) attribute, with the syntax [CmdletProvider()].

You can set attribute keywords to further declare the class if necessary. Notice that the [System.Management.Automation.Provider.CmdletProviderAttribute](#) attribute declared here includes two parameters. The first attribute parameter specifies the default-friendly name for the provider, which the user can modify later. The second parameter specifies the Windows PowerShell-defined capabilities that the provider exposes to the Windows PowerShell runtime during command processing. The possible values for the provider capabilities are defined by the [System.Management.Automation.Provider.ProviderCapabilities](#) enumeration. Because this is a base provider, it supports no capabilities.

ⓘ Note

The fully qualified name of the Windows PowerShell provider includes the assembly name and other attributes determined by Windows PowerShell upon registration of the provider.

Defining Provider-Specific State Information

The [System.Management.Automation.Provider.CmdletProvider](#) base class and all derived classes are considered stateless because the Windows PowerShell runtime creates provider instances only as required. Therefore, if your provider requires full control and state maintenance for provider-specific data, it must derive a class from the [System.Management.Automation.ProviderInfo](#) class. Your derived class should define the members necessary to maintain the state so that the provider-specific data can be accessed when the Windows PowerShell runtime calls the [System.Management.Automation.Provider.CmdletProvider.Start*](#) method to initialize the provider.

A Windows PowerShell provider can also maintain connection-based state. For more information about maintaining connection state, see [Creating a PowerShell Drive Provider](#).

Initializing the Provider

To initialize the provider, the Windows PowerShell runtime calls the [System.Management.Automation.Provider.CmdletProvider.Start*](#) method when Windows PowerShell is started. For the most part, your provider can use the default implementation of this method, which simply returns the [System.Management.Automation.ProviderInfo](#) object that describes your provider. However, in the case where you want to add additional initialization information, you should implement your own [System.Management.Automation.Provider.CmdletProvider.Start*](#) method that returns a modified version of the [System.Management.Automation.ProviderInfo](#) object that is passed to your provider. In general, this method should return the provided [System.Management.Automation.ProviderInfo](#) object passed to it or a modified [System.Management.Automation.ProviderInfo](#) object that contains other initialization information.

This basic provider does not override this method. However, the following code shows the default implementation of this method:

The provider can maintain the state of provider-specific information as described in [Defining Provider-specific Data State](#). In this case, your implementation must override the [System.Management.Automation.Provider.CmdletProvider.Start*](#) method to return an instance of the derived class.

Start Dynamic Parameters

Your provider implementation of the [System.Management.Automation.Provider.CmdletProvider.Start*](#) method might require additional parameters. In this case, the provider should override the [System.Management.Automation.Provider.CmdletProvider.StartDynamicParameters*](#) method and return an object that has properties and fields with parsing attributes similar to a cmdlet class or a [System.Management.Automation.RuntimeDefinedParameterDictionary](#) object.

This basic provider does not override this method. However, the following code shows the default implementation of this method:

Uninitializing the Provider

To free resources that the Windows PowerShell provider uses, your provider should implement its own [System.Management.Automation.Provider.CmdletProvider.Stop*](#)

method. This method is called by the Windows PowerShell runtime to uninitialized the provider at the close of a session.

This basic provider does not override this method. However, the following code shows the default implementation of this method:

Code Sample

For complete sample code, see [AccessDbProviderSample01 Code Sample](#).

Testing the Windows PowerShell Provider

Once your Windows PowerShell provider has been registered with Windows PowerShell, you can test it by running the supported cmdlets on the command line. For this basic provider, run the new shell and use the `Get-PSProvider` cmdlet to retrieve the list of providers and ensure that the AccessDb provider is present.

```
PowerShell
Get-PSProvider
```

The following output appears:

```
Output
Name          Capabilities      Drives
----          -----
AccessDb      None
Alias         ShouldProcess
Environment   ShouldProcess
FileSystem    Filter, ShouldProcess
Function      ShouldProcess
Registry      ShouldProcess
```

[Designing Your Windows PowerShell Provider](#)

Creating a Windows PowerShell Drive Provider

Article • 03/24/2025

This topic describes how to create a Windows PowerShell drive provider that provides a way to access a data store through a Windows PowerShell drive. This type of provider is also referred to as Windows PowerShell drive providers. The Windows PowerShell drives used by the provider provide the means to connect to the data store.

The Windows PowerShell drive provider described here provides access to a Microsoft Access database. For this provider, the Windows PowerShell drive represents the database (it is possible to add any number of drives to a drive provider), the top-level containers of the drive represent the tables in the database, and the items of the containers represent the rows in the tables.

Defining the Windows PowerShell Provider Class

Your drive provider must define a .NET class that derives from the [System.Management.Automation.Provider.DriveCmdletProvider](#) base class. Here is the class definition for this drive provider:

```
C#
```

```
[CmdletProvider("AccessDB", ProviderCapabilities.None)]
public class AccessDBProvider : DriveCmdletProvider
```

Notice that in this example, the [System.Management.Automation.Provider.CmdletProviderAttribute](#) attribute specifies a user-friendly name for the provider and the Windows PowerShell specific capabilities that the provider exposes to the Windows PowerShell runtime during command processing. The possible values for the provider capabilities are defined by the [System.Management.Automation.ProviderCapabilities](#) enumeration. This drive provider does not support any of these capabilities.

Defining Base Functionality

As described in [Design Your Windows PowerShell Provider](#), the [System.Management.Automation.Provider.DriveCmdletProvider](#) class derives from the

`System.Management.Automation.Provider.CmdletProvider` base class that defines the methods needed for initializing and uninitialized the provider. To implement functionality for adding session-specific initialization information and for releasing resources that are used by the provider, see [Creating a Basic Windows PowerShell Provider](#). However, most providers (including the provider described here) can use the default implementation of this functionality that is provided by Windows PowerShell.

Creating Drive State Information

All Windows PowerShell providers are considered stateless, which means that your drive provider needs to create any state information that is needed by the Windows PowerShell runtime when it calls your provider.

For this drive provider, state information includes the connection to the database that is kept as part of the drive information. Here is code that shows how this information is stored in the `System.Management.Automation.PSDriveinfo` object that describes the drive:

C#

```
internal class AccessDBPSDriveInfo : PSDriveInfo
{
    private OdbcConnection connection;

    /// <summary>
    /// ODBC connection information.
    /// </summary>
    public OdbcConnection Connection
    {
        get { return connection; }
        set { connection = value; }
    }

    /// <summary>
    /// Constructor that takes one argument
    /// </summary>
    /// <param name="driveInfo">Drive provided by this provider</param>
    public AccessDBPSDriveInfo(PSDriveInfo driveInfo)
        : base(driveInfo)
    { }

} // class AccessDBPSDriveInfo
```

Creating a Drive

To allow the Windows PowerShell runtime to create a drive, the drive provider must implement the [System.Management.Automation.Provider.DriveCmdletProvider.NewDrive*](#) method. The following code shows the implementation of the [System.Management.Automation.Provider.DriveCmdletProvider.NewDrive*](#) method for this drive provider:

C#

```
protected override PSDriveInfo NewDrive(PSDriveInfo drive)
{
    // check if drive object is null
    if (drive == null)
    {
        WriteError(new ErrorRecord(
            new ArgumentNullException("drive"),
            "NullDrive",
            ErrorCategory.InvalidArgument,
            null)
        );
        return null;
    }

    // check if drive root is not null or empty
    // and if its an existing file
    if (String.IsNullOrEmpty(drive.Root) || (File.Exists(drive.Root)
== false))
    {
        WriteError(new ErrorRecord(
            new ArgumentException("drive.Root"),
            "NoRoot",
            ErrorCategory.InvalidArgument,
            drive)
        );
        return null;
    }

    // create a new drive and create an ODBC connection to the new
    // drive
    AccessDBPSDriveInfo accessDBPSDriveInfo = new
    AccessDBPSDriveInfo(drive);

    OdbcConnectionStringBuilder builder = new
    OdbcConnectionStringBuilder();

    builder.Driver = "Microsoft Access Driver (*.mdb)";
    builder.Add("DBQ", drive.Root);

    OdbcConnection conn = new
    OdbcConnection(builder.ConnectionString);
```

```
conn.Open();
accessDBPSDriveInfo.Connection = conn;

return accessDBPSDriveInfo;
} // NewDrive
```

Your override of this method should do the following:

- Verify that the [System.Management.Automation.PSDriveinfo.Root*](#) member exists and that a connection to the data store can be made.
- Create a drive and populate the connection member, in support of the [New-PSDrive](#) cmdlet.
- Validate the [System.Management.Automation.PSDriveinfo](#) object for the proposed drive.
- Modify the [System.Management.Automation.PSDriveinfo](#) object that describes the drive with any required performance or reliability information, or provide extra data for callers using the drive.
- Handle failures using the [System.Management.Automation.Provider.CmdletProvider.WriteError](#) method and then return `null`.

This method returns either the drive information that was passed to the method or a provider-specific version of it.

Attaching Dynamic Parameters to NewDrive

The [New-PSDrive](#) cmdlet supported by your drive provider might require additional parameters. To attach these dynamic parameters to the cmdlet, the provider implements the

[System.Management.Automation.Provider.DriveCmdletProvider.NewDriveDynamicParameters*](#) method. This method returns an object that has properties and fields with parsing attributes similar to a cmdlet class or a [System.Management.Automation.RuntimeDefinedParameterDictionary](#) object.

This drive provider does not override this method. However, the following code shows the default implementation of this method:

Removing a Drive

To close the database connection, the drive provider must implement the [System.Management.Automation.Provider.DriveCmdletProvider.RemoveDrive*](#) method. This method closes the connection to the drive after cleaning up any provider-specific information.

The following code shows the implementation of the [System.Management.Automation.Provider.DriveCmdletProvider.RemoveDrive*](#) method for this drive provider:

C#

```
protected override PSDriveInfo RemoveDrive(PSDriveInfo drive)
{
    // check if drive object is null
    if (drive == null)
    {
        WriteError(new ErrorRecord(
            new ArgumentNullException("drive"),
            "NullDrive",
            ErrorCategory.InvalidArgument,
            drive)
    );
    return null;
}

// close ODBC connection to the drive
AccessDBPSDriveInfo accessDBPSDriveInfo = drive as AccessDBPSDriveInfo;

if (accessDBPSDriveInfo == null)
{
    return null;
}
accessDBPSDriveInfo.Connection.Close();

return accessDBPSDriveInfo;
} // RemoveDrive
```

If the drive can be removed, the method should return the information passed to the method through the `drive` parameter. If the drive cannot be removed, the method should write an exception and then return `null`. If your provider does not override this method, the default implementation of this method just returns the drive information passed as input.

Initializing Default Drives

Your drive provider implements the [System.Management.Automation.Provider.DriveCmdletProvider.InitializeDefaultDrives*](#) method to mount drives. For example, the Active Directory provider might mount a drive for the default naming context if the computer is joined to a domain.

This method returns a collection of drive information about the initialized drives, or an empty collection. The call to this method is made after the Windows PowerShell runtime calls the [System.Management.Automation.Provider.CmdletProvider.Start*](#) method to initialize the provider.

This drive provider does not override the [System.Management.Automation.Provider.DriveCmdletProvider.InitializeDefaultDrives*](#) method. However, the following code shows the default implementation, which returns an empty drive collection:

Things to Remember About Implementing InitializeDefaultDrives

All drive providers should mount a root drive to help the user with discoverability. The root drive might list locations that serve as roots for other mounted drives. For example, the Active Directory provider might create a drive that lists the naming contexts found in the `namingContext` attributes on the root Distributed System Environment (DSE). This helps users discover mount points for other drives.

Code Sample

For complete sample code, see [AccessDbProviderSample02 Code Sample](#).

Testing the Windows PowerShell Drive Provider

When your Windows PowerShell provider has been registered with Windows PowerShell, you can test it by running the supported cmdlets on the command line, including any cmdlets made available by derivation. Let's test the sample drive provider.

1. Run the `Get-PSPProvider` cmdlet to retrieve the list of providers to ensure that the AccessDB drive provider is present:

```
PS> Get-PSPProvider
```

The following output appears:

```
Output
```

Name	Capabilities	Drives
AccessDB	None	{}
Alias	ShouldProcess	{Alias}
Environment	ShouldProcess	{Env}
FileSystem	Filter, ShouldProcess	{C, Z}
Function	ShouldProcess	{function}
Registry	ShouldProcess	{HKLM, HKCU}

2. Ensure that a database server name (DSN) exists for the database by accessing the **Data Sources** portion of the **Administrative Tools** for the operating system. In the **User DSN** table, double-click **MS Access Database** and add the drive path

C:\ps\northwind.mdb.

3. Create a new drive using the sample drive provider:

PowerShell

```
New-PSDrive -Name mydb -Root C:\ps\northwind.mdb -PSPrinter AccessDb`
```

The following output appears:

Output

Name	Provider	Root	CurrentLocation
mydb	AccessDB	C:\ps\northwind.mdb	

4. Validate the connection. Because the connection is defined as a member of the drive, you can check it using the Get-PDDrive cmdlet.

(!) Note

The user cannot yet interact with the provider as a drive, as the provider needs container functionality for that interaction. For more information, see [Creating a Windows PowerShell Container Provider](#).

PS> (Get-PSDrive mydb).Connection

The following output appears:

Output

```
ConnectionString : Driver={Microsoft Access Driver (*.mdb)};DBQ=C:\ps\northwind.mdb
ConnectionTimeout : 15
Database        : C:\ps\northwind
DataSource       : ACCESS
ServerVersion    : 04.00.0000
Driver           : odbcjt32.dll
State            : Open
Site             :
Container        :
```

5. Remove the drive and exit the shell:

```
PowerShell
```

```
PS> Remove-PSDrive mydb
PS> exit
```

[Creating a Basic Windows PowerShell Provider](#)

Creating a Windows PowerShell item provider

Article • 05/12/2022

This topic describes how to create a Windows PowerShell provider that can manipulate the data in a data store. In this topic, the elements of data in the store are referred to as the "items" of the data store. As a consequence, a provider that can manipulate the data in the store is referred to as a Windows PowerShell item provider.

ⓘ Note

You can download the C# source file (`AccessDBSampleProvider03.cs`) for this provider using the Microsoft Windows Software Development Kit for Windows Vista and .NET Framework 3.0 Runtime Components. For download instructions, see [How to Install Windows PowerShell and Download the Windows PowerShell SDK](#). The downloaded source files are available in the `PowerShell Samples` directory. For more information about other Windows PowerShell provider implementations, see [Designing Your Windows PowerShell Provider](#).

The Windows PowerShell item provider described in this topic gets items of data from an Access database. In this case, an "item" is either a table in the Access database or a row in a table.

Defining the Windows PowerShell item provider class

A Windows PowerShell item provider must define a .NET class that derives from the [System.Management.Automation.Provider.ItemCmdletProvider](#) base class. The following is the class definition for the item provider described in this section.

```
C#
```

```
[CmdletProvider("AccessDB", ProviderCapabilities.None)]  
public class AccessDBProvider : ItemCmdletProvider
```

Note that in this class definition, the [System.Management.Automation.Provider.CmdletProviderAttribute](#) attribute includes two parameters. The first parameter specifies a user-friendly name for the provider that

is used by Windows PowerShell. The second parameter specifies the Windows PowerShell specific capabilities that the provider exposes to the Windows PowerShell runtime during command processing. For this provider, there are no added Windows PowerShell specific capabilities.

Defining base functionality

As described in [Design Your Windows PowerShell Provider](#), the `System.Management.Automation.Provider.DriveCmdletProvider` class derives from several other classes that provided different provider functionality. A Windows PowerShell item provider, therefore, must define all of the functionality provided by those classes.

For more information about how to implement functionality for adding session-specific initialization information and for releasing resources used by the provider, see [Creating a Basic Windows PowerShell Provider](#). However, most providers, including the provider described here, can use the default implementation of this functionality that is provided by Windows PowerShell.

Before the Windows PowerShell item provider can manipulate the items in the store, it must implement the methods of the `System.Management.Automation.Provider.DriveCmdletProvider` base class to access to the data store. For more information about implementing this class, see [Creating a Windows PowerShell Drive Provider](#).

Checking for path validity

When looking for an item of data, the Windows PowerShell runtime furnishes a Windows PowerShell path to the provider, as defined in the "PSPPath Concepts" section of [How Windows PowerShell Works](#). A Windows PowerShell item provider must verify the syntactic and semantic validity of any path passed to it by implementing the `System.Management.Automation.Provider.ItemCmdletProvider.IsValidPath` method. This method returns `true` if the path is valid, and `false` otherwise. Be aware that the implementation of this method should not verify the existence of the item at the path, but only that the path is syntactically and semantically correct.

Here is the implementation of the `System.Management.Automation.Provider.ItemCmdletProvider.IsValidPath` method for this provider. Note that this implementation calls a `NormalizePath` helper method to convert all separators in the path to a uniform one.

C#

```
protected override bool IsValidPath(string path)
{
    bool result = true;

    // check if the path is null or empty
    if (String.IsNullOrEmpty(path))
    {
        result = false;
    }

    // convert all separators in the path to a uniform one
    path = NormalizePath(path);

    // split the path into individual chunks
    string[] pathChunks = path.Split(pathSeparator.ToCharArray());

    foreach (string pathChunk in pathChunks)
    {
        if (pathChunk.Length == 0)
        {
            result = false;
        }
    }
    return result;
} // IsValidPath
```

Determining if an item exists

After verifying the path, the Windows PowerShell runtime must determine if an item of data exists at that path. To support this type of query, the Windows PowerShell item provider implements the

[System.Management.Automation.Provider.ItemCmdletProvider.ItemExists](#) method. This method returns `true` if an item is found at the specified path and `false` (default) otherwise.

Here is the implementation of the

[System.Management.Automation.Provider.ItemCmdletProvider.ItemExists](#) method for this provider. Note that this method calls the `PathIsDrive`, `ChunkPath`, and `GetTable` helper methods, and uses a provider defined `DatabaseTableInfo` object.

C#

```
protected override bool ItemExists(string path)
{
    // check if the path represented is a drive
    if (PathIsDrive(path))
```

```

    {
        return true;
    }

    // Obtain type, table name and row number from path
    string tableName;
    int rowCount;

    PathType type = GetNamesFromPath(path, out tableName, out rowCount);

    DatabaseTableInfo table = GetTable(tableName);

    if (type == PathType.Table)
    {
        // if specified path represents a table then DatabaseTableInfo
        // object for the same should exist
        if (table != null)
        {
            return true;
        }
    }
    else if (type == PathType.Row)
    {
        // if specified path represents a row then DatabaseTableInfo should
        // exist for the table and then specified row number must be within
        // the maximum row count in the table
        if (table != null && rowCount < table.RowCount)
        {
            return true;
        }
    }

    return false;
}

} // ItemExists

```

Things to remember about implementing ItemExists

The following conditions may apply to your implementation of [System.Management.Automation.Provider.ItemCmdletProvider.ItemExists](#):

- When defining the provider class, a Windows PowerShell item provider might declare provider capabilities of `ExpandWildcards`, `Filter`, `Include`, or `Exclude`, from the [System.Management.Automation.Provider.ProviderCapabilities](#) enumeration. In these cases, the implementation of the [System.Management.Automation.Provider.ItemCmdletProvider.ItemExists](#) method must ensure that the path passed to the method meets the requirements of the specified capabilities. To do this, the method should access the appropriate property, for example, the

`System.Management.Automation.Provider.CmdletProvider.Exclude` and
`System.Management.Automation.Provider.CmdletProvider.Include` properties.

- The implementation of this method should handle any form of access to the item that might make the item visible to the user. For example, if a user has write access to a file through the `FileSystem` provider (supplied by Windows PowerShell), but not read access, the file still exists and `System.Management.Automation.Provider.ItemCmdletProvider.ItemExists` returns `true`. Your implementation might require checking a parent item to see if the child item can be enumerated.

Attaching dynamic parameters to the `Test-Path` cmdlet

Sometimes the `Test-Path` cmdlet calls

`System.Management.Automation.Provider.ItemCmdletProvider.ItemExists` requires additional parameters that are specified dynamically at runtime. To provide these dynamic parameters the Windows PowerShell item provider must implement the `System.Management.Automation.Provider.ItemCmdletProvider.ItemExistsDynamicParameters` method. This method retrieves the dynamic parameters for the item at the indicated path and returns an object that has properties and fields with parsing attributes similar to a cmdlet class or a `System.Management.Automation.RuntimeDefinedParameterDictionary` object. The Windows PowerShell runtime uses the returned object to add the parameters to the `Test-Path` cmdlet.

This Windows PowerShell item provider does not implement this method. However, the following code is the default implementation of this method.

Retrieving an item

To retrieve an item, the Windows PowerShell item provider must override `System.Management.Automation.Provider.ItemCmdletProvider.GetItem` method to support calls from the `Get-Item` cmdlet. This method writes the item using the `System.Management.Automation.Provider.CmdletProvider.WriteLineObject` method.

Here is the implementation of the

`System.Management.Automation.Provider.ItemCmdletProvider.GetItem` method for this provider. Note that this method uses the `GetTable` and `GetRow` helper methods to retrieve items that are either tables in the Access database or rows in a data table.

C#

```
protected override void GetItem(string path)
{
    // check if the path represented is a drive
    if (PathIsDrive(path))
    {
        WriteItemObject(this.PSDriveInfo, path, true);
        return;
    } // if (PathIsDrive...

    // Get table name and row information from the path and do
    // necessary actions
    string tableName;
    int rowNumber;

    PathType type = GetNamesFromPath(path, out tableName, out rowNumber);

    if (type == PathType.Table)
    {
        DatabaseTableInfo table = GetTable(tableName);
        WriteItemObject(table, path, true);
    }
    else if (type == PathType.Row)
    {
        DatabaseRowInfo row = GetRow(tableName, rowNumber);
        WriteItemObject(row, path, false);
    }
    else
    {
        ThrowTerminatingInvalidOperationException(path);
    }

} // GetItem
```

Things to remember about implementing GetItem

The following conditions may apply to an implementation of [System.Management.Automation.Provider.ItemCmdletProvider.GetItem](#):

- When defining the provider class, a Windows PowerShell item provider might declare provider capabilities of `ExpandWildcards`, `Filter`, `Include`, or `Exclude`, from the [System.Management.Automation.Provider.ProviderCapabilities](#) enumeration. In these cases, the implementation of [System.Management.Automation.Provider.ItemCmdletProvider.GetItem](#) must ensure that the path passed to the method meets those requirements. To do this, the method should access the appropriate property, for example, the

`System.Management.Automation.Provider.CmdletProvider.Exclude` and `System.Management.Automation.Provider.CmdletProvider.Include` properties.

- By default, overrides of this method should not retrieve objects that are generally hidden from the user unless the `System.Management.Automation.Provider.CmdletProvider.Force` property is set to `true`. For example, the `System.Management.Automation.Provider.ItemCmdletProvider.GetItem` method for the `FileSystem` provider checks the `System.Management.Automation.Provider.CmdletProvider.Force` property before it attempts to call `System.Management.Automation.Provider.CmdletProvider.WriteLineObject` for hidden or system files.

Attaching dynamic parameters to the Get-Item cmdlet

Sometimes the `Get-Item` cmdlet requires additional parameters that are specified dynamically at runtime. To provide these dynamic parameters the Windows PowerShell item provider must implement the `System.Management.Automation.Provider.ItemCmdletProvider.GetItemDynamicParameters` method. This method retrieves the dynamic parameters for the item at the indicated path and returns an object that has properties and fields with parsing attributes similar to a cmdlet class or a `System.Management.Automation.RuntimeDefinedParameterDictionary` object. The Windows PowerShell runtime uses the returned object to add the parameters to the `Get-Item` cmdlet.

This provider does not implement this method. However, the following code is the default implementation of this method.

Setting an item

To set an item, the Windows PowerShell item provider must override the `System.Management.Automation.Provider.ItemCmdletProvider.SetItem` method to support calls from the `Set-Item` cmdlet. This method sets the value of the item at the specified path.

This provider does not provide an override for the `System.Management.Automation.Provider.ItemCmdletProvider.SetItem` method.

However, the following is the default implementation of this method.

Things to remember about implementing SetItem

The following conditions may apply to your implementation of [System.Management.Automation.Provider.ItemCmdletProvider.SetItem](#):

- When defining the provider class, a Windows PowerShell item provider might declare provider capabilities of `ExpandWildcards`, `Filter`, `Include`, or `Exclude`, from the [System.Management.Automation.Provider.ProviderCapabilities](#) enumeration. In these cases, the implementation of [System.Management.Automation.Provider.ItemCmdletProvider.SetItem](#) must ensure that the path passed to the method meets those requirements. To do this, the method should access the appropriate property, for example, the [System.Management.Automation.Provider.CmdletProvider.Exclude](#) and [System.Management.Automation.Provider.CmdletProvider.Include](#) properties.
- By default, overrides of this method should not set or write objects that are hidden from the user unless the [System.Management.Automation.Provider.CmdletProvider.Force](#) property is set to `true`. An error should be sent to the [System.Management.Automation.Provider.CmdletProvider.WriteError](#) method if the path represents a hidden item and [System.Management.Automation.Provider.CmdletProvider.Force](#) is set to `false`.
- Your implementation of the [System.Management.Automation.Provider.ItemCmdletProvider.SetItem](#) method should call [System.Management.Automation.Provider.CmdletProvider.ShouldProcess](#) and verify its return value before making any changes to the data store. This method is used to confirm execution of an operation when a change is made to the data store, for example, deleting files. The [System.Management.Automation.Provider.CmdletProvider.ShouldProcess](#) method sends the name of the resource to be changed to the user, with the Windows PowerShell runtime taking into account any command-line settings or preference variables in determining what should be displayed.

After the call to

[System.Management.Automation.Provider.CmdletProvider.ShouldProcess](#) returns `true`, the [System.Management.Automation.Provider.ItemCmdletProvider.SetItem](#) method should call the [System.Management.Automation.Provider.CmdletProvider.ShouldContinue](#)

method. This method sends a message to the user to allow feedback to verify if the operation should be continued. The call to [System.Management.Automation.Provider.CmdletProvider.ShouldContinue](#) allows an additional check for potentially dangerous system modifications.

Retrieving dynamic parameters for SetItem

Sometimes the `Set-Item` cmdlet requires additional parameters that are specified dynamically at runtime. To provide these dynamic parameters the Windows PowerShell item provider must implement the

[System.Management.Automation.Provider.ItemCmdletProvider.SetItemDynamicParameters](#) method. This method retrieves the dynamic parameters for the item at the indicated path and returns an object that has properties and fields with parsing attributes similar to a cmdlet class or a

[System.Management.Automation.RuntimeDefinedParameterDictionary](#) object. The Windows PowerShell runtime uses the returned object to add the parameters to the `Set-Item` cmdlet.

This provider does not implement this method. However, the following code is the default implementation of this method.

Clearing an item

To clear an item, the Windows PowerShell item provider implements the [System.Management.Automation.Provider.ItemCmdletProvider.ClearItem](#) method to support calls from the `Clear-Item` cmdlet. This method erases the data item at the specified path.

This provider does not implement this method. However, the following code is the default implementation of this method.

Things to remember about implementing ClearItem

The following conditions may apply to an implementation of [System.Management.Automation.Provider.ItemCmdletProvider.ClearItem](#):

- When defining the provider class, a Windows PowerShell item provider might declare provider capabilities of `ExpandWildcards`, `Filter`, `Include`, or `Exclude`, from the [System.Management.Automation.Provider.ProviderCapabilities](#) enumeration. In these cases, the implementation of [System.Management.Automation.Provider.ItemCmdletProvider.ClearItem](#) must

ensure that the path passed to the method meets those requirements. To do this, the method should access the appropriate property, for example, the [System.Management.Automation.Provider.CmdletProvider.Exclude](#) and [System.Management.Automation.Provider.CmdletProvider.Include](#) properties.

- By default, overrides of this method should not set or write objects that are hidden from the user unless the [System.Management.Automation.Provider.CmdletProvider.Force](#) property is set to `true`. An error should be sent to the [System.Management.Automation.Provider.CmdletProvider.WriteError](#) method if the path represents an item that is hidden from the user and [System.Management.Automation.Provider.CmdletProvider.Force](#) is set to `false`.
- Your implementation of the [System.Management.Automation.Provider.ItemCmdletProvider.SetItem](#) method should call [System.Management.Automation.Provider.CmdletProvider.ShouldProcess](#) and verify its return value before making any changes to the data store. This method is used to confirm execution of an operation when a change is made to the data store, for example, deleting files. The [System.Management.Automation.Provider.CmdletProvider.ShouldProcess](#) method sends the name of the resource to be changed to the user, with the Windows PowerShell runtime and handle any command-line settings or preference variables in determining what should be displayed.

After the call to

[System.Management.Automation.Provider.CmdletProvider.ShouldProcess](#) returns `true`, the [System.Management.Automation.Provider.ItemCmdletProvider.SetItem](#) method should call the [System.Management.Automation.Provider.CmdletProvider.ShouldContinue](#) method. This method sends a message to the user to allow feedback to verify if the operation should be continued. The call to [System.Management.Automation.Provider.CmdletProvider.ShouldContinue](#) allows an additional check for potentially dangerous system modifications.

Retrieve dynamic parameters for ClearItem

Sometimes the `Clear-Item` cmdlet requires additional parameters that are specified dynamically at runtime. To provide these dynamic parameters the Windows PowerShell item provider must implement the [System.Management.Automation.Provider.ItemCmdletProvider.ClearItemDynamicParam](#)

`eters` method. This method retrieves the dynamic parameters for the item at the indicated path and returns an object that has properties and fields with parsing attributes similar to a cmdlet class or a `System.Management.Automation.RuntimeDefinedParameterDictionary` object. The Windows PowerShell runtime uses the returned object to add the parameters to the `Clear-Item` cmdlet.

This item provider does not implement this method. However, the following code is the default implementation of this method.

Performing a default action for an item

A Windows PowerShell item provider can implement the `System.Management.Automation.Provider.ItemCmdletProvider.InvokeDefaultAction` method to support calls from the `Invoke-Item` cmdlet, which allows the provider to perform a default action for the item at the specified path. For example, the FileSystem provider might use this method to call `ShellExecute` for a specific item.

This provider does not implement this method. However, the following code is the default implementation of this method.

Things to remember about implementing `InvokeDefaultAction`

The following conditions may apply to an implementation of `System.Management.Automation.Provider.ItemCmdletProvider.InvokeDefaultAction`:

- When defining the provider class, a Windows PowerShell item provider might declare provider capabilities of `ExpandWildcards`, `Filter`, `Include`, or `Exclude`, from the `System.Management.Automation.Provider.ProviderCapabilities` enumeration. In these cases, the implementation of `System.Management.Automation.Provider.ItemCmdletProvider.InvokeDefaultAction` must ensure that the path passed to the method meets those requirements. To do this, the method should access the appropriate property, for example, the `System.Management.Automation.Provider.CmdletProvider.Exclude` and `System.Management.Automation.Provider.CmdletProvider.Include` properties.
- By default, overrides of this method should not set or write objects hidden from the user unless the `System.Management.Automation.Provider.CmdletProvider.Force` property is set to `true`. An error should be sent to the `System.Management.Automation.Provider.CmdletProvider.WriteError` method if

the path represents an item that is hidden from the user and [System.Management.Automation.Provider.CmdletProvider.Force](#) is set to `false`.

Retrieve dynamic parameters for InvokeDefaultAction

Sometimes the [Invoke-Item](#) cmdlet requires additional parameters that are specified dynamically at runtime. To provide these dynamic parameters the Windows PowerShell item provider must implement the

[System.Management.Automation.Provider.ItemCmdletProvider.InvokeDefaultActionDynamicParameters](#) method. This method retrieves the dynamic parameters for the item at the indicated path and returns an object that has properties and fields with parsing attributes similar to a cmdlet class or a [System.Management.Automation.RuntimeDefinedParameterDictionary](#) object. The Windows PowerShell runtime uses the returned object to add the dynamic parameters to the [Invoke-Item](#) cmdlet.

This item provider does not implement this method. However, the following code is the default implementation of this method.

Implementing helper methods and classes

This item provider implements several helper methods and classes that are used by the public override methods defined by Windows PowerShell. The code for these helper methods and classes are shown in the [Code Sample](#) section.

NormalizePath method

This item provider implements a **NormalizePath** helper method to ensure that the path has a consistent format. The format specified uses a backslash (\) as a separator.

PathIsDrive method

This item provider implements a **PathIsDrive** helper method to determine if the specified path is actually the drive name.

ChunkPath method

This item provider implements a **ChunkPath** helper method that breaks up the specified path so that the provider can identify its individual elements. It returns an array composed of the path elements.

GetTable method

This item provider implements the **GetTables** helper method that returns a **DatabaseTableInfo** object that represents information about the table specified in the call.

GetRow method

The [System.Management.Automation.Provider.ItemCmdletProvider.GetItem](#) method of this item provider calls the **GetRows** helper method. This helper method retrieves a **DatabaseRowInfo** object that represents information about the specified row in the table.

DatabaseTableInfo class

This item provider defines a **DatabaseTableInfo** class that represents a collection of information in a data table in the database. This class is similar to the [System.IO.DirectoryInfo](#) class.

The sample item provider defines a **DatabaseTableInfo.GetTables** method that returns a collection of table information objects defining the tables in the database. This method includes a try/catch block to ensure that any database error shows up as a row with zero entries.

DatabaseRowInfo class

This item provider defines the **DatabaseRowInfo** helper class that represents a row in a table of the database. This class is similar to the [System.IO.FileInfo](#) class.

The sample provider defines a **DatabaseRowInfo.GetRows** method to return a collection of row information objects for the specified table. This method includes a try/catch block to trap exceptions. Any errors will result in no row information.

Code sample

For complete sample code, see [AccessDbProviderSample03 Code Sample](#).

Defining object types and formatting

When writing a provider, it may be necessary to add members to existing objects or define new objects. When finished, create a Types file that Windows PowerShell can use to identify the members of the object and a Format file that defines how the object is displayed. For more information, see [Extending Object Types and Formatting](#).

Building the Windows PowerShell provider

See [How to Register Cmdlets, Providers, and Host Applications](#).

Testing the Windows PowerShell provider

When this Windows PowerShell item provider is registered with Windows PowerShell, you can only test the basic and drive functionality of the provider. To test the manipulation of items, you must also implement container functionality described in [Implementing a Container Windows PowerShell Provider](#).

Creating a Windows PowerShell Container Provider

Article • 03/24/2025

This topic describes how to create a Windows PowerShell provider that can work on multi-layer data stores. For this type of data store, the top level of the store contains the root items and each subsequent level is referred to as a node of child items. By allowing the user to work on these child nodes, a user can interact hierarchically through the data store.

Providers that can work on multi-level data stores are referred to as Windows PowerShell container providers. However, be aware that a Windows PowerShell container provider can be used only when there is one container (no nested containers) with items in it. If there are nested containers, then you must implement a Windows PowerShell navigation provider. For more information about implementing Windows PowerShell navigation provider, see [Creating a Windows PowerShell Navigation Provider](#).

ⓘ Note

You can download the C# source file (AccessDBSampleProvider04.cs) for this provider using the Microsoft Windows Software Development Kit for Windows Vista and .NET Framework 3.0 Runtime Components. For download instructions, see [How to Install Windows PowerShell and Download the Windows PowerShell SDK](#). The downloaded source files are available in the <PowerShell Samples> directory. For more information about other Windows PowerShell provider implementations, see [Designing Your Windows PowerShell Provider](#).

The Windows PowerShell container provider described here defines the database as its single container, with the tables and rows of the database defined as items of the container.

✖ Caution

Be aware that this design assumes a database that has a field with the name ID, and that the type of the field is LongInteger.

Defining a Windows PowerShell Container Provider Class

A Windows PowerShell container provider must define a .NET class that derives from the [System.Management.Automation.Provider.ContainerCmdletProvider](#) base class. Here is the class definition for the Windows PowerShell container provider described in this section.

C#

```
[CmdletProvider("AccessDB", ProviderCapabilities.None)]
public class AccessDBProvider : ContainerCmdletProvider
```

Notice that in this class definition, the [System.Management.Automation.Provider.CmdletProviderAttribute](#) attribute includes two parameters. The first parameter specifies a user-friendly name for the provider that is used by Windows PowerShell. The second parameter specifies the Windows PowerShell specific capabilities that the provider exposes to the Windows PowerShell runtime during command processing. For this provider, there are no Windows PowerShell specific capabilities that are added.

Defining Base Functionality

As described in [Designing Your Windows PowerShell Provider](#), the [System.Management.Automation.Provider.ContainerCmdletProvider](#) class derives from several other classes that provided different provider functionality. A Windows PowerShell container provider, therefore, needs to define all of the functionality provided by those classes.

To implement functionality for adding session-specific initialization information and for releasing resources that are used by the provider, see [Creating a Basic Windows PowerShell Provider](#). However, most providers (including the provider described here) can use the default implementation of this functionality that is provided by Windows PowerShell.

To get access to the data store, the provider must implement the methods of the [System.Management.Automation.Provider.DriveCmdletProvider](#) base class. For more information about implementing these methods, see [Creating a Windows PowerShell Drive Provider](#).

To manipulate the items of a data store, such as getting, setting, and clearing items, the provider must implement the methods provided by the [System.Management.Automation.Provider.ItemCmdletProvider](#) base class. For more information about implementing these methods, see [Creating a Windows PowerShell Item Provider](#).

Retrieving Child Items

To retrieve a child item, the Windows PowerShell container provider must override the [System.Management.Automation.Provider.ContainerCmdletProvider.GetChildItems*](#) method to support calls from the `Get-ChildItem` cmdlet. This method retrieves child items from the data store and writes them to the pipeline as objects. If the `recurse` parameter of the cmdlet is specified, the method retrieves all children regardless of what level they are at. If the `recurse` parameter is not specified, the method retrieves only a single level of children.

Here is the implementation of the [System.Management.Automation.Provider.ContainerCmdletProvider.GetChildItems*](#) method for this provider. Notice that this method retrieves the child items in all database tables when the path indicates the Access database, and retrieves the child items from the rows of that table if the path indicates a data table.

C#

```
protected override void GetChildItems(string path, bool recurse)
{
    // If path represented is a drive then the children in the path are
    // tables. Hence all tables in the drive represented will have to be
    // returned
    if (PathIsDrive(path))
    {
        foreach (DatabaseTableInfo table in GetTables())
        {
            WriteItemObject(table, path, true);

            // if the specified item exists and recurse has been set then
            // all child items within it have to be obtained as well
            if (ItemExists(path) && recurse)
            {
                GetChildItems(path + pathSeparator + table.Name, recurse);
            }
        } // foreach (DatabaseTableInfo...
    } // if (PathIsDrive...
    else
    {
        // Get the table name, row number and type of path from the
        // path specified
```

```

        string tableName;
        int rowNumber;

        PathType type = GetNamesFromPath(path, out tableName, out
rowNumber);

        if (type == PathType.Table)
        {
            // Obtain all the rows within the table
            foreach (DatabaseRowInfo row in GetRows(tableName))
            {
                WriteItemObject(row, path + pathSeparator + row.RowNumber,
                    false);
            } // foreach (DatabaseRowInfo...
        }
        else if (type == PathType.Row)
        {
            // In this case the user has directly specified a row, hence
            // just give that particular row
            DatabaseRowInfo row = GetRow(tableName, rowNumber);
            WriteItemObject(row, path + pathSeparator + row.RowNumber,
                false);
        }
        else
        {
            // In this case, the path specified is not valid
            ThrowTerminatingInvalidOperationException(path);
        }
    } // else
} // GetChildItems

```

Things to Remember About Implementing GetChildItems

The following conditions may apply to your implementation of [System.Management.Automation.Provider.ContainerCmdletProvider.GetChildItems*](#):

- When defining the provider class, a Windows PowerShell container provider might declare provider capabilities of ExpandWildcards, Filter, Include, or Exclude, from the [System.Management.Automation.Provider.ProviderCapabilities](#) enumeration. In these cases, the implementation of the [System.Management.Automation.Provider.ContainerCmdletProvider.GetChildItems](#) * method needs to ensure that the path passed to the method meets the requirements of the specified capabilities. To do this, the method should access the appropriate property, for example, the [System.Management.Automation.Provider.CmdletProvider.Exclude*](#) and [System.Management.Automation.Provider.CmdletProvider.Include*](#) properties.

- The implementation of this method should take into account any form of access to the item that might make the item visible to the user. For example, if a user has write access to a file through the FileSystem provider (supplied by Windows PowerShell), but not read access, the file still exists and [System.Management.Automation.Provider.ItemCmdletProvider.ItemExists*](#) returns `true`. Your implementation might require the checking of a parent item to see if the child can be enumerated.
- When writing multiple items, the [System.Management.Automation.Provider.ContainerCmdletProvider.GetChildItems*](#) method can take some time. You can design your provider to write the items using the [System.Management.Automation.Provider.CmdletProvider.WriteLineObject*](#) method one at a time. Using this technique will present the items to the user in a stream.
- Your implementation of [System.Management.Automation.Provider.ContainerCmdletProvider.GetChildItems*](#) is responsible for preventing infinite recursion when there are circular links, and the like. An appropriate terminating exception should be thrown to reflect such a condition.

Attaching Dynamic Parameters to the Get-ChildItem Cmdlet

Sometimes the `Get-ChildItem` cmdlet that calls

[System.Management.Automation.Provider.ContainerCmdletProvider.GetChildItems*](#) requires additional parameters that are specified dynamically at runtime. To provide these dynamic parameters, the Windows PowerShell container provider must implement the

[System.Management.Automation.Provider.ContainerCmdletProvider.GetChildItemsDynamicParameters*](#) method. This method retrieves dynamic parameters for the item at the indicated path and returns an object that has properties and fields with parsing attributes similar to a cmdlet class or a

[System.Management.Automation.RuntimeDefinedParameterDictionary](#) object. The Windows PowerShell runtime uses the returned object to add the parameters to the `Get-ChildItem` cmdlet.

This Windows PowerShell container provider does not implement this method. However, the following code is the default implementation of this method.

Retrieving Child Item Names

To retrieve the names of child items, the Windows PowerShell container provider must override the

`System.Management.Automation.Provider.ContainerCmdletProvider.GetChildNames*` method to support calls from the `Get-ChildItem` cmdlet when its `Name` parameter is specified. This method retrieves the names of the child items for the specified path or child item names for all containers if the `returnAllContainers` parameter of the cmdlet is specified. A child name is the leaf portion of a path. For example, the child name for the path `C:\windows\system32\abc.dll` is "abc.dll". The child name for the directory `C:\windows\system32` is "system32".

Here is the implementation of the

`System.Management.Automation.Provider.ContainerCmdletProvider.GetChildNames*` method for this provider. Notice that the method retrieves table names if the specified path indicates the Access database (drive) and row numbers if the path indicates a table.

C#

```
protected override void GetChildNames(string path,
                                      ReturnContainers returnContainers)
{
    // If the path represented is a drive, then the child items are
    // tables. get the names of all the tables in the drive.
    if (PathIsDrive(path))
    {
        foreach (DatabaseTableInfo table in GetTables())
        {
            WriteItemObject(table.Name, path, true);
        } // foreach (DatabaseTableInfo...
    } // if (PathIsDrive...
    else
    {
        // Get type, table name and row number from path specified
        string tableName;
        int rowCount;

        PathType type = GetNamesFromPath(path, out tableName, out
rowCount);

        if (type == PathType.Table)
        {
            // Get all the rows in the table and then write out the
            // row numbers.
            foreach (DatabaseRowInfo row in GetRows(tableName))
            {
                WriteItemObject(row.RowNumber, path, false);
            } // foreach (DatabaseRowInfo...
        }
    }
}
```

```

    else if (type == PathType.Row)
    {
        // In this case the user has directly specified a row, hence
        // just give that particular row
        DatabaseRowInfo row = GetRow(tableName, rowNumber);

        WriteItemObject(row.RowNumber, path, false);
    }
    else
    {
        ThrowTerminatingInvalidOperationException(path);
    }
} // else
} // GetChildNames

```

Things to Remember About Implementing GetChildNames

The following conditions may apply to your implementation of [System.Management.Automation.Provider.ContainerCmdletProvider.GetChildItems*](#):

- When defining the provider class, a Windows PowerShell container provider might declare provider capabilities of ExpandWildcards, Filter, Include, or Exclude, from the [System.Management.Automation.Provider.ProviderCapabilities](#) enumeration. In these cases, the implementation of the [System.Management.Automation.Provider.ContainerCmdletProvider.GetChildItems](#) * method needs to ensure that the path passed to the method meets the requirements of the specified capabilities. To do this, the method should access the appropriate property, for example, the [System.Management.Automation.Provider.CmdletProvider.Exclude*](#) and [System.Management.Automation.Provider.CmdletProvider.Include*](#) properties.

① Note

An exception to this rule occurs when the `returnAllContainers` parameter of the cmdlet is specified. In this case, the method should retrieve any child name for a container, even if it does not match the values of the [System.Management.Automation.Provider.CmdletProvider.Filter*](#), [System.Management.Automation.Provider.CmdletProvider.Include*](#), or [System.Management.Automation.Provider.CmdletProvider.Exclude*](#) properties.

- By default, overrides of this method should not retrieve names of objects that are generally hidden from the user unless the

`System.Management.Automation.Provider.CmdletProvider.Force`* property is specified. If the specified path indicates a container, the `System.Management.Automation.Provider.CmdletProvider.Force`* property is not required.

- Your implementation of `System.Management.Automation.Provider.ContainerCmdletProvider.GetChildNamesDynamicParameters`* is responsible for preventing infinite recursion when there are circular links, and the like. An appropriate terminating exception should be thrown to reflect such a condition.

Attaching Dynamic Parameters to the Get-ChildItem Cmdlet (Name)

Sometimes the `Get-ChildItem` cmdlet (with the `Name` parameter) requires additional parameters that are specified dynamically at runtime. To provide these dynamic parameters, the Windows PowerShell container provider must implement the `System.Management.Automation.Provider.ContainerCmdletProvider.GetChildNamesDynamicParameters`* method. This method retrieves the dynamic parameters for the item at the indicated path and returns an object that has properties and fields with parsing attributes similar to a cmdlet class or a `System.Management.Automation.RuntimeDefinedParameterDictionary` object. The Windows PowerShell runtime uses the returned object to add the parameters to the `Get-ChildItem` cmdlet.

This provider does not implement this method. However, the following code is the default implementation of this method.

Renaming Items

To rename an item, a Windows PowerShell container provider must override the `System.Management.Automation.Provider.ContainerCmdletProvider.RenameItem`* method to support calls from the `Rename-Item` cmdlet. This method changes the name of the item at the specified path to the new name provided. The new name must always be relative to the parent item (container).

This provider does not override the `System.Management.Automation.Provider.ContainerCmdletProvider.RenameItem`* method. However, the following is the default implementation.

Things to Remember About Implementing RenameItem

The following conditions may apply to your implementation of [System.Management.Automation.Provider.ContainerCmdletProvider.RenameItem](#)*:

- When defining the provider class, a Windows PowerShell container provider might declare provider capabilities of ExpandWildcards, Filter, Include, or Exclude, from the [System.Management.Automation.Provider.ProviderCapabilities](#) enumeration. In these cases, the implementation of the [System.Management.Automation.Provider.ContainerCmdletProvider.GetChildItems](#) * method needs to ensure that the path passed to the method meets the requirements of the specified capabilities. To do this, the method should access the appropriate property, for example, the [System.Management.Automation.Provider.CmdletProvider.Exclude](#)* and [System.Management.Automation.Provider.CmdletProvider.Include](#)* properties.
- The [System.Management.Automation.Provider.ContainerCmdletProvider.RenameItem](#)* method is intended for the modification of the name of an item only, and not for move operations. Your implementation of the method should write an error if the `newName` parameter contains path separators, or might otherwise cause the item to change its parent location.
- By default, overrides of this method should not rename objects unless the [System.Management.Automation.Provider.CmdletProvider.Force](#)* property is specified. If the specified path indicates a container, the [System.Management.Automation.Provider.CmdletProvider.Force](#)* property is not required.
- Your implementation of the [System.Management.Automation.Provider.ContainerCmdletProvider.RenameItem](#)* method should call [System.Management.Automation.Provider.CmdletProvider.ShouldProcess](#) and check its return value before making any changes to the data store. This method is used to confirm execution of an operation when a change is made to system state, for example, renaming files.
[System.Management.Automation.Provider.CmdletProvider.ShouldProcess](#) sends the name of the resource to be changed to the user, with the Windows PowerShell runtime taking into account any command line settings or preference variables in determining what should be displayed.

After the call to

[System.Management.Automation.Provider.CmdletProvider.ShouldProcess](#) returns

`true`, the

[System.Management.Automation.Provider.ContainerCmdletProvider.RenameItem*](#) method should call the [System.Management.Automation.Provider.CmdletProvider.ShouldContinue](#) method. This method sends a message a confirmation message to the user to allow additional feedback to say if the operation should be continued. A provider should call [System.Management.Automation.Provider.CmdletProvider.ShouldContinue](#) as an additional check for potentially dangerous system modifications.

Attaching Dynamic Parameters to the Rename-Item Cmdlet

Sometimes the `Rename-Item` cmdlet requires additional parameters that are specified dynamically at runtime. To provide these dynamic parameters, Windows PowerShell container provider must implement the

[System.Management.Automation.Provider.ContainerCmdletProvider.RenameItemDynamicParameters*](#) method. This method retrieves the parameters for the item at the indicated path and returns an object that has properties and fields with parsing attributes similar to a cmdlet class or a [System.Management.Automation.RuntimeDefinedParameterDictionary](#) object. The Windows PowerShell runtime uses the returned object to add the parameters to the `Rename-Item` cmdlet.

This container provider does not implement this method. However, the following code is the default implementation of this method.

Creating New Items

To create new items, a container provider must implement the

[System.Management.Automation.Provider.ContainerCmdletProvider.NewItem*](#) method to support calls from the `New-Item` cmdlet. This method creates a data item located at the specified path. The `type` parameter of the cmdlet contains the provider-defined type for the new item. For example, the FileSystem provider uses a `type` parameter with a value of "file" or "directory". The `newValue` parameter of the cmdlet specifies a provider-specific value for the new item.

Here is the implementation of the

[System.Management.Automation.Provider.ContainerCmdletProvider.NewItem*](#) method for this provider.

C#

```
protected override void NewItem( string path, string type, object newItemValue )
{
    // Create the new item here after
    // performing necessary validations
    //
    // WriteItemObject(newItemValue, path, false);

    // Example
    //
    // if (ShouldProcess(path, "new item"))
    // {
    //     // Create a new item and then call WriteObject
    //     WriteObject(newItemValue, path, false);
    // }

} // NewItem
```

C#

```
{
    case 1:
    {
        string name = pathChunks[0];

        if (TableNameIsValid(name))
        {
            tableName = name;
            retVal = PathType.Table;
        }
    }
    break;

    case 2:
    {
        string name = pathChunks[0];
```

Things to Remember About Implementing NewItem

The following conditions may apply to your implementation of [System.Management.Automation.Provider.ContainerCmdletProvider.NewItem*](#):

- The [System.Management.Automation.Provider.ContainerCmdletProvider.NewItem*](#) method should perform a case-insensitive comparison of the string passed in the `type` parameter. It should also allow for least ambiguous matches. For example, for the types "file" and "directory", only the first letter is required to disambiguate. If

the `type` parameter indicates a type your provider cannot create, the `System.Management.Automation.Provider.ContainerCmdletProvider.NewItem*` method should write an `ArgumentException` with a message indicating the types the provider can create.

- For the `newValue` parameter, the implementation of the `System.Management.Automation.Provider.ContainerCmdletProvider.NewItem*` method is recommended to accept strings at a minimum. It should also accept the type of object that is retrieved by the `System.Management.Automation.Provider.ItemCmdletProvider.GetItem*` method for the same path. The `System.Management.Automation.Provider.ContainerCmdletProvider.NewItem*` method can use the `System.Management.Automation.LanguagePrimitives.ConvertTo*` method to convert types to the desired type.
- Your implementation of the `System.Management.Automation.Provider.ContainerCmdletProvider.NewItem*` method should call `System.Management.Automation.Provider.CmdletProvider.ShouldProcess` and check its return value before making any changes to the data store. After the call to `System.Management.Automation.Provider.CmdletProvider.ShouldProcess` returns true, the `System.Management.Automation.Provider.ContainerCmdletProvider.NewItem*` method should call the `System.Management.Automation.Provider.CmdletProvider.ShouldContinue` method as an additional check for potentially dangerous system modifications.

Attaching Dynamic Parameters to the New-Item Cmdlet

Sometimes the `New-Item` cmdlet requires additional parameters that are specified dynamically at runtime. To provide these dynamic parameters, the container provider must implement the

`System.Management.Automation.Provider.ContainerCmdletProvider.NewItemDynamicParameters*` method. This method retrieves the parameters for the item at the indicated path and returns an object that has properties and fields with parsing attributes similar to a cmdlet class or a `System.Management.Automation.RuntimeDefinedParameterDictionary` object. The

Windows PowerShell runtime uses the returned object to add the parameters to the `New-Item` cmdlet.

This provider does not implement this method. However, the following code is the default implementation of this method.

Removing Items

To remove items, the Windows PowerShell provider must override the [System.Management.Automation.Provider.ContainerCmdletProvider.RemoveItem*](#) method to support calls from the `Remove-Item` cmdlet. This method deletes an item from the data store at the specified path. If the `recurse` parameter of the `Remove-Item` cmdlet is set to `true`, the method removes all child items regardless of their level. If the parameter is set to `false`, the method removes only a single item at the specified path.

This provider does not support item removal. However, the following code is the default implementation of

[System.Management.Automation.Provider.ContainerCmdletProvider.RemoveItem*](#).

Things to Remember About Implementing RemoveItem

The following conditions may apply to your implementation of

[System.Management.Automation.Provider.ContainerCmdletProvider.NewItem*](#):

- When defining the provider class, a Windows PowerShell container provider might declare provider capabilities of `ExpandWildcards`, `Filter`, `Include`, or `Exclude`, from the [System.Management.Automation.Provider.ProviderCapabilities](#) enumeration. In these cases, the implementation of the [System.Management.Automation.Provider.ContainerCmdletProvider.GetChildItems](#) * method needs to ensure that the path passed to the method meets the requirements of the specified capabilities. To do this, the method should access the appropriate property, for example, the [System.Management.Automation.Provider.CmdletProvider.Exclude*](#) and [System.Management.Automation.Provider.CmdletProvider.Include*](#) properties.
- By default, overrides of this method should not remove objects unless the [System.Management.Automation.Provider.CmdletProvider.Force*](#) property is set to true. If the specified path indicates a container, the [System.Management.Automation.Provider.CmdletProvider.Force*](#) property is not required.

- Your implementation of `System.Management.Automation.Provider.ContainerCmdletProvider.RemoveItem*` is responsible for preventing infinite recursion when there are circular links, and the like. An appropriate terminating exception should be thrown to reflect such a condition.
- Your implementation of the `System.Management.Automation.Provider.ContainerCmdletProvider.RemoveItem*` method should call `System.Management.Automation.Provider.CmdletProvider.ShouldProcess` and check its return value before making any changes to the data store. After the call to `System.Management.Automation.Provider.CmdletProvider.ShouldProcess` returns `true`, the `System.Management.Automation.Provider.ContainerCmdletProvider.RemoveItem*` method should call the `System.Management.Automation.Provider.CmdletProvider.ShouldContinue` method as an additional check for potentially dangerous system modifications.

Attaching Dynamic Parameters to the Remove-Item Cmdlet

Sometimes the `Remove-Item` cmdlet requires additional parameters that are specified dynamically at runtime. To provide these dynamic parameters, the container provider must implement the

`System.Management.Automation.Provider.ContainerCmdletProvider.RemoveItemDynamicParameters*` method to handle these parameters. This method retrieves the dynamic parameters for the item at the indicated path and returns an object that has properties and fields with parsing attributes similar to a cmdlet class or a `System.Management.Automation.RuntimeDefinedParameterDictionary` object. The Windows PowerShell runtime uses the returned object to add the parameters to the `Remove-Item` cmdlet.

This container provider does not implement this method. However, the following code is the default implementation of

`System.Management.Automation.Provider.ContainerCmdletProvider.RemoveItemDynamicParameters*`.

Querying for Child Items

To check to see if child items exist at the specified path, the Windows PowerShell container provider must override the [System.Management.Automation.Provider.ContainerCmdletProvider.HasChildItems*](#) method. This method returns `true` if the item has children, and `false` otherwise. For a null or empty path, the method considers any items in the data store to be children and returns `true`.

Here is the override for the [System.Management.Automation.Provider.ContainerCmdletProvider.HasChildItems*](#) method. If there are more than two path parts created by the `ChunkPath` helper method, the method returns `false`, since only a database container and a table container are defined. For more information about this helper method, see the `ChunkPath` method is discussed in [Creating a Windows PowerShell Item Provider](#).

```
C#  
  
protected override bool HasChildItems( string path )  
{  
    return false;  
} // HasChildItems
```

```
C#  
  
    ErrorCategory.InvalidOperation, tableName));  
}  
  
return results;
```

Things to Remember About Implementing HasChildItems

The following conditions may apply to your implementation of [System.Management.Automation.Provider.ContainerCmdletProvider.HasChildItems*](#):

- If the container provider exposes a root that contains interesting mount points, the implementation of the [System.Management.Automation.Provider.ContainerCmdletProvider.HasChildItems*](#) method should return `true` when a null or an empty string is passed in for the path.

Copying Items

To copy items, the container provider must implement the [System.Management.Automation.Provider.ContainerCmdletProvider.CopyItem](#) method to support calls from the `Copy-Item` cmdlet. This method copies a data item from the location indicated by the `path` parameter of the cmdlet to the location indicated by the `copyPath` parameter. If the `recurse` parameter is specified, the method copies all sub-containers. If the parameter is not specified, the method copies only a single level of items.

This provider does not implement this method. However, the following code is the default implementation of [System.Management.Automation.Provider.ContainerCmdletProvider.CopyItem](#).

Things to Remember About Implementing CopyItem

The following conditions may apply to your implementation of [System.Management.Automation.Provider.ContainerCmdletProvider.CopyItem](#):

- When defining the provider class, a Windows PowerShell container provider might declare provider capabilities of `ExpandWildcards`, `Filter`, `Include`, or `Exclude`, from the [System.Management.Automation.Provider.ProviderCapabilities](#) enumeration. In these cases, the implementation of the [System.Management.Automation.Provider.ContainerCmdletProvider.GetChildItems](#) * method needs to ensure that the path passed to the method meets the requirements of the specified capabilities. To do this, the method should access the appropriate property, for example, the [System.Management.Automation.Provider.CmdletProvider.Exclude](#)* and [System.Management.Automation.Provider.CmdletProvider.Include](#)* properties.
- By default, overrides of this method should not copy objects over existing objects unless the [System.Management.Automation.Provider.CmdletProvider.Force](#)* property is set to `true`. For example, the `FileSystem` provider will not copy `C:\temp\abc.txt` over an existing `C:\abc.txt` file unless the [System.Management.Automation.Provider.CmdletProvider.Force](#)* property is set to `true`. If the path specified in the `copyPath` parameter exists and indicates a container, the [System.Management.Automation.Provider.CmdletProvider.Force](#)* property is not required. In this case, [System.Management.Automation.Provider.ContainerCmdletProvider.CopyItem](#) should copy the item indicated by the `path` parameter to the container indicated by the `copyPath` parameter as a child.

- Your implementation of [System.Management.Automation.Provider.ContainerCmdletProvider.CopyItem](#) is responsible for preventing infinite recursion when there are circular links, and the like. An appropriate terminating exception should be thrown to reflect such a condition.
- Your implementation of the [System.Management.Automation.Provider.ContainerCmdletProvider.CopyItem](#) method should call [System.Management.Automation.Provider.CmdletProvider.ShouldProcess](#) and check its return value before making any changes to the data store. After the call to [System.Management.Automation.Provider.CmdletProvider.ShouldProcess](#) returns true, the [System.Management.Automation.Provider.ContainerCmdletProvider.CopyItem](#) method should call the [System.Management.Automation.Provider.CmdletProvider.ShouldContinue](#) method as an additional check for potentially dangerous system modifications. For more information about calling these methods, see [Rename Items](#).

Attaching Dynamic Parameters to the Copy-Item Cmdlet

Sometimes the `Copy-Item` cmdlet requires additional parameters that are specified dynamically at runtime. To provide these dynamic parameters, the Windows PowerShell container provider must implement the [System.Management.Automation.Provider.ContainerCmdletProvider.CopyItemDynamicParameters*](#) method to handle these parameters. This method retrieves the parameters for the item at the indicated path and returns an object that has properties and fields with parsing attributes similar to a cmdlet class or a [System.Management.Automation.RuntimeDefinedParameterDictionary](#) object. The Windows PowerShell runtime uses the returned object to add the parameters to the `Copy-Item` cmdlet.

This provider does not implement this method. However, the following code is the default implementation of [System.Management.Automation.Provider.ContainerCmdletProvider.CopyItemDynamicParameters*](#).

Code Sample

For complete sample code, see [AccessDbProviderSample04 Code Sample](#).

Building the Windows PowerShell Provider

See [How to Register Cmdlets, Providers, and Host Applications](#).

Testing the Windows PowerShell Provider

When your Windows PowerShell provider has been registered with Windows PowerShell, you can test it by running the supported cmdlets on the command line. Be aware that the following example output uses a fictitious Access database.

1. Run the `Get-ChildItem` cmdlet to retrieve the list of child items from a Customers table in the Access database.

```
PowerShell  
  
Get-ChildItem mydb:customers
```

The following output appears.

```
Output  
  
PSPPath      : AccessDB::customers  
PSDrive      : mydb  
PSProvider   : System.Management.Automation.ProviderInfo  
PSIsContainer : True  
Data         : System.Data.DataRow  
Name         : Customers  
RowCount     : 91  
Columns      :
```

2. Run the `Get-ChildItem` cmdlet again to retrieve the data of a table.

```
PowerShell  
  
(Get-ChildItem mydb:customers).Data
```

The following output appears.

```
Output  
  
TABLE_CAT    : C:\PS\northwind  
TABLE_SCHEM  :
```

```
TABLE_NAME : Customers
TABLE_TYPE  : TABLE
REMARKS     :
```

3. Now use the `Get-Item` cmdlet to retrieve the items at row 0 in the data table.

```
PowerShell
```

```
Get-Item mydb:\customers\0
```

The following output appears.

```
Output
```

```
PSPath      : AccessDB::customers\0
PSDrive     : mydb
PSProvider   : System.Management.Automation.ProviderInfo
PSIsContainer: False
Data        : System.Data.DataRow
RowNumber    : 0
```

4. Reuse `Get-Item` to retrieve the data for the items in row 0.

```
PowerShell
```

```
(Get-Item mydb:\customers\0).Data
```

The following output appears.

```
Output
```

```
CustomerID   : 1234
CompanyName  : Fabrikam
ContactName   : Eric Gruber
ContactTitle  : President
Address       : 4567 Main Street
City          : Buffalo
Region        : NY
PostalCode    : 98052
Country       : USA
Phone         : (425) 555-0100
Fax           : (425) 555-0101
```

5. Now use the `New-Item` cmdlet to add a row to an existing table. The `Path` parameter specifies the full path to the row, and must indicate a row number that is greater than the existing number of rows in the table. The `Type` parameter

indicates `Row` to specify that type of item to add. Finally, the `Value` parameter specifies a comma-delimited list of column values for the row.

PowerShell

```
New-Item -Path mydb:\Customers\3 -ItemType "Row" -Value  
"3,CustomerFirstName,CustomerLastName,CustomerEmailAddress,CustomerTitle,  
CustomerCompany,CustomerPhone,  
CustomerAddress,CustomerCity,CustomerState,CustomerZip,CustomerCountry"
```

6. Verify the correctness of the new item operation as follows.

none

```
PS mydb:\> cd Customers  
PS mydb:\Customers> (Get-Item 3).Data
```

The following output appears.

Output

```
ID      : 3  
FirstName : Eric  
LastName  : Gruber  
Email    : ericgruber@fabrikam.com  
Title    : President  
Company   : Fabrikam  
WorkPhone : (425) 555-0100  
Address   : 4567 Main Street  
City     : Buffalo  
State    : NY  
Zip      : 98052  
Country   : USA
```

Creating a Windows PowerShell Navigation Provider

Article • 03/24/2025

This topic describes how to create a Windows PowerShell navigation provider that can navigate the data store. This type of provider supports recursive commands, nested containers, and relative paths.

ⓘ Note

You can download the C# source file (AccessDBSampleProvider05.cs) for this provider using the Microsoft Windows Software Development Kit for Windows Vista and .NET Framework 3.0 Runtime Components. For download instructions, see [How to Install Windows PowerShell and Download the Windows PowerShell SDK](#). The downloaded source files are available in the <PowerShell Samples> directory. For more information about other Windows PowerShell provider implementations, see [Designing Your Windows PowerShell Provider](#).

The provider described here enables the user handle an Access database as a drive so that the user can navigate to the data tables in the database. When creating your own navigation provider, you can implement methods that can make drive-qualified paths required for navigation, normalize relative paths, move items of the data store, as well as methods that get child names, get the parent path of an item, and test to identify if an item is a container.

ⓘ Caution

Be aware that this design assumes a database that has a field with the name ID, and that the type of the field is LongInteger.

Define the Windows PowerShell provider

A Windows PowerShell navigation provider must create a .NET class that derives from the [System.Management.Automation.Provider.NavigationCmdletProvider](#) base class. Here is the class definition for the navigation provider described in this section.

C#

```
[CmdletProvider("AccessDB", ProviderCapabilities.None)]
public class AccessDBProvider : NavigationCmdletProvider
```

Note that in this provider, the

[System.Management.Automation.Provider.CmdletProviderAttribute](#) attribute includes two parameters. The first parameter specifies a user-friendly name for the provider that is used by Windows PowerShell. The second parameter specifies the Windows PowerShell specific capabilities that the provider exposes to the Windows PowerShell runtime during command processing. For this provider, there are no Windows PowerShell specific capabilities that are added.

Defining Base Functionality

As described in [Design Your PS Provider](#), the [System.Management.Automation.Provider.NavigationCmdletProvider](#) base class derives from several other classes that provided different provider functionality. A Windows PowerShell navigation provider, therefore, must define all of the functionality provided by those classes.

To implement functionality for adding session-specific initialization information and for releasing resources that are used by the provider, see [Creating a Basic PS Provider](#). However, most providers (including the provider described here) can use the default implementation of this functionality provided by Windows PowerShell.

To get access to the data store through a Windows PowerShell drive, you must implement the methods of the [System.Management.Automation.Provider.DriveCmdletProvider](#) base class. For more information about implementing these methods, see [Creating a Windows PowerShell Drive Provider](#).

To manipulate the items of a data store, such as getting, setting, and clearing items, the provider must implement the methods provided by the [System.Management.Automation.Provider.ItemCmdletProvider](#) base class. For more information about implementing these methods, see [Creating a Windows PowerShell Item Provider](#).

To get to the child items, or their names, of the data store, as well as methods that create, copy, rename, and remove items, you must implement the methods provided by the [System.Management.Automation.Provider.ContainerCmdletProvider](#) base class. For more information about implementing these methods, see [Creating a Windows PowerShell Container Provider](#).

Creating a Windows PowerShell Path

Windows PowerShell navigation provider use a provider-internal Windows PowerShell path to navigate the items of the data store. To create a provider-internal path the provider must implement the

[System.Management.Automation.Provider.NavigationCmdletProvider.MakePath*](#)

method to supports calls from the Combine-Path cmdlet. This method combines a parent and child path into a provider-internal path, using a provider-specific path separator between the parent and child paths.

The default implementation takes paths with "/" or "\" as the path separator, normalizes the path separator to "\", combines the parent and child path parts with the separator between them, and then returns a string that contains the combined paths.

This navigation provider does not implement this method. However, the following code is the default implementation of the

[System.Management.Automation.Provider.NavigationCmdletProvider.MakePath*](#) method.

Things to Remember About Implementing MakePath

The following conditions may apply to your implementation of

[System.Management.Automation.Provider.NavigationCmdletProvider.MakePath*:](#)

- Your implementation of the [System.Management.Automation.Provider.NavigationCmdletProvider.MakePath*](#) method should not validate the path as a legal fully-qualified path in the provider namespace. Be aware that each parameter can only represent a part of a path, and the combined parts might not generate a fully-qualified path. For example, the [System.Management.Automation.Provider.NavigationCmdletProvider.MakePath*](#) method for the FileSystem provider might receive "windows\system32" in the `parent` parameter and "abc.dll" in the `child` parameter. The method joins these values with the "\" separator and returns "windows\system32\abc.dll", which is not a fully-qualified file system path.

Important

The path parts provided in the call to

[System.Management.Automation.Provider.NavigationCmdletProvider.MakePath*](#) might contain characters not allowed in the provider namespace. These

characters are most likely used for wildcard expansion and the implementation of this method should not remove them.

Retrieving the Parent Path

Windows PowerShell navigation providers implement the [System.Management.Automation.Provider.NavigationCmdletProvider.GetParentPath*](#) method to retrieve the parent part of the indicated full or partial provider-specific path. The method removes the child part of the path and returns the parent path part. The `root` parameter specifies the fully-qualified path to the root of a drive. This parameter can be null or empty if a mounted drive is not in use for the retrieval operation. If a root is specified, the method must return a path to a container in the same tree as the root.

The sample navigation provider does not override this method, but uses the default implementation. It accepts paths that use both "/" and "\\" as path separators. It first normalizes the path to have only "\\" separators, then splits the parent path off at the last "\\" and returns the parent path.

To Remember About Implementing GetParentPath

Your implementation of the [System.Management.Automation.Provider.NavigationCmdletProvider.GetParentPath*](#) method should split the path lexically on the path separator for the provider namespace. For example, the FileSystem provider uses this method to look for the last "\\" and returns everything to the left of the separator.

Retrieve the Child Path Name

Your navigation provider implements the [System.Management.Automation.Provider.NavigationCmdletProvider.GetChildName*](#) method to retrieve the name (leaf element) of the child of the item located at the indicated full or partial provider-specific path.

The sample navigation provider does not override this method. The default implementation is shown below. It accepts paths that use both "/" and "\\" as path separators. It first normalizes the path to have only "\\" separators, then splits the parent path off at the last "\\" and returns the name of the child path part.

Things to Remember About Implementing GetChildName

Your implementation of the [System.Management.Automation.Provider.NavigationCmdletProvider.GetChildNames*](#) method should split the path lexically on the path separator. If the supplied path contains no path separators, the method should return the path unmodified.

 **Important**

The path provided in the call to this method might contain characters that are illegal in the provider namespace. These characters are most likely used for wildcard expansion or regular expression matching, and the implementation of this method should not remove them.

Determining if an Item is a Container

The navigation provider can implement the [System.Management.Automation.Provider.NavigationCmdletProvider.IsItemContainer*](#) method to determine if the specified path indicates a container. It returns true if the path represents a container, and false otherwise. The user needs this method to be able to use the `Test-Path` cmdlet for the supplied path.

The following code shows the

[System.Management.Automation.Provider.NavigationCmdletProvider.IsItemContainer*](#) implementation in our sample navigation provider. The method verifies that the specified path is correct and if the table exists, and returns true if the path indicates a container.

C#

```
protected override bool IsItemContainer(string path)
{
    if (PathIsDrive(path))
    {
        return true;
    }

    string[] pathChunks = ChunkPath(path);
    string tableName;
    int rowNumber;

    PathType type = GetNamesFromPath(path, out tableName, out rowNumber);

    if (type == PathType.Table)
    {
        foreach (DatabaseTableInfo ti in GetTables())
        {
            if (ti.Name == tableName)
            {
                return true;
            }
        }
    }
}
```

```
        if (string.Equals(ti.Name, tableName,
 StringComparison.OrdinalIgnoreCase))
    {
        return true;
    }
} // foreach (DatabaseTableInfo...
} // if (pathChunks...

return false;
} // IsItemContainer
```

Things to Remember About Implementing `IsItemContainer`

Your navigation provider .NET class might declare provider capabilities of `ExpandWildcards`, `Filter`, `Include`, or `Exclude`, from the [System.Management.Automation.Provider.ProviderCapabilities](#) enumeration. In this case, the implementation of [System.Management.Automation.Provider.NavigationCmdletProvider.IsItemContainer*](#) needs to ensure that the path passed meets requirements. To do this, the method should access the appropriate property, for example, the [System.Management.Automation.Provider.CmdletProvider.Exclude*](#) property.

Moving an Item

In support of the `Move-Item` cmdlet, your navigation provider implements the [System.Management.Automation.Provider.NavigationCmdletProvider.MoveItem*](#) method. This method moves the item specified by the `path` parameter to the container at the path supplied in the `destination` parameter.

The sample navigation provider does not override the [System.Management.Automation.Provider.NavigationCmdletProvider.MoveItem*](#) method. The following is the default implementation.

Things to Remember About Implementing `MoveItem`

Your navigation provider .NET class might declare provider capabilities of `ExpandWildcards`, `Filter`, `Include`, or `Exclude`, from the [System.Management.Automation.Provider.ProviderCapabilities](#) enumeration. In this case, the implementation of [System.Management.Automation.Provider.NavigationCmdletProvider.MoveItem*](#) must ensure that the path passed meets requirements. To do this, the method should access the appropriate property, for example, the [CmdletProvider.Exclude](#) property.

By default, overrides of this method should not move objects over existing objects unless the `System.Management.Automation.Provider.CmdletProvider.Force*` property is set to `true`. For example, the `FileSystem` provider will not copy `C:\temp\abc.txt` over an existing `C:\bar.txt` file unless the

`System.Management.Automation.Provider.CmdletProvider.Force*` property is set to `true`. If the path specified in the `destination` parameter exists and is a container, the `System.Management.Automation.Provider.CmdletProvider.Force*` property is not required. In this case,

`System.Management.Automation.Provider.NavigationCmdletProvider.MoveItem*` should move the item indicated by the `path` parameter to the container indicated by the `destination` parameter as a child.

Your implementation of the

`System.Management.Automation.Provider.NavigationCmdletProvider.MoveItem*` method should call

`System.Management.Automation.Provider.CmdletProvider.ShouldProcess` and check its return value before making any changes to the data store. This method is used to confirm execution of an operation when a change is made to system state, for example, deleting files. `System.Management.Automation.Provider.CmdletProvider.ShouldProcess` sends the name of the resource to be changed to the user, with the Windows PowerShell runtime taking into account any command line settings or preference variables in determining what should be displayed to the user.

After the call to

`System.Management.Automation.Provider.CmdletProvider.ShouldProcess` returns `true`, the `System.Management.Automation.Provider.NavigationCmdletProvider.MoveItem*` method should call the

`System.Management.Automation.Provider.CmdletProvider.ShouldContinue` method. This method sends a message to the user to allow feedback to say if the operation should be continued. Your provider should call

`System.Management.Automation.Provider.CmdletProvider.ShouldContinue` as an additional check for potentially dangerous system modifications.

Attaching Dynamic Parameters to the Move-Item Cmdlet

Sometimes the `Move-Item` cmdlet requires additional parameters that are provided dynamically at runtime. To provide these dynamic parameters, the navigation provider must implement the

`System.Management.Automation.Provider.NavigationCmdletProvider.MoveItemDynamic`

[Parameters*](#) method to get the required parameter values from the item at the indicated path, and return an object that has properties and fields with parsing attributes similar to a cmdlet class or a [System.Management.Automation.RuntimeDefinedParameterDictionary](#) object.

This navigation provider does not implement this method. However, the following code is the default implementation of [System.Management.Automation.Provider.NavigationCmdletProvider.MoveItemDynamicParameters*](#).

Normalizing a Relative Path

Your navigation provider implements the [System.Management.Automation.Provider.NavigationCmdletProvider.NormalizeRelativePath*](#) method to normalize the fully-qualified path indicated in the `path` parameter as being relative to the path specified by the `basePath` parameter. The method returns a string representation of the normalized path. It writes an error if the `path` parameter specifies a nonexistent path.

The sample navigation provider does not override this method. The following is the default implementation.

Things to Remember About Implementing NormalizeRelativePath

Your implementation of [System.Management.Automation.Provider.NavigationCmdletProvider.NormalizeRelativePath*](#) should parse the `path` parameter, but it does not have to use purely syntactical parsing. You are encouraged to design this method to use the path to look up the path information in the data store and create a path that matches the casing and standardized path syntax.

Code Sample

For complete sample code, see [AccessDbProviderSample05 Code Sample](#).

Defining Object Types and Formatting

It is possible for a provider to add members to existing objects or define new objects. For more information, see [Extending Object Types and Formatting](#).

Building the Windows PowerShell provider

For more information, see [How to Register Cmdlets, Providers, and Host Applications](#).

Testing the Windows PowerShell provider

When your Windows PowerShell provider has been registered with Windows PowerShell, you can test it by running the supported cmdlets on the command line, including cmdlets made available by derivation. This example will test the sample navigation provider.

1. Run your new shell and use the `Set-Location` cmdlet to set the path to indicate the Access database.

PowerShell

```
Set-Location mydb:
```

2. Now run the `Get-ChildItem` cmdlet to retrieve a list of the database items, which are the available database tables. For each table, this cmdlet also retrieves the number of table rows.

PowerShell

```
Get-ChildItem | Format-Table RowCount, Name -AutoSize
```

Output

RowCount	Name
-----	-----
180	MSysAccessObjects
0	MSysACEs
1	MSysCmdbars
0	MSysIMEXColumns
0	MSysIMEXSpecs
0	MSysObjects
0	MSysQueries
7	MSysRelationships
8	Categories
91	Customers
9	Employees
2155	Order Details
830	Orders
77	Products

```
3    Shippers  
29   Suppliers
```

3. Use the `Set-Location` cmdlet again to set the location of the Employees data table.

```
PowerShell  
  
Set-Location Employees
```

4. Let's now use the `Get-Location` cmdlet to retrieve the path to the Employees table.

```
PowerShell  
  
Get-Location  
  
Output  
  
Path  
----  
mydb:\Employees
```

5. Now use the `Get-ChildItem` cmdlet piped to the `Format-Table` cmdlet. This set of cmdlets retrieves the items for the Employees data table, which are the table rows. They are formatted as specified by the `Format-Table` cmdlet.

```
PowerShell  
  
Get-ChildItem | Format-Table RowNumber, PSIsContainer, Data -AutoSize
```

```
Output  
  
RowNumber PSIsContainer Data  
----- -----  
0          False        System.Data.DataRow  
1          False        System.Data.DataRow  
2          False        System.Data.DataRow  
3          False        System.Data.DataRow  
4          False        System.Data.DataRow  
5          False        System.Data.DataRow  
6          False        System.Data.DataRow  
7          False        System.Data.DataRow  
8          False        System.Data.DataRow
```

6. You can now run the `Get-Item` cmdlet to retrieve the items for row 0 of the Employees data table.

PowerShell

```
Get-Item 0
```

Output

```
PSPath      : AccessDB::C:\PS\Northwind.mdb\Employees\0
PSParentPath : AccessDB::C:\PS\Northwind.mdb\Employees
PSChildName  : 0
PSDrive      : mydb
PSProvider    : System.Management.Automation.ProviderInfo
PSIsContainer : False
Data         : System.Data.DataRow
RowNumber     : 0
```

7. Use the `Get-Item` cmdlet again to retrieve the employee data for the items in row 0.

PowerShell

```
(Get-Item 0).Data
```

Output

```
EmployeeID   : 1
LastName     : Davis
FirstName    : Sara
Title        : Sales Representative
TitleOfCourtesy : Ms.
BirthDate    : 12/8/1968 12:00:00 AM
HireDate     : 5/1/1992 12:00:00 AM
Address       : 4567 Main Street
                  Apt. 2A
City          : Buffalo
Region        : NY
PostalCode    : 98052
Country       : USA
HomePhone     : (206) 555-9857

Creating a Windows PowerShell Content Provider

Article • 03/24/2025

This topic describes how to create a Windows PowerShell provider that enables the user to manipulate the contents of the items in a data store. As a consequence, a provider that can manipulate the contents of items is referred to as a Windows PowerShell content provider.

ⓘ Note

You can download the C# source file (AccessDBSampleProvider06.cs) for this provider using the Microsoft Windows Software Development Kit for Windows Vista and .NET Framework 3.0 Runtime Components. For download instructions, see [How to Install Windows PowerShell and Download the Windows PowerShell SDK](#). The downloaded source files are available in the <PowerShell Samples> directory. For more information about other Windows PowerShell provider implementations, see [Designing Your Windows PowerShell Provider](#).

Define the Windows PowerShell Content Provider Class

A Windows PowerShell content provider must create a .NET class that supports the [System.Management.Automation.Provider.IContentCmdletProvider](#) interface. Here is the class definition for the item provider described in this section.

C#

```
[CmdletProvider("AccessDB", ProviderCapabilities.None)]
public class AccessDBProvider : NavigationCmdletProvider,
IContentCmdletProvider
```

Note that in this class definition, the [System.Management.Automation.Provider.CmdletProviderAttribute](#) attribute includes two parameters. The first parameter specifies a user-friendly name for the provider that is used by Windows PowerShell. The second parameter specifies the Windows PowerShell specific capabilities that the provider exposes to the Windows PowerShell

runtime during command processing. For this provider, there are no added Windows PowerShell specific capabilities.

Define Functionality of Base Class

As described in [Design Your Windows PowerShell Provider](#), the `System.Management.Automation.Provider.NavigationCmdletProvider` class derives from several other classes that provided different provider functionality. A Windows PowerShell content provider, therefore, typically defines all of the functionality provided by those classes.

For more information about how to implement functionality for adding session-specific initialization information and for releasing resources that are used by the provider, see [Creating a Basic Windows PowerShell Provider](#). However, most providers, including the provider described here, can use the default implementation of this functionality that is provided by Windows PowerShell.

To access the data store, the provider must implement the methods of the `System.Management.Automation.Provider.DriveCmdletProvider` base class. For more information about implementing these methods, see [Creating a Windows PowerShell Drive Provider](#).

To manipulate the items of a data store, such as getting, setting, and clearing items, the provider must implement the methods provided by the `System.Management.Automation.Provider.ItemCmdletProvider` base class. For more information about implementing these methods, see [Creating a Windows PowerShell Item Provider](#).

To work on multi-layer data stores, the provider must implement the methods provided by the `System.Management.Automation.Provider.ContainerCmdletProvider` base class. For more information about implementing these methods, see [Creating a Windows PowerShell Container Provider](#).

To support recursive commands, nested containers, and relative paths, the provider must implement the `System.Management.Automation.Provider.NavigationCmdletProvider` base class. In addition, this Windows PowerShell content provider can attach the `System.Management.Automation.Provider.IContentCmdletProvider` interface to the `System.Management.Automation.Provider.NavigationCmdletProvider` base class, and must therefore implement the methods provided by that class. For more information, see implementing those methods, see [Implement a Navigation Windows PowerShell Provider](#).

Implementing a Content Reader

To read content from an item, a provider must implements a content reader class that derives from [System.Management.Automation.Provider.IContentReader](#). The content reader for this provider allows access to the contents of a row in a data table. The content reader class defines a **Read** method that retrieves the data from the indicated row and returns a list representing that data, a **Seek** method that moves the content reader, a **Close** method that closes the content reader, and a **Dispose** method.

C#

```
public class AccessDBContentReader : IContentReader
{
    // A provider instance is required so as to get "content"
    private AccessDBProvider provider;
    private string path;
    private long currentOffset;

    internal AccessDBContentReader(string path, AccessDBProvider provider)
    {
        this.path = path;
        this.provider = provider;
    }

    /// <summary>
    /// Read the specified number of rows from the source.
    /// </summary>
    /// <param name="readCount">The number of items to
    /// return.</param>
    /// <returns>An array of elements read.</returns>
    public IList Read(long readCount)
    {
        // Read the number of rows specified by readCount and increment
        // offset
        string tableName;
        int lineNumber;
        PathType type = provider.GetNamesFromPath(path, out tableName, out
rowNumber);

        Collection<DatabaseRowInfo> rows =
            provider.GetRows(tableName);
        Collection<DataRow> results = new Collection<DataRow>();

        if (currentOffset < 0 || currentOffset >= rows.Count)
        {
            return null;
        }

        int rowsRead = 0;

        while (rowsRead < readCount && currentOffset < rows.Count)
```

```

        {
            results.Add(rows[(int)currentOffset].Data);
            rowsRead++;
            currentOffset++;
        }

        return results;
    } // Read

    /// <summary>
    /// Moves the content reader specified number of rows from the
    /// origin
    /// </summary>
    /// <param name="offset">Number of rows to offset</param>
    /// <param name="origin">Starting row from which to offset</param>
    public void Seek(long offset, System.IO.SeekOrigin origin)
    {
        // get the number of rows in the table which will help in
        // calculating current position
        string tableName;
        int rowCount;

        PathType type = provider.GetNamesFromPath(path, out tableName, out
rowCount);

        if (type == PathType.Invalid)
        {
            throw new ArgumentException("Path specified must represent a
table or a row :" + path);
        }

        if (type == PathType.Table)
        {
            Collection<DatabaseRowInfo> rows = provider.GetRows(tableName);

            int numRows = rows.Count;

            if (offset > rows.Count)
            {
                throw new
                    ArgumentException(
                        "Offset cannot be greater than the number of rows
available"
                    );
            }

            if (origin == System.IO.SeekOrigin.Begin)
            {
                // starting from Beginning with an index 0, the current
                offset
                // has to be advanced to offset - 1
                currentOffset = offset - 1;
            }
            else if (origin == System.IO.SeekOrigin.End)
            {

```

```

        // starting from the end which is numRows - 1, the current
        // offset is so much less than numRows - 1
        currentOffset = numRows - 1 - offset;
    }
    else
    {
        // calculate from the previous value of current offset
        // advancing forward always
        currentOffset += offset;
    }
} // if (type...
else
{
    // for row, the offset will always be set to 0
    currentOffset = 0;
}

} // Seek

/// <summary>
/// Closes the content reader, so all members are reset
/// </summary>
public void Close()
{
    Dispose();
} // Close

/// <summary>
/// Dispose any resources being used
/// </summary>
public void Dispose()
{
    Seek(0, System.IO.SeekOrigin.Begin);

    GC.SuppressFinalize(this);
} // Dispose
} // AccessDBContentReader

```

Implementing a Content Writer

To write content to an item, a provider must implement a content writer class derives from [System.Management.Automation.Provider.IContentWriter](#). The content writer class defines a **Write** method that writes the specified row content, a **Seek** method that moves the content writer, a **Close** method that closes the content writer, and a **Dispose** method.

C#

```

public class AccessDBContentWriter : IContentWriter
{

```

```
// A provider instance is required so as to get "content"
private AccessDBProvider provider;
private string path;
private long currentOffset;

internal AccessDBContentWriter(string path, AccessDBProvider provider)
{
    this.path = path;
    this.provider = provider;
}

/// <summary>
/// Write the specified row contents in the source
/// </summary>
/// <param name="content"> The contents to be written to the source.
/// </param>
/// <returns>An array of elements which were successfully written to
/// the source</returns>
///
public IList Write(IList content)
{
    if (content == null)
    {
        return null;
    }

    // Get the total number of rows currently available it will
    // determine how much to overwrite and how much to append at
    // the end
    string tableName;
    int rowNumber;
    PathType type = provider.GetNamesFromPath(path, out tableName, out
rowNumber);

    if (type == PathType.Table)
    {
        OdbcDataAdapter da = provider.GetAdapterForTable(tableName);
        if (da == null)
        {
            return null;
        }

        DataSet ds = provider.GetDataSetForTable(da, tableName);
        DataTable table = provider.GetDataTable(ds, tableName);

        string[] colValues = (content[0] as string).Split(',');
        // set the specified row
        DataRow row = table.NewRow();

        for (int i = 0; i < colValues.Length; i++)
        {
            if (!String.IsNullOrEmpty(colValues[i]))
            {
                row[i] = colValues[i];
            }
        }

        table.Rows.Add(row);
        provider.UpdateTable(table, tableName);
    }
}
```

```

        }

        //table.Rows.InsertAt(row, rowNumber);
        // Update the table
        table.Rows.Add(row);
        da.Update(ds, tableName);

    }
    else
    {
        throw new InvalidOperationException("Operation not supported.
Content can be added only for tables");
    }

    return null;
} // Write

/// <summary>
/// Moves the content reader specified number of rows from the
/// origin
/// </summary>
/// <param name="offset">Number of rows to offset</param>
/// <param name="origin">Starting row from which to offset</param>
public void Seek(long offset, System.IO.SeekOrigin origin)
{
    // get the number of rows in the table which will help in
    // calculating current position
    string tableName;
    int rowNumber;

    PathType type = provider.GetNamesFromPath(path, out tableName, out
rowNumber);

    if (type == PathType.Invalid)
    {
        throw new ArgumentException("Path specified should represent
either a table or a row : " + path);
    }

    Collection<DatabaseRowInfo> rows =
        provider.GetRows(tableName);

    int numRows = rows.Count;

    if (offset > rows.Count)
    {
        throw new
            ArgumentException(
                "Offset cannot be greater than the number of rows
available"
            );
    }

    if (origin == System.IO.SeekOrigin.Begin)

```

```

    {
        // starting from Beginning with an index 0, the current offset
        // has to be advanced to offset - 1
        currentOffset = offset - 1;
    }
    else if (origin == System.IO.SeekOrigin.End)
    {
        // starting from the end which is numRows - 1, the current
        // offset is so much less than numRows - 1
        currentOffset = numRows - 1 - offset;
    }
    else
    {
        // calculate from the previous value of current offset
        // advancing forward always
        currentOffset += offset;
    }
}

} // Seek

/// <summary>
/// Closes the content reader, so all members are reset
/// </summary>
public void Close()
{
    Dispose();
} // Close

/// <summary>
/// Dispose any resources being used
/// </summary>
public void Dispose()
{
    Seek(0, System.IO.SeekOrigin.Begin);

    GC.SuppressFinalize(this);
} // Dispose
} // AccessDBContentWriter

```

Retrieving the Content Reader

To get content from an item, the provider must implement the [System.Management.Automation.Provider.IContentCmdletProvider.GetContentReader*](#) to support the `Get-Content` cmdlet. This method returns the content reader for the item located at the specified path. The reader object can then be opened to read the content.

Here is the implementation of

[System.Management.Automation.Provider.IContentCmdletProvider.GetContentReader*](#) for this method for this provider.

C#

```
public IContentReader GetContentReader(string path)
{
    string tableName;
    int rowNumber;

    PathType type = GetNamesFromPath(path, out tableName, out rowNumber);

    if (type == PathType.Invalid)
    {
        ThrowTerminatingInvalidPathException(path);
    }
    else if (type == PathType.Row)
    {
        throw new InvalidOperationException("contents can be obtained only
for tables");
    }

    return new AccessDBContentReader(path, this);
} // GetContentReader
```

C#

```
public IContentReader GetContentReader(string path)
{
    string tableName;
    int rowNumber;

    PathType type = GetNamesFromPath(path, out tableName, out rowNumber);

    if (type == PathType.Invalid)
    {
        ThrowTerminatingInvalidPathException(path);
    }
    else if (type == PathType.Row)
    {
        throw new InvalidOperationException("contents can be obtained only
for tables");
    }

    return new AccessDBContentReader(path, this);
} // GetContentReader
```

Things to Remember About Implementing GetContentReader

The following conditions may apply to an implementation of
`System.Management.Automation.Provider.IContentCmdletProvider.GetContentReader`*:

- When defining the provider class, a Windows PowerShell content provider might declare provider capabilities of `ExpandWildcards`, `Filter`, `Include`, or `Exclude`, from the `System.Management.Automation.Provider.ProviderCapabilities` enumeration. In these cases, the implementation of the `System.Management.Automation.Provider.IContentCmdletProvider.GetContentReader*` method must ensure that the path passed to the method meets the requirements of the specified capabilities. To do this, the method should access the appropriate property, for example, the `System.Management.Automation.Provider.CmdletProvider.Exclude*` and `System.Management.Automation.Provider.CmdletProvider.Include*` properties.
- By default, overrides of this method should not retrieve a reader for objects that are hidden from the user unless the `System.Management.Automation.Provider.CmdletProvider.Force*` property is set to `true`. An error should be written if the path represents an item that is hidden from the user and `System.Management.Automation.Provider.CmdletProvider.Force*` is set to `false`.

Attaching Dynamic Parameters to the Get-Content Cmdlet

The `Get-Content` cmdlet might require additional parameters that are specified dynamically at runtime. To provide these dynamic parameters, the Windows PowerShell content provider must implement the `System.Management.Automation.Provider.IContentCmdletProvider.GetContentReaderDynamicParameters*` method. This method retrieves dynamic parameters for the item at the indicated path and returns an object that has properties and fields with parsing attributes similar to a cmdlet class or a `System.Management.Automation.RuntimeDefinedParameterDictionary` object. The Windows PowerShell runtime uses the returned object to add the parameters to the cmdlet.

This Windows PowerShell container provider does not implement this method. However, the following code is the default implementation of this method.

C#

```
public object GetContentReaderDynamicParameters(string path)
{
    return null;
}
```

```
C#
```

```
public object GetContentReaderDynamicParameters(string path)
{
    return null;
}
```

Retrieving the Content Writer

To write content to an item, the provider must implement the [System.Management.Automation.Provider.IContentCmdletProvider.GetContentWriter*](#) to support the `Set-Content` and `Add-Content` cmdlets. This method returns the content writer for the item located at the specified path.

Here is the implementation of [System.Management.Automation.Provider.IContentCmdletProvider.GetContentWriter*](#) for this method.

```
C#
```

```
public IContentWriter GetContentWriter(string path)
{
    string tableName;
    int rowCount;

    PathType type = GetNamesFromPath(path, out tableName, out rowCount);

    if (type == PathType.Invalid)
    {
        ThrowTerminatingInvalidOperationException(path);
    }
    else if (type == PathType.Row)
    {
        throw new InvalidOperationException("contents can be added only to
tables");
    }

    return new AccessDBContentWriter(path, this);
}
```

```
C#
```

```
public IContentWriter GetContentWriter(string path)
{
    string tableName;
    int rowCount;

    PathType type = GetNamesFromPath(path, out tableName, out rowCount);
```

```

    if (type == PathType.Invalid)
    {
        ThrowTerminatingInvalidOperationException(path);
    }
    else if (type == PathType.Row)
    {
        throw new InvalidOperationException("contents can be added only to
tables");
    }

    return new AccessDBContentWriter(path, this);
}

```

Things to Remember About Implementing GetContentWriter

The following conditions may apply to your implementation of [System.Management.Automation.Provider.IContentCmdletProvider.GetContentWriter*](#):

- When defining the provider class, a Windows PowerShell content provider might declare provider capabilities of ExpandWildcards, Filter, Include, or Exclude, from the [System.Management.Automation.Provider.ProviderCapabilities](#) enumeration. In these cases, the implementation of the [System.Management.Automation.Provider.IContentCmdletProvider.GetContentWriter*](#) method must ensure that the path passed to the method meets the requirements of the specified capabilities. To do this, the method should access the appropriate property, for example, the [System.Management.Automation.Provider.CmdletProvider.Exclude*](#) and [System.Management.Automation.Provider.CmdletProvider.Include*](#) properties.
- By default, overrides of this method should not retrieve a writer for objects that are hidden from the user unless the [System.Management.Automation.Provider.CmdletProvider.Force*](#) property is set to `true`. An error should be written if the path represents an item that is hidden from the user and [System.Management.Automation.Provider.CmdletProvider.Force*](#) is set to `false`.

Attaching Dynamic Parameters to the Add-Content and Set-Content Cmdlets

The `Add-Content` and `Set-Content` cmdlets might require additional dynamic parameters that are added at runtime. To provide these dynamic parameters, the Windows PowerShell content provider must implement the

`System.Management.Automation.Provider.IContentCmdletProvider.GetContentWriterDynamicParameters*` method to handle these parameters. This method retrieves dynamic parameters for the item at the indicated path and returns an object that has properties and fields with parsing attributes similar to a cmdlet class or a `System.Management.Automation.RuntimeDefinedParameterDictionary` object. The Windows PowerShell runtime uses the returned object to add the parameters to the cmdlets.

This Windows PowerShell container provider does not implement this method. However, the following code is the default implementation of this method.

```
C#
```

```
public object GetContentWriterDynamicParameters(string path)
{
    return null;
}
```

Clearing Content

Your content provider implements the `System.Management.Automation.Provider.IContentCmdletProvider.ClearContent*` method in support of the `clear-Content` cmdlet. This method removes the contents of the item at the specified path, but leaves the item intact.

Here is the implementation of the `System.Management.Automation.Provider.IContentCmdletProvider.ClearContent*` method for this provider.

```
C#
```

```
public void ClearContent(string path)
{
    string tableName;
    int rowCount;

    PathType type = GetNamesFromPath(path, out tableName, out rowCount);

    if (type != PathType.Table)
    {
        WriteError(new ErrorRecord(
            new InvalidOperationException("Operation not supported. Content
can be cleared only for table"),
            "NotValidRow", ErrorCategory.InvalidArgument,
            path));
    }
}
```

```

}

OdbcDataAdapter da = GetAdapterForTable(tableName);

if (da == null)
{
    return;
}

DataSet ds = GetDataSetForTable(da, tableName);
DataTable table = GetDataTable(ds, tableName);

// Clear contents at the specified location
for (int i = 0; i < table.Rows.Count; i++)
{
    table.Rows[i].Delete();
}

if (ShouldProcess(path, "ClearContent"))
{
    da.Update(ds, tableName);
}

} // ClearContent

```

Things to Remember About Implementing `ClearContent`

The following conditions may apply to an implementation of [System.Management.Automation.Provider.IContentCmdletProvider.ClearContent*](#):

- When defining the provider class, a Windows PowerShell content provider might declare provider capabilities of `ExpandWildcards`, `Filter`, `Include`, or `Exclude`, from the [System.Management.Automation.Provider.ProviderCapabilities](#) enumeration. In these cases, the implementation of the [System.Management.Automation.Provider.IContentCmdletProvider.ClearContent*](#) method must ensure that the path passed to the method meets the requirements of the specified capabilities. To do this, the method should access the appropriate property, for example, the [System.Management.Automation.Provider.CmdletProvider.Exclude*](#) and [System.Management.Automation.Provider.CmdletProvider.Include*](#) properties.
- By default, overrides of this method should not clear the contents of objects that are hidden from the user unless the [System.Management.Automation.Provider.CmdletProvider.Force*](#) property is set to `true`. An error should be written if the path represents an item that is hidden from the user and [System.Management.Automation.Provider.CmdletProvider.Force*](#) is set to `false`.

- Your implementation of the [System.Management.Automation.Provider.IContentCmdletProvider.ClearContent*](#) method should call [System.Management.Automation.Provider.CmdletProvider.ShouldProcess](#) and verify its return value before making any changes to the data store. This method is used to confirm execution of an operation when a change is made to the data store, such as clearing content. The [System.Management.Automation.Provider.CmdletProvider.ShouldProcess](#) method sends the name of the resource to be changed to the user, with the Windows PowerShell runtime handling any command-line settings or preference variables in determining what should be displayed.

After the call to

[System.Management.Automation.Provider.CmdletProvider.ShouldProcess](#) returns `true`, the

[System.Management.Automation.Provider.IContentCmdletProvider.ClearContent*](#) method should call the

[System.Management.Automation.Provider.CmdletProvider.ShouldContinue](#) method. This method sends a message to the user to allow feedback to verify if the operation should be continued. The call to

[System.Management.Automation.Provider.CmdletProvider.ShouldContinue](#) allows an additional check for potentially dangerous system modifications.

Attaching Dynamic Parameters to the Clear-Content Cmdlet

The `Clear-Content` cmdlet might require additional dynamic parameters that are added at runtime. To provide these dynamic parameters, the Windows PowerShell content provider must implement the

[System.Management.Automation.Provider.IContentCmdletProvider.ClearContentDynamicParameters*](#) method to handle these parameters. This method retrieves the parameters for the item at the indicated path. This method retrieves dynamic parameters for the item at the indicated path and returns an object that has properties and fields with parsing attributes similar to a cmdlet class or a

[System.Management.Automation.RuntimeDefinedParameterDictionary](#) object. The Windows PowerShell runtime uses the returned object to add the parameters to the cmdlet.

This Windows PowerShell container provider does not implement this method. However, the following code is the default implementation of this method.

```
C#
```

```
public object ClearContentDynamicParameters(string path)
{
    return null;
}
```

```
C#
```

```
public object ClearContentDynamicParameters(string path)
{
    return null;
}
```

Code Sample

For complete sample code, see [AccessDbProviderSample06 Code Sample](#).

Defining Object Types and Formatting

When writing a provider, it may be necessary to add members to existing objects or define new objects. When this is done, you must create a Types file that Windows PowerShell can use to identify the members of the object and a Format file that defines how the object is displayed. For more information, see [Extending Object Types and Formatting](#).

Building the Windows PowerShell Provider

See [How to Register Cmdlets, Providers, and Host Applications](#).

Testing the Windows PowerShell Provider

When your Windows PowerShell provider has been registered with Windows PowerShell, you can test it by running the supported cmdlets on the command line. For example, test the sample content provider.

Use the `Get-Content` cmdlet to retrieve the contents of specified item in the database table at the path specified by the `Path` parameter. The `ReadCount` parameter specifies the number of items for the defined content reader to read (default 1). With the following command entry, the cmdlet retrieves two rows (items) from the table and

displays their contents. Note that the following example output uses a fictitious Access database.

PowerShell

```
Get-Content -Path mydb:\Customers -ReadCount 2
```

Output

```
ID      : 1
FirstName : Eric
LastName  : Gruber
Email    : ericgruber@fabrikam.com
Title    : President
Company  : Fabrikam
WorkPhone : (425) 555-0100
Address   : 4567 Main Street
City     : Buffalo
State    : NY
Zip      : 98052
Country   : USA
ID      : 2
FirstName : Eva
LastName  : Corets
Email    : evacorets@cohowinery.com
Title    : Sales Representative

Creating a Windows PowerShell Property Provider

Article • 03/24/2025

This topic describes how to create a provider that enables the user to manipulate the properties of items in a data store. As a consequence, this type of provider is referred to as a Windows PowerShell property provider. For example, the Registry provider provided by Windows PowerShell handles registry key values as properties of the registry key item. This type of provider must add the

`System.Management.Automation.Provider.IPropertyCmdletProvider` interface to the implementation of the .NET class.

ⓘ Note

Windows PowerShell provides a template file that you can use to develop a Windows PowerShell provider. The `TemplateProvider.cs` file is available on the Microsoft Windows Software Development Kit for Windows Vista and .NET Framework 3.0 Runtime Components. For download instructions, see [How to Install Windows PowerShell and Download the Windows PowerShell SDK](#). The downloaded template is available in the <PowerShell Samples> directory. You should make a copy of this file and use the copy for creating a new Windows PowerShell provider, removing any functionality that you do not need. For more information about other Windows PowerShell provider implementations, see [Designing Your Windows PowerShell Provider](#).

✖ Caution

The methods of your property provider should write any objects using the [`System.Management.Automation.Provider.CmdletProvider.Writepropertyobject*`](#) method.

Defining the Windows PowerShell provider

A property provider must create a .NET class that supports the `System.Management.Automation.Provider.IPropertyCmdletProvider` interface. Here is the default class declaration from the `TemplateProvider.cs` file provided by Windows PowerShell.

Defining Base Functionality

The [System.Management.Automation.Provider.IPropertyCmdletProvider](#) interface can be attached to any of the provider base classes, with the exception of the [System.Management.Automation.Provider.DriveCmdletProvider](#) class. Add the base functionality that is required by the base class you are using. For more information about base classes, see [Designing Your Windows PowerShell Provider](#).

Retrieving Properties

To retrieve properties, the provider must implement the [System.Management.Automation.Provider.IPropertyCmdletProvider.GetProperty*](#) method to support calls from the `Get-ItemProperty` cmdlet. This method retrieves the properties of the item located at the specified provider-internal path (fully-qualified).

The `providerSpecificPickList` parameter indicates which properties to retrieve. If this parameter is `null` or empty, the method should retrieve all properties. In addition, [System.Management.Automation.Provider.IPropertyCmdletProvider.GetProperty*](#) writes an instance of a [System.Management.Automation.PSObject](#) object that represents a property bag of the retrieved properties. The method should return nothing.

It is recommended that the implementation of [System.Management.Automation.Provider.IPropertyCmdletProvider.GetProperty*](#) supports the wildcard expansion of property names for each element in the pick list. To do this, use the [System.Management.Automation.WildcardPattern](#) class to perform the wildcard pattern matching.

Here is the default implementation of [System.Management.Automation.Provider.IPropertyCmdletProvider.GetProperty*](#) from the `TemplateProvider.cs` file provided by Windows PowerShell.

Things to Remember About Implementing GetProperty

The following conditions may apply to your implementation of [System.Management.Automation.Provider.IPropertyCmdletProvider.GetProperty*](#):

- When defining the provider class, a Windows PowerShell property provider might declare provider capabilities of `ExpandWildcards`, `Filter`, `Include`, or `Exclude`, from the [System.Management.Automation.Provider.ProviderCapabilities](#) enumeration. In these cases, the implementation of the [System.Management.Automation.Provider.IPropertyCmdletProvider.GetProperty*](#)

method needs to ensure that the path passed to the method meets the requirements of the specified capabilities. To do this, the method should access the appropriate property, for example, the [System.Management.Automation.Provider.CmdletProvider.Exclude*](#) and [System.Management.Automation.Provider.CmdletProvider.Include*](#) properties.

- By default, overrides of this method should not retrieve a reader for objects that are hidden from the user unless the [System.Management.Automation.Provider.CmdletProvider.Force*](#) property is set to `true`. An error should be written if the path represents an item that is hidden from the user and [System.Management.Provider.CmdletProvider.Force*](#) is set to `false`.

Attaching Dynamic Parameters to the Get-ItemProperty Cmdlet

The `Get-ItemProperty` cmdlet might require additional parameters that are specified dynamically at runtime. To provide these dynamic parameters, the Windows PowerShell property provider must implement the [System.Management.Automation.Provider.IPropertyCmdletProvider.GetPropertyDynamicParameters*](#) method. The `path` parameter indicates a fully-qualified provider-internal path, while the `providerSpecificPickList` parameter specifies the provider-specific properties entered on the command line. This parameter might be `null` or empty if the properties are piped to the cmdlet. In this case, this method returns an object that has properties and fields with parsing attributes similar to a cmdlet class or a [System.Management.Automation.RuntimeDefinedParameterDictionary](#) object. The Windows PowerShell runtime uses the returned object to add the parameters to the cmdlet.

Here is the default implementation of [System.Management.Automation.Provider.IPropertyCmdletProvider.GetPropertyDynamicParameters*](#) from the `TemplateProvider.cs` file provided by Windows PowerShell.

Setting Properties

To set properties, the Windows PowerShell property provider must implement the [System.Management.Automation.Provider.IPropertyCmdletProvider SetProperty*](#) method to support calls from the `Set-ItemProperty` cmdlet. This method sets one or more properties of the item at the specified path, and overwrites the supplied properties as required.

[System.Management.Automation.Provider.IPropertyCmdletProvider SetProperty](#)* also writes an instance of a [System.Management.Automation.PSObject](#) object that represents a property bag of the updated properties.

Here is the default implementation of

[System.Management.Automation.Provider.IPropertyCmdletProvider SetProperty](#)* from the TemplateProvider.cs file provided by Windows PowerShell.

Things to Remember About Implementing Set-ItemProperty

The following conditions may apply to an implementation of

[System.Management.Automation.Provider.IPropertyCmdletProvider SetProperty](#)*:

- When defining the provider class, a Windows PowerShell property provider might declare provider capabilities of ExpandWildcards, Filter, Include, or Exclude, from the [System.Management.Automation.Provider.ProviderCapabilities](#) enumeration. In these cases, the implementation of the [System.Management.Automation.Provider.IPropertyCmdletProvider SetProperty](#)* method must ensure that the path passed to the method meets the requirements of the specified capabilities. To do this, the method should access the appropriate property, for example, the [System.Management.Automation.Provider.CmdletProvider.Exclude](#)* and [System.Management.Automation.Provider.CmdletProvider.Include](#)* properties.
- By default, overrides of this method should not retrieve a reader for objects that are hidden from the user unless the [System.Management.Automation.Provider.CmdletProvider.Force](#)* property is set to `true`. An error should be written if the path represents an item that is hidden from the user and [System.Management.Automation.Provider.CmdletProvider.Force](#)* is set to `false`.
- Your implementation of the [System.Management.Automation.Provider.IPropertyCmdletProvider SetProperty](#)* method should call [System.Management.Automation.Provider.CmdletProvider.ShouldProcess](#) and verify its return value before making any changes to the data store. This method is used to confirm execution of an operation when a change is made to system state, for example, renaming files. [System.Management.Automation.Provider.CmdletProvider.ShouldProcess](#) sends the name of the resource to be changed to the user, with the Windows PowerShell runtime and handling any command-line settings or preference variables in determining what should be displayed.

After the call to `System.Management.Automation.Provider.CmdletProvider.ShouldProcess` returns `true`, if potentially dangerous system modifications can be made, the `System.Management.Automation.Provider.IPropertyCmdletProvider SetProperty*` method should call the `System.Management.Automation.Provider.CmdletProvider.ShouldContinue` method. This method sends a confirmation message to the user to allow additional feedback to indicate that the operation should be continued.

Attaching Dynamic Parameters for the Set-ItemProperty Cmdlet

The `Set-ItemProperty` cmdlet might require additional parameters that are specified dynamically at runtime. To provide these dynamic parameters, the Windows PowerShell property provider must implement the `System.Management.Automation.Provider.IPropertyCmdletProvider SetPropertyDynamicParameters*` method. This method returns an object that has properties and fields with parsing attributes similar to a cmdlet class or a `System.Management.Automation.RuntimeDefinedParameterDictionary` object. The `null` value can be returned if no dynamic parameters are to be added.

Here is the default implementation of `System.Management.Automation.Provider.IPropertyCmdletProvider GetPropertyDynamicParameters*` from the `TemplateProvider.cs` file provided by Windows PowerShell.

Clearing Properties

To clear properties, the Windows PowerShell property provider must implement the `System.Management.Automation.Provider.IPropertyCmdletProvider.ClearProperty*` method to support calls from the `Clear-ItemProperty` cmdlet. This method sets one or more properties for the item located at the specified path.

Here is the default implementation of `System.Management.Automation.Provider.IPropertyCmdletProvider.ClearProperty*` from the `TemplateProvider.cs` file provided by Windows PowerShell.

Thing to Remember About Implementing ClearProperty

The following conditions may apply to your implementation of `System.Management.Automation.Provider.IPropertyCmdletProvider.ClearProperty*`:

- When defining the provider class, a Windows PowerShell property provider might declare provider capabilities of `ExpandWildcards`, `Filter`, `Include`, or `Exclude`, from the `System.Management.Automation.Provider.ProviderCapabilities` enumeration. In these cases, the implementation of the `System.Management.Automation.Provider.IPropertyCmdletProvider.ClearProperty*` method needs to ensure that the path passed to the method meets the requirements of the specified capabilities. To do this, the method should access the appropriate property, for example, the `System.Management.Automation.Provider.CmdletProvider.Exclude*` and `System.Management.Automation.Provider.CmdletProvider.Include*` properties.
- By default, overrides of this method should not retrieve a reader for objects that are hidden from the user unless the `System.Management.Automation.Provider.CmdletProvider.Force*` property is set to `true`. An error should be written if the path represents an item that is hidden from the user and `System.Management.Automation.Provider.CmdletProvider.Force*` is set to `false`.
- Your implementation of the `System.Management.Automation.Provider.IPropertyCmdletProvider.ClearProperty*` method should call `System.Management.Automation.Provider.CmdletProvider.ShouldProcess` and verify its return value before making any changes to the data store. This method is used to confirm execution of an operation before a change is made to system state, such as clearing content.
`System.Management.Automation.Provider.CmdletProvider.ShouldProcess` sends the name of the resource to be changed to the user, with the Windows PowerShell runtime taking into account any command line settings or preference variables in determining what should be displayed.

After the call to

`System.Management.Automation.Provider.CmdletProvider.ShouldProcess` returns `true`, if potentially dangerous system modifications can be made, the `System.Management.Automation.Provider.IPropertyCmdletProvider.ClearProperty*` method should call the `System.Management.Automation.Provider.CmdletProvider.ShouldContinue` method. This method sends a confirmation message to the user to allow additional feedback to indicate that the potentially dangerous operation should be continued.

Attaching Dynamic Parameters to the Clear-ItemProperty Cmdlet

The `Clear-ItemProperty` cmdlet might require additional parameters that are specified dynamically at runtime. To provide these dynamic parameters, the Windows PowerShell property provider must implement the

`System.Management.Automation.Provider.IPropertyCmdletProvider.ClearPropertyDynamicParameters*` method. This method returns an object that has properties and fields with parsing attributes similar to a cmdlet class or a

`System.Management.Automation.RuntimeDefinedParameterDictionary` object. The `null` value can be returned if no dynamic parameters are to be added.

Here is the default implementation of

`System.Management.Automation.Provider.IPropertyCmdletProvider.ClearPropertyDynamicParameters*` from the `TemplateProvider.cs` file provided by Windows PowerShell.

Windows PowerShell Programmer's Guide

Article • 09/17/2021

This programmer's guide is targeted at developers who are interested in providing a command-line management environment for system administrators. Windows PowerShell provides a simple way for you to build management commands that expose .NET objects, while allowing Windows PowerShell to do most of the work for you.

In traditional command development, you are required to write a parameter parser, a parameter binder, filters, and all other functionality exposed by each command. Windows PowerShell provides the following to make it easy for you to write commands:

- A powerful Windows PowerShell runtime (execution engine) with its own parser and a mechanism for automatically binding command parameters.
- Utilities for formatting and displaying command results using a command line interpreter (CLI).
- Support for high levels of functionality (through Windows PowerShell providers) that make it easy to access stored data.

At little cost, you can represent a .NET object by a rich command or set of commands that will offer a complete command-line experience to the administrator.

The next section covers the key Windows PowerShell concepts and terms. Familiarize yourself with these concepts and terms before starting development.

About Windows PowerShell

Windows PowerShell defines several types of commands that you can use in development. These commands include: functions, filters, scripts, aliases, and executables (applications). The main command type discussed in this guide is a simple, small command called a "cmdlet". Windows PowerShell furnishes a set of cmdlets and fully supports cmdlet customization to suit your environment. The Windows PowerShell runtime processes all command types just as it does cmdlets, using pipelines.

In addition to commands, Windows PowerShell supports various customizable Windows PowerShell providers that make available specific sets of cmdlets. The shell operates within the Windows PowerShell-provided host application (`powershell.exe`), but it is equally accessible from a custom host application that you can develop to meet specific requirements. For more information, see [How Windows PowerShell Works](#).

Windows PowerShell Cmdlets

A cmdlet is a lightweight command that is used in the Windows PowerShell environment. The Windows PowerShell runtime invokes these cmdlets within the context of automation scripts that are provided at the command line, and the Windows PowerShell runtime also invokes them programmatically through Windows PowerShell APIs.

For more information about cmdlets, see [Writing a Windows PowerShell Cmdlet](#).

Windows PowerShell Providers

In performing administrative tasks, the user may need to examine data stored in a data store (for example, the file system, the Windows Registry, or a certificate store). To make these operations easier, Windows PowerShell defines a module called a Windows PowerShell provider that can be used to access a specific data store, such as the Windows Registry. Each provider supports a set of related cmdlets to give the user a symmetrical view of the data in the store.

Windows PowerShell provides several default Windows PowerShell providers. For example, the Registry provider supports navigation and manipulation of the Windows Registry. Registry keys are represented as items, and registry values are treated as properties.

If you expose a data store that the user will need to access, you might need to write your own Windows PowerShell provider, as described in [Creating Windows PowerShell Providers](#). For more information about Windows PowerShell providers, see [How Windows PowerShell Works](#).

Host Application

Windows PowerShell includes the default host application powershell.exe, which is a console application that interacts with the user and hosts the Windows PowerShell runtime using a console window.

Only rarely will you need to write your own host application for Windows PowerShell, although customization is supported. One case in which you might need your own application is when you have a requirement for a GUI interface that is richer than the interface provided by the default host application. You might also want a custom application when you are basing your GUI on the command line. For more information, see [How to Create a Windows PowerShell Host Application](#).

Windows PowerShell Runtime

The Windows PowerShell runtime is the execution engine that implements command processing. It includes the classes that provide the interface between the host application and Windows PowerShell commands and providers. The Windows PowerShell runtime is implemented as a runspace object for the current Windows PowerShell session, which is the operational environment in which the shell and the commands execute. For operational details, see [How Windows PowerShell Works](#).

Windows PowerShell Language

The Windows PowerShell language provides scripting functions and mechanisms to invoke commands. For complete scripting information, see the Windows PowerShell Language Reference shipped with Windows PowerShell.

Extended Type System (ETS)

Windows PowerShell provides access to a variety of different objects, such as .NET and XML objects. As a consequence, to present a common abstraction for all object types the shell uses its extended type system (ETS). Most ETS functionality is transparent to the user, but the script or .NET developer uses it for the following purposes:

- Viewing a subset of the members of specific objects. Windows PowerShell provides an "adapted" view of several specific object types.
- Adding members to existing objects.
- Access to serialized objects.
- Writing customized objects.

Using ETS, you can create flexible new "types" that are compatible with the Windows PowerShell language. If you are a .NET developer, you are able to work with objects using the same semantics as the Windows PowerShell language applies to scripting, for example, to determine if an object evaluates to `true`.

For more information about ETS and how Windows PowerShell uses objects, see [Windows PowerShell Object Concepts](#).

Programming for Windows PowerShell

Windows PowerShell defines its code for commands, providers, and other program modules using the .NET Framework. You are not confined to the use of Microsoft Visual Studio in creating customized modules for Windows PowerShell, although the samples provided in this

guide are known to run in this tool. You can use any .NET language that supports class inheritance and the use of attributes. In some cases, Windows PowerShell APIs require the programming language to be able to access generic types.

Programmer's Reference

For reference when developing for Windows PowerShell, see the [Windows PowerShell SDK](#).

Getting Started Using Windows PowerShell

For more information about starting to use the Windows PowerShell shell, see the [Getting Started with Windows PowerShell](#) shipped with Windows PowerShell. A Quick Reference tri-fold document is also supplied as a primer for cmdlet use.

Windows PowerShell Sample Code

Article • 09/15/2023

Windows PowerShell samples are available through the Windows SDK. This section contains the sample code that is contained in the Windows SDK samples.

ⓘ Note

When the Windows SDK is installed, a **Samples** directory is created in which all the Windows PowerShell samples are made available. A typical installation directory is **C:\Program Files\Microsoft SDKs\Windows\v6.0**. Start Windows PowerShell and type "`cd Samples\SysMgmt\PowerShell`" to locate the samples' directory. In this document, the Windows PowerShell Samples directory is referred to as **<PowerShell Samples>**.

Sample Code Listing

AccessDbProviderSample01 Code Sample

Article • 09/17/2021

The following code shows the implementation of the Windows PowerShell provider described in [Creating a Basic Windows PowerShell Provider](#). This implementation provides methods for starting and stopping the provider, and although it does not provide a means to access a data store or to get or set the data in the data store, it does provide the basic functionality that is required by all providers.

ⓘ Note

You can download the C# source file (AccessDBSampleProvider01.cs) for this provider by using the Windows Software Development Kit for Windows Vista and Microsoft .NET Framework 3.0 Runtime Components. For download instructions, see [How to Install Windows PowerShell and Download the Windows PowerShell SDK](#). The downloaded source files are available in the <PowerShell Samples> directory. For more information about other Windows PowerShell provider implementations, see [Designing Your Windows PowerShell Provider](#).

Code Sample

C#

```
using System.Management.Automation;
using System.Management.Automation.Provider;
using System.ComponentModel;

namespace Microsoft.Samples.PowerShell.Providers
{
    #region AccessDBProvider

        /// <summary>
        /// Simple provider.
        /// </summary>
        [CmdletProvider("AccessDB", ProviderCapabilities.None)]
        public class AccessDBProvider : CmdletProvider
    {

    }
```

```
#endregion AccessDBProvider  
}
```

AccessDbProviderSample02 Code Sample

Article • 09/17/2021

The following code shows the implementation of the Windows PowerShell provider described in [Creating a Windows PowerShell Drive Provider](#). This implementation creates a path, makes a connection to an Access database, and then removes the drive.

ⓘ Note

You can download the C# source file (AccessDBSampleProvider02.cs) for this provider using the Microsoft Windows Software Development Kit for Windows Vista and Microsoft .NET Framework 3.0 Runtime Components. For download instructions, see [How to Install Windows PowerShell and Download the Windows PowerShell SDK](#). The downloaded source files are available in the <PowerShell Samples> directory. For more information about other Windows PowerShell provider implementations, see [Designing Your Windows PowerShell Provider](#).

Code Sample

C#

```
using System;
using System.IO;
using System.Data;
using System.Data.Odbc;
using System.Management.Automation;
using System.Management.Automation.Provider;
using System.ComponentModel;

namespace Microsoft.Samples.PowerShell.Providers
{
    #region AccessDBProvider

        /// <summary>
        /// A PowerShell Provider which acts upon a access data store.
        /// </summary>
        /// <remarks>
        /// This example only demonstrates the drive overrides
        /// </remarks>
        [CmdletProvider("AccessDB", ProviderCapabilities.None)]
        public class AccessDBProvider : DriveCmdletProvider
    {
        #region Drive Manipulation
```

```

/// <summary>
/// Create a new drive. Create a connection to the database file and
set
/// the Connection property in the PSDriveInfo.
/// </summary>
/// <param name="drive">
/// Information describing the drive to add.
/// </param>
/// <returns>The added drive.</returns>
protected override PSDriveInfo NewDrive(PSDriveInfo drive)
{
    // check if drive object is null
    if (drive == null)
    {
        WriteError(new ErrorRecord(
            new ArgumentNullException("drive"),
            "NullDrive",
            ErrorCategory.InvalidArgument,
            null)
        );
    }

    return null;
}

// check if drive root is not null or empty
// and if its an existing file
if (String.IsNullOrEmpty(drive.Root) || (File.Exists(drive.Root)
== false))
{
    WriteError(new ErrorRecord(
        new ArgumentException("drive.Root"),
        "NoRoot",
        ErrorCategory.InvalidArgument,
        drive)
    );
}

return null;
}

// create a new drive and create an ODBC connection to the new
drive
AccessDBPSDriveInfo accessDBPSDriveInfo = new
AccessDBPSDriveInfo(drive);

OdbcConnectionStringBuilder builder = new
OdbcConnectionStringBuilder();

builder.Driver = "Microsoft Access Driver (*.mdb)";
builder.Add("DBQ", drive.Root);

OdbcConnection conn = new
OdbcConnection(builder.ConnectionString);
conn.Open();
accessDBPSDriveInfo.Connection = conn;

```

```

        return accessDBPSDriveInfo;
    } // NewDrive

    /// <summary>
    /// Removes a drive from the provider.
    /// </summary>
    /// <param name="drive">The drive to remove.</param>
    /// <returns>The drive removed.</returns>
    protected override PSDriveInfo RemoveDrive(PSDriveInfo drive)

AccessDbProviderSample03 Code Sample

Article • 11/05/2021

The following code shows the implementation of the Windows PowerShell provider described in [Creating a Windows PowerShell Item Provider](#). This provider that can manipulate the data in a data store.

ⓘ Note

You can download the C# source file (AccessDBSampleProvider03.cs) for this provider using the Microsoft Windows Software Development Kit for Windows Vista and .NET Framework 3.0 Runtime Components. For download instructions, see [How to Install Windows PowerShell and Download the Windows PowerShell SDK](#). The downloaded source files are available in the <PowerShell Samples> directory. For more information about other Windows PowerShell provider implementations, see [Designing Your Windows PowerShell Provider](#).

AccessDbProviderSample04 Code Sample

Article • 09/17/2021

The following code shows the implementation of the Windows PowerShell provider described in [Creating a Windows PowerShell Container Provider](#). This provider works on multi-layer data stores. For this type of data store, the top level of the store contains the root items and each subsequent level is referred to as a node of child items. By allowing the user to work on these child nodes, a user can interact hierarchically through the data store.

AccessDbProviderSample05 Code Sample

Article • 09/17/2021

The following code shows the implementation of the Windows PowerShell navigation provider described in [Creating a Windows PowerShell Navigation Provider](#). This provider supports recursive commands, nested containers, and relative paths that allow it to navigate the data store.

Code Sample

C#

```
using System;
using System.IO;
using System.Data;
using System.Data.Odbc;
using System.Diagnostics;
using System.Collections.ObjectModel;
using System.Text;
using System.Text.RegularExpressions;
using System.Management.Automation;
using System.Management.Automation.Provider;
using System.ComponentModel;
using System.Globalization;

AccessDbProviderSample06 Code Sample

Article • 09/17/2021

The following code shows the implementation of the Windows PowerShell content provider described in [Creating a Windows PowerShell Content Provider](#). This provider enables the user to manipulate the contents of the items in a data store.

ⓘ Note

You can download the C# source file (AccessDBSampleProvider06.cs) for this provider by using the Microsoft Windows Software Development Kit for Windows Vista and Microsoft .NET Framework 3.0 Runtime Components. For download instructions, see [How to Install Windows PowerShell and Download the Windows PowerShell SDK](#). The downloaded source files are available in the <PowerShell Samples> directory. For more information about other Windows PowerShell provider implementations, see [Designing Your Windows PowerShell Provider](#).

GetProc01 Code Samples

Article • 09/17/2021

Here are the code samples for the GetProc01 sample cmdlet. This is the basic `Get-Process` cmdlet sample described in [Creating Your First Cmdlet](#). A `Get-Process` cmdlet is designed to retrieve information about all the processes running on the local computer.

For complete sample code, see the following topics.

GetProc01 (C#) Sample Code

Article • 09/17/2021

The following code shows the implementation of the GetProc01 sample cmdlet. Notice that the cmdlet is simplified by leaving the actual work of process retrieval to the [System.Diagnostics.Process.Getprocesses*](#) method.

ⓘ Note

You can download the C# source file (getproc01.cs) for this Get-Proc cmdlet using the Microsoft Windows Software Development Kit for Windows Vista and .NET Framework 3.0 Runtime Components. For download instructions, see [How to Install Windows PowerShell and Download the Windows PowerShell SDK](#). The downloaded source files are available in the <PowerShell Samples> directory.

Code Sample

C#

```
using System;
using System.Diagnostics;
using System.Management.Automation; //Windows PowerShell
namespace

using System.ComponentModel;

// This sample shows how to create a simple cmdlet. To test this
// cmdlet, the snapin must be registered. First, run the command:
//     installutil GetProcessSample01.dll
// Then run:
//     Add-PSSnapin GetProcessSnapIn01
// After the snapin has been loaded, you can run:
//     get-proc

namespace Microsoft.Samples.PowerShell.Commands
{
    #region GetProcCommand

    /// <summary>
    /// This class implements the Get-Proc cmdlet.
    /// </summary>
    [Cmdlet(VerbsCommon.Get, "Proc")]
    public class GetProcCommand : Cmdlet
    {
        #region Cmdlet Overrides
```

```

/// <summary>
/// The ProcessRecord method calls the Process.GetProcesses
/// method to retrieve the processes of the local computer.
/// Then, the WriteObject method writes the associated processes
/// to the pipeline.
/// </summary>
protected override void ProcessRecord()
{
    // Retrieve the current processes.
    Process[] processes = Process.GetProcesses();

    // Write the processes to the pipeline to make them available
    // to the next cmdlet. The second argument (true) tells Windows
    // PowerShell to enumerate the array and to send one process
    // object at a time to the pipeline.
    WriteObject(processes, true);
}

#endregion Overrides

} //GetProcCommand

#endregion GetProcCommand

#region PowerShell snap-in

/// <summary>
/// Create this sample as an PowerShell snap-in
/// </summary>
[RunInstaller(true)]

StopProc01 Code Samples

Article • 09/17/2021

Here is the code sample for the StopProc01 sample cmdlet. This is the `Stop-Process` cmdlet sample described in [Creating a Cmdlet that Modifies the System](#). The `Stop-Process` cmdlet is designed to stop processes that are retrieved using the `Get-Proc` cmdlet (described in [Creating Your First Cmdlet](#)).

Note

You can download the C# (stopproc01.cs) source file for the Stop-Proc cmdlet using the Microsoft Windows Software Development Kit for Windows Vista and .NET Framework 3.0 Runtime Components. For download instructions, see [How to Install Windows PowerShell and Download the Windows PowerShell SDK](#).

The downloaded source files are available in the <PowerShell Samples> directory.

StopProc01 (C#) Sample Code

Article • 09/17/2021

Here is the complete C# code for the StopProc01 sample cmdlet.

ⓘ Note

You can download the C# (stopproc01.cs) source file for the Stop-Proc cmdlet using the Microsoft Windows Software Development Kit for Windows Vista and .NET Framework 3.0 Runtime Components. For download instructions, see [How to Install Windows PowerShell and Download the Windows PowerShell SDK](#). The downloaded source files are available in the <PowerShell Samples> directory.

C#

```
using System;
using System.Diagnostics;
using System.Collections;
using Win32Exception = System.ComponentModel.Win32Exception;
using System.Management.Automation;    // Windows PowerShell namespace
using System.Globalization;

// This sample shows how to implement a PassThru parameter that indicates
// that
// the user wants the cmdlet to return an object, and how to request
// user feedback by calls to the ShouldProcess and ShouldContinue methods.
//
// To test this cmdlet, create a module folder that has the same name as
// this assembly (StopProcesssample01), save the assembly in the module
// folder, and then run the
// following command:
// import-module stopprocesssample01

namespace Microsoft.Samples.PowerShell.Commands
{
    #region StopProcCommand

        /// <summary>
        /// This class implements the stop-proc cmdlet.

StopProcessSample04 (VB.NET) Sample Code

Article • 12/18/2023

Here is the complete VB.NET sample code for the StopProc04 sample cmdlet. This is the code for the `Stop-Process` cmdlet described in [Adding Parameter Sets to a Cmdlet](#). The `Stop-Process` cmdlet is designed to stop processes that are retrieved using the Get-Proc cmdlet (described in [Creating Your First Cmdlet](#)).

ⓘ Note

You can download the VB.NET (stopprocesssample04.vb) source file for this Stop-Proc cmdlet using the Microsoft Windows Software Development Kit for Windows Vista and .NET Framework 3.0 Runtime Components. For download instructions, see [How to Install Windows PowerShell and Download the Windows PowerShell SDK](#).

The downloaded source files are available in the <PowerShell Samples> directory.

Runspace02 (VB.NET) Code Sample

Article • 09/17/2021

Here is the VB.NET source code for the Runspace02 sample. This sample uses the [System.Management.Automation.RunspacesInvoke](#) class to execute the `Get-Process` cmdlet synchronously. Windows Forms and data binding are then used to display the results in a DataGridView control.

Code Sample

VB

```
Imports System
Imports System.Collections
Imports System.Collections.ObjectModel
Imports System.Windows.Forms
Imports System.Management.Automation.Runspaces
Imports System.Management.Automation

Namespace Microsoft.Samples.PowerShell.Runspaces

    Class Runspace02

        Shared Sub CreateForm()
            Dim form As New Form()
            Dim grid As New DataGridView()
            form.Controls.Add(grid)
            grid.Dock = DockStyle.Fill

            ' Create an instance of the RunspaceInvoke class.
            ' This takes care of all building all of the other
            ' data structures needed...
            Dim invoker As New RunspaceInvoke()

            Dim results As Collection(Of PSObject) = _
                invoker.Invoke("Get-Process | Sort-Object ID")

            ' The generic collection needs to be re-wrapped in an ArrayList
            ' for data-binding to work...
            Dim objects As New ArrayList()
            objects.AddRange(results)

            ' The DataGridView will use the PSObjectTypeDescriptor type
            ' to retrieve the properties.
            grid.DataSource = objects

            form.ShowDialog()

        End Sub 'CreateForm
    End Class
End Namespace
```

```
''' <summary>
''' This sample uses the RunspaceInvoke class to execute
''' the Get-Process cmdlet synchronously. Windows Forms and data
''' binding are then used to display the results in a
''' DataGridView control.
''' </summary>
''' <param name="args">Unused</param>
''' <remarks>

RunSpace03 (C#) Code Sample

Article • 03/24/2025

Here is the C# source code for the console application described in "Creating a Console Application That Runs a Specified Script". This sample uses the [System.Management.Automation.RunspaceInvoke](#) class to execute a script that retrieves process information by using the list of process names passed into the script. It shows how to pass input objects to a script and how to retrieve error objects as well as the output objects.

ⓘ Note

You can download the C# source file (runspace03.cs) for this sample using the Microsoft Windows Software Development Kit for Windows Vista and Microsoft .NET Framework 3.0 Runtime Components. For download instructions, see [How to Install Windows PowerShell and Download the Windows PowerShell SDK](#). The downloaded source files are available in the <PowerShell Samples> directory.

Code Sample

C#

```
namespace Microsoft.Samples.PowerShell.Runspaces
{
    using System;
    using System.Collections;
    using System.Management.Automation;
    using System.Management.Automation.Runspaces;
    using PowerShell = System.Management.Automation.PowerShell;

    /// <summary>
    /// This class contains the Main entry point for this host application.
    /// </summary>
    internal class Runspace03
    {
        /// <summary>
        /// This sample uses the PowerShell class to execute
        /// a script that retrieves process information for the
        /// list of process names passed into the script.
        /// It shows how to pass input objects to a script and
        /// how to retrieve error objects as well as the output objects.
        /// </summary>
        /// <param name="args">Parameter not used.</param>
        /// <remarks>
        /// This sample demonstrates the following:
    }
}
```

```

    /// 1. Creating an instance of the PowerShell class.
    /// 2. Using this instance to execute a string as a PowerShell
script.
    /// 3. Passing input objects to the script from the calling program.
    /// 4. Using PSObject to extract and display properties from the
objects
    ///     returned by this command.
    /// 5. Retrieving and displaying error records that were generated
    ///     during the execution of that script.
    /// </remarks>
private static void Main(string[] args)
{
    // Define a list of processes to look for
    string[] processNames = new string[]
    {
        "lsass", "nosuchprocess", "services", "nosuchprocess2"
    };

    // The script to run to get these processes. Input passed
    // to the script will be available in the $input variable.
    string script = "$input | get-process -name ${_}";

    // Create an instance of the PowerShell class.
    using (PowerShell powershell = PowerShell.Create())
    {
        powershell.AddScript(script);

        Console.WriteLine("Process           HandleCount");
        Console.WriteLine("-----");

        // Now invoke the PowerShell and display the objects that
are
        // returned...
        foreach (PSObject result in powershell.Invoke(processNames))
        {
            Console.WriteLine(
                "{0,-20} {1}",
                result.Members["ProcessName"].Value,
                result.Members["HandleCount"].Value);
        }

        // Now process any error records that were generated while
running the script.
        Console.WriteLine("\nThe following non-terminating errors
occurred:\n");

RunSpace06 Code Sample

Article • 09/17/2021

Here is the source code for the Runspace06 sample described in [Configuring a Runspace Using a Windows PowerShell Snap-in](#). This sample application creates a runspace based on a Windows PowerShell snap-in, which is then used to run a pipeline with a single command. To do this, the application creates the runspace configuration information, creates a runspace, creates a pipeline with a single command, and then executes the pipeline.

ⓘ Note

You can download the C# source file (runspace06.cs) by using the Windows Software Development Kit for Windows Vista and Microsoft .NET Framework 3.0 Runtime Components. For download instructions, see [How to Install Windows PowerShell and Download the Windows PowerShell SDK](#). The downloaded source files are available in the <PowerShell Samples> directory.

Code Sample

C#

```
namespace Microsoft.Samples.PowerShell.Runspaces
{
    using System;
    using System.Collections.ObjectModel;
    using System.Management.Automation;
    using System.Management.Automation.Runspaces;
    using PowerShell = System.Management.Automation.PowerShell;

    /// <summary>
    /// This class contains the Main entry point for this host application.
    /// </summary>
    internal class Runspace06
    {
        /// <summary>
        /// This sample uses an initial session state to create a runspace.
        /// The sample invokes a command from binary module that is loaded by
        /// the
        /// initial session state.
        /// </summary>
        /// <param name="args">Parameter not used.</param>
        /// <remarks>
        /// This sample assumes that user has the GetProcessSample02.dll that is
        /// produced by the GetProcessSample02 sample copied to the current
```

```
directory.

/// This sample demonstrates the following:
/// 1. Creating a default initial session state.
/// 2. Creating a runspace using the initial session state.
/// 3. Creating a PowerShell object that uses the runspace.
/// 4. Adding the get-proc cmdlet to the PowerShell object from a
///    module.
/// 5. Using PSObject objects to extract and display properties from
///    the objects returned by the cmdlet.
/// </remarks>
private static void Main(string[] args)
{
    // Create an initial session state.
    InitialSessionState iss = InitialSessionState.CreateDefault();
    iss.ImportPSModule(new string[] { @"\.\GetProcessSample02.dll" });

    // Create a runspace. Notice that no PSHost object is supplied to the
    // CreateRunspace method so the default host is used. See the Host
    // samples for more information on creating your own custom host.
    using (Runspace myRunSpace = RunspaceFactory.CreateRunspace(iss))
    {
        myRunSpace.Open();

        // Create a PowerShell object.
        using (PowerShell powershell = PowerShell.Create())
        {
            // Add the cmdlet and specify the runspace.
            powershell.AddCommand(@"GetProcessSample02\get-proc");
            powershell.Runspace = myRunSpace;

            Collection<PSObject> results = powershell.Invoke();

            Console.WriteLine("Process           HandleCount");
            Console.WriteLine("-----");

            // Display the results.
            foreach (PSObject result in results)
            {

RunSpace07 Code Sample

Article • 09/17/2021

Here is the source code for the Runspace07 sample described in [Creating a Console Application That Adds Commands to a Pipeline](#). This sample application creates a runspace, creates a pipeline, adds two commands to the pipeline, and then executes the pipeline. The commands added to the pipeline are the `Get-Process` and `Measure-Object` cmdlets.

ⓘ Note

You can download the C# source file (`runspace07.cs`) using the Microsoft Windows Software Development Kit for Windows Vista and Microsoft .NET Framework 3.0 Runtime Components. For download instructions, see [How to Install Windows PowerShell and Download the Windows PowerShell SDK](#). The downloaded source files are available in the `<PowerShell Samples>` directory.

Code Sample

C#

```
namespace Microsoft.Samples.PowerShell.Runspaces
{
    using System;
    using System.Collections.ObjectModel;
    using System.Management.Automation;
    using System.Management.Automation.Runspaces;
    using PowerShell = System.Management.Automation.PowerShell;

    /// <summary>
    /// This class contains the Main entry point for this host application.
    /// </summary>
    internal class Runspace07
    {
        /// <summary>
        /// This sample shows how to create a runspace and how to run
        /// commands using a PowerShell object. It builds a pipeline
        /// that runs the get-process cmdlet, which is piped to the measure-
        object
        /// cmdlet to count the number of processes running on the system.
        /// </summary>
        /// <param name="args">Parameter is not used.</param>
        /// <remarks>
        /// This sample demonstrates the following:
        /// 1. Creating a runspace using the RunspaceFactory class.
    }
}
```

```
/// 2. Creating a PowerShell object
/// 3. Adding individual cmdlets to the PowerShell object.
/// 4. Running the cmdlets synchronously.
/// 5. Working with PSObject objects to extract properties
///     from the objects returned by the cmdlets.
/// </remarks>
private static void Main(string[] args)
{
    Collection<PSObject> result;      // Will hold the result
                                       // of running the cmdlets.

    // Create a runspace. We can not use the RunspaceInvoke class
    // because we need to get at the underlying runspace to
    // explicitly add the commands. Notice that no PSHost object is
    // supplied to the CreateRunspace method so the default host is
    // used. See the Host samples for more information on creating
    // your own custom host.
    using (Runspace myRunSpace = RunspaceFactory.CreateRunspace())
    {
        myRunSpace.Open();

        // Create a PowerShell object and specify the runspace.
        PowerShell powershell = PowerShell.Create();
        powershell.Runspace = myRunSpace;

        // Use the using statement so we dispose of the PowerShell object
        // when we're done.
        using (powershell)
        {
            // Add the get-process cmdlet to the PowerShell object. Notice
            // we are specify the name of the cmdlet, not a script.
            powershell.AddCommand("get-process");

            // Add the measure-object cmdlet to count the number
            // of objects being returned. Commands are always added to the end
            // of the pipeline.
            powershell.AddCommand("measure-object");

            // Run the cmdlets synchronously and save the objects returned.
            result = powershell.Invoke();
        }

        // Even after disposing of the pipeline, we still need to set
        // the powershell variable to null so that the garbage collector
        // can clean it up.
        powershell = null;

        // Display the results of running the commands (checking that
        // everything is ok first).
        if (result == null || result.Count != 1)
        {
            throw new InvalidOperationException(
                "pipeline.Invoke() returned the wrong number of
objects");
        }
    }
}
```

```
PSMemberInfo count = result[0].Properties["Count"];
if (count == null)
{
    throw new InvalidOperationException(
        "The object returned doesn't have a 'count' property");
}

Console.WriteLine(
    "Runspace07: The get-process cmdlet returned {0}
objects",
    count.Value);

// Close the runspace to release any resources.
myRunSpace.Close();
}

System.Console.WriteLine("Hit any key to exit...");
System.Console.ReadKey();
}
}
}
```

RunSpace08 Code Sample

Article • 09/17/2021

Here is the source code for the Runspace08 sample described in [Creating a Console Application That Adds Parameters to a Command](#). This sample application creates a runspace, creates a pipeline, adds two commands to the pipeline, adds two parameters to the second command, and then executes the pipeline. The commands that are added to the pipeline are the `Get-Process` and `Sort-Object` cmdlets.

Code Sample

C#

```
namespace Microsoft.Samples.PowerShell.Runspaces
{
    using System;
    using System.Collections.Generic;
    using System.Collections.ObjectModel;
    using System.Management.Automation;
    using System.Management.Automation.Runspaces;
    using PowerShell = System.Management.Automation.PowerShell;

    /// <summary>
    /// This class contains the Main entry point for this host application.
    /// </summary>
    internal class Runspace08
    {
        /// <summary>
        /// This sample shows how to use a PowerShell object to run commands.
        The
        /// PowerShell object builds a pipeline that include the get-process
        cmdlet,
        /// which is then piped to the sort-object cmdlet. Parameters are added
        to the
        /// sort-object cmdlet to sort the HandleCount property in descending
        order.
        /// </summary>
        /// <param name="args">Parameter is not used.</param>
        /// <remarks>
        /// This sample demonstrates:
        /// 1. Creating a PowerShell object
        /// 2. Adding individual commands to the PowerShell object.
        /// 3. Adding parameters to the commands.
        /// 4. Running the pipeline of the PowerShell object synchronously.
        /// 5. Working with PSObject objects to extract properties
        ///     from the objects returned by the commands.
        /// </remarks>
        private static void Main(string[] args)
```

```
{  
    Collection<PSObject> results; // Holds the result of the pipeline  
    execution.  
  
    // Create the PowerShell object. Notice that no runspace is specified  
    so a  
    // new default runspace is used.  
    PowerShell powershell = PowerShell.Create();  
  
    // Use the using statement so that we can dispose of the PowerShell  
    object  
    // when we are done.  
    using (powershell)  
    {  
        // Add the get-process cmdlet to the pipeline of the PowerShell  
        object.  
        powershell.AddCommand("get-process");  
  
        // Add the sort-object cmdlet and its parameters to the pipeline of  
        // the PowerShell object so that we can sort the HandleCount  
        property  
        // in descending order.  
        powershell.AddCommand("sort-  
        object").AddParameter("descending").AddParameter("property", "handlecount");  
  
        // Run the pipeline of the PowerShell object synchronously.  
        results = powershell.Invoke();  
    }  
  
    // Even after disposing of the PowerShell object, we still  
    // need to set the powershell variable to null so that the  
    // garbage collector can clean it up.  
    powershell = null;  
  
    Console.WriteLine("Process           HandleCount");  
    Console.WriteLine("-----");  
  
    // Display the results returned by the commands.  
    foreach (PSObject result in results)  
    {  
        Console.WriteLine(  
            "{0,-20} {1}",  
            result.Members["ProcessName"].Value,  
            result.Members["HandleCount"].Value);  
    }  
  
    System.Console.WriteLine("Hit any key to exit...");  
    System.Console.ReadKey();  
}  
}
```

RunSpace09 Code Sample

Article • 09/17/2021

This sample application creates and opens a runspace, creates and asynchronously invokes a pipeline, and then uses pipeline events to process the script asynchronously. The script that is run by this application creates the integers 1 through 10 in 0.5-second intervals (500 ms).

Code Sample

C#

```
namespace Microsoft.Samples.PowerShell.Runspaces
{
    using System;
    using System.Collections.Generic;
    using System.Collections.ObjectModel;
    using System.Diagnostics;
    using System.Management.Automation;
    using System.Management.Automation.Runspaces;
    using PowerShell = System.Management.Automation.PowerShell;

    /// <summary>
    /// This class contains the Main entry point for this host application.
    /// </summary>
    internal class Runspace09
    {
        /// <summary>
        /// This sample shows how to use a PowerShell object to run a
        /// script that generates the numbers from 1 to 10 with delays
        /// between each number. The pipeline of the PowerShell object
        /// is run asynchronously and events are used to handle the output.
        /// </summary>
        /// <param name="args">This parameter is not used.</param>
        /// <remarks>
        /// This sample demonstrates the following:
        /// 1. Creating a PowerShell object.
        /// 2. Adding a script to the pipeline of the PowerShell object.
        /// 3. Using the BeginInvoke method to run the pipeline asynchronously.
        /// 4. Using the events of the PowerShell object to process the
        ///     output of the script.
        /// 5. Using the PowerShell.Stop() method to interrupt an executing
        pipeline.
        /// </remarks>
        private static void Main(string[] args)
        {
            Console.WriteLine("Print the numbers from 1 to 10. Hit any key to halt
processing\n");
        }
    }
}
```

```

        using (PowerShell powershell = PowerShell.Create())
    {
        // Add a script to the PowerShell object. The script generates the
        // numbers from 1 to 10 in half second intervals.
        powershell.AddScript("1..10 | foreach {$_ ; start-sleep -milli
500}");

        // Add the event handlers. If we did not care about hooking the
DataAdded
        // event, we would let BeginInvoke create the output stream for us.
        PSDataCollection<PSObject> output = new PSDataCollection<PSObject>

RunSpace10 Code Sample

Article • 09/17/2021

Here is the source code for the Runspace10 sample. This sample application adds a cmdlet to [System.Management.Automation.Runspaces.RunspaceConfiguration](#) and then uses the modified configuration information to create the runspace.

ⓘ Note

You can download the C# source file (runspace10.cs) by using the Windows Software Development Kit for Windows Vista and Microsoft .NET Framework 3.0 Runtime Components. For download instructions, see [How to Install Windows PowerShell and Download the Windows PowerShell SDK](#). The downloaded source files are available in the <PowerShell Samples> directory.

Code Sample

C#

```
namespace Microsoft.Samples.PowerShell.Runspaces
{
    using System;
    using System.Collections.Generic;
    using System.Collections.ObjectModel;
    using System.Diagnostics;
    using System.Management.Automation;
    using System.Management.Automation.Runspaces;
    using PowerShell = System.Management.Automation.PowerShell;

    #region GetProcCommand

    /// <summary>
    /// Class that implements the GetProcCommand.
    /// </summary>
    [Cmdlet(VerbsCommon.Get, "Proc")]
    public class GetProcCommand : Cmdlet
    {
        #region Cmdlet Overrides

        /// <summary>
        /// For each of the requested process names, retrieve and write
        /// the associated processes.
        /// </summary>
        protected override void ProcessRecord()
        {
            // Get the current processes.
```

```

        Process[] processes = Process.GetProcesses();

        // Write the processes to the pipeline making them available
        // to the next cmdlet. The second argument (true) tells the
        // system to enumerate the array, and send one process object
        // at a time to the pipeline.
        WriteObject(processes, true);
    }

    #endregion Overrides
} // End GetProcCommand class.

#endregion GetProcCommand

/// <summary>
/// This class contains the Main entry point for this host application.
/// </summary>
internal class Runspace10
{
    /// <summary>
    /// This sample shows how to add a cmdlet to an InitialSessionState
    object and then
    /// uses the modified InitialSessionState object when creating a

[Windows PowerShell Programmer's Guide](#)

[Windows PowerShell SDK](#)

Contributing to PowerShell documentation

Article • 03/30/2025

Thank you for your support of PowerShell!

The Contributor's Guide is a collection of articles that describe the tools and processes we use to create documentation at Microsoft. Some of these guides cover information common to any documentation set published to learn.microsoft.com. Other guides are specific to how we write documentation for PowerShell.

The common articles are available in our centralized [Contributor's Guide](#). The PowerShell-specific guides are available here.

Ways to contribute

There are two ways to contribute. Both contributions are valuable to us.

- [Filing issues](#) helps us identify problems and gaps in our documentation. Sometimes the issues are difficult to resolve, requiring more investigation and research. The issue process allows us to have a conversation about the problem and develop a satisfactory resolution.
- [Submitting a pull request](#) to add or change content is a more involved process. The following information outlines the tools, processes, and standards for submitting content to the documentation.

Prepare to make a contribution

Contributing to the documentation requires a GitHub account. Use the following checklist to install and configure the tools you need to make contributions.

1. [Sign up for GitHub](#)
2. [Install Git and Markdown tools](#)
3. [Install the Docs Authoring Pack](#)
4. [Install Posh-Git](#) ↗ - not required but recommended
5. [Set up a local Git repository](#)
6. [Review Git and GitHub fundamentals](#)

Get started writing docs

There are two ways to contribute changes to the documentation:

1. [Quick edits to existing docs](#) - Minor corrections, fixing typos, or small additions
2. [Full GitHub workflow for docs](#) - large changes, multiple versions, adding or changing images, or contributing new articles

Also, read the [Writing essentials](#) section of the centralized Contributor's Guide. Another excellent resource is the [Microsoft Writing Style Guide](#).

Minor corrections or clarifications to documentation and code examples in public repositories are covered by the [learn.microsoft.com Terms of Use](#).

Use the full GitHub workflow when you're making significant changes. If you're not an employee of Microsoft, our PR validation system adds a comment to the pull request asking you to sign the online [Contribution Licensing Agreement \(CLA\)](#). You must complete this step before we can review or accept your pull request. Signing the CLA is only required the first time you submit a PR in the repository. You might be asked to sign the CLA for each time you contribute to a new repository.

Code of conduct

All repositories that publish to Microsoft Learn adhere to the [Microsoft Open Source Code of Conduct](#) or the [.NET Foundation Code of Conduct](#). For more information, see the [Code of Conduct FAQ](#).

Next steps

The following articles cover information specific to PowerShell documentation. Where there's overlap with the guidance in the centralized Contributor's Guide, we call out how those rules differ for the PowerShell content.

Review the following documents:

- [Get started writing docs](#)
- [Markdown best practices](#)
- [PowerShell-Docs style guide](#)
- [How to file an issue](#)
- [Submitting a pull request](#)

Additional resources

- Editorial checklist
- How we manage issues
- How we manage pull requests

Get started contributing to PowerShell documentation

Article • 03/30/2025

This article is an overview of how to get started as a contributor to the PowerShell documentation.

PowerShell-Docs structure

There are three categories of content in the [PowerShell-Docs](#) repository:

- reference content
- conceptual content
- metadata and configuration files

Reference content

The reference content is the PowerShell cmdlet reference for the cmdlets that ship in PowerShell. The cmdlet [reference](#) is collected in versioned folders (like 5.1, 7.4, 7.5, and 7.6), which contain the reference for the modules that ship with PowerShell. This content is also used to create the help information displayed by the `Get-Help` cmdlet.

Conceptual content

The [conceptual documentation](#) isn't organized by version. All articles are displayed for every version of PowerShell.

 **Note**

Anytime a conceptual article is added, removed, or renamed, the TOC must be updated and deleted or renamed files must be redirected.

Metadata files

This project contains several types of metadata files. The metadata files control the behavior of our build tools and the publishing system. Only PowerShell-Docs maintainers and approved contributors are allowed to change these files. If you think that a meta file should be changed, open an issue to discuss the needed changes.

Meta files in the root of the repository

- `.*` - configuration files in the root of the repository
- `*.md` - Project documentation in the root of the repository
- `*.yml` - Project documentation in the root of the repository
- `.devcontainer/*` - devcontainer configuration files
- `.github/**/*` - GitHub templates, actions, and other meta files
- `.vscode/**/*` - VS Code extension configurations
- `assets/*` - contains downloadable files linked in the documentation
- `redir/*` - contain redirection mapping files
- `tests/*` - test tools used by the build system
- `tools/*` - other tools used by the build system

Meta files in the documentation set

- `reference/**/*.json` - docset configuration files
- `reference/**/*.yml` - TOC and other structured content files
- `reference/bread/*` - breadcrumb navigation configuration
- `reference/includes/*` - markdown include files
- `reference/mapping/*` - version mapping configuration
- `reference/**/media/**` - image files used in documentation
- `reference/module/*` - Module Browser page configuration

Creating new articles

A GitHub issue must be created for any new document you want to contribute. Check for existing issues to make sure you're not duplicating efforts. Assigned issues are considered to be `in progress`. If you wish to collaborate on an issue, contact the person assigned to the issue.

Similar to the PowerShell [RFC process](#), create an issue before you write the content. The issue ensures you don't waste time and effort on work that gets rejected by the PowerShell-Docs team. The issue allows us to consult with you on the scope of the content and where it fits in the PowerShell documentation. All articles must be included in the Table of Contents (TOC). The proposed TOC location should be included in the issue discussion.

Note

The publishing system autogenerates the TOC for reference content. You don't have to update the TOC.

Updating existing articles

Where applicable, cmdlet reference articles are duplicated across all versions of PowerShell maintained in this repository. When reporting an issue about a cmdlet reference or an `About_` article, list the versions of the article that have the problem.

Apply the appropriate change to each version of the file.

Localized content

The PowerShell documentation is written in English and translated into 17 other languages. The English content is stored in the GitHub repository named [MicrosoftDocs/PowerShell-Docs](#). Issues found in the translated content should be submitted to this repository.

All translations start from the English content first. We use both human and machine translation.

[+] Expand table

Translation method	Languages
Human translation	de-DE, es-ES, fr-FR, it-IT, ja-JP, ko-KR, pt-BR, ru-RU, zh-CN, zh-TW
Machine translation	cs-CZ, hu-HU, nl-NL, pl-PL, pt-PT, sv-SE, tr-TR

The content translated by machine translation might not always result in correct word choices and grammar. If you find an error in translation for any language, rather than in the technical details of the article, open an issue explaining why you think the translation is wrong.

Some translation issues can be fixed by changing the English source files. However, some issues can require updates to our internal translation system. For those cases, we must submit the issue to our internal localization team for review and response.

Next steps

There are two common ways of submitting changes in GitHub. Both methods are described in the central Contributor's Guide:

1. You can make [quick edits to existing documents](#) in the GitHub web interface.
2. Use the [full GitHub workflow](#) for adding new articles, updating multiple files, or other large changes.

Before starting any changes, you should create a fork of the PowerShell-Docs repository. The changes should be made in a working branch in your copy of the PowerShell-Docs. If you're using the [quick edit](#) method in GitHub, these steps are handled for you. If you're using the [full GitHub workflow](#), you must be set up to [work locally](#).

Both methods end with the creation of a Pull Request (PR). For more information and best practices, see [Submitting a pull request](#).

Contribute using GitHub Codespaces

Article • 03/30/2025

GitHub has a feature called [Codespaces](#) that you can use to contribute to the PowerShell documentation without having to install or configure any software locally. When you use a codespace, you get the same authoring tools the team uses for writing and editing.

You can use a codespace in your browser, making your contributions in VS Code hosted over the internet. If you have VS Code installed locally, you can connect to the codespace there too.

Available tools

When you use a codespace to contribute to the PowerShell documentation, your editor has these tools already available for you:

- [Markdownlint](#) for checking your Markdown syntax.
- [cSpell](#) for checking your spelling.
- [Vale](#) for checking your prose.
- The [Learn Authoring Pack](#) for inserting platform-specific syntax, previewing your contribution, and more.
- The [Reflow Markdown](#) extension for wrapping your Markdown as needed, making reading and editing easier.
- The [Table Formatter](#) extension for making your tables more readable without having to manually align columns.
- The [change-case](#) extension for converting the casing of your headings and prose.
- The [GitLens](#) extension for reviewing historical file changes.
- The [PowerShell](#) extension for interacting with PowerShell examples.
- The [Gremlins tracker for Visual Studio Code](#) for finding problematic characters in your Markdown.

Cost

GitHub Codespaces can be used for free up to 120 core-hours per month. The monthly usage is calculated across all your repositories, not just documentation.

For more information about pricing, see [About billing for GitHub Codespaces](#).

💡 Tip

If you're comfortable using containers and Docker, you can get the same experience by using the devcontainer defined for the PowerShell documentation repositories. There's no cost associated with using devcontainers. For more information, see the [Dev Containers tutorial](#).

Creating your GitHub Codespace

To create your GitHub Codespace for contributing to PowerShell documentation, follow these steps:

1. Open <https://github.com/codespaces> in your browser.
2. Select the "New codespace" button in the top right of the page.
3. In the "Create a new codespace" page, select the "Select a repository" button and type the name of the repository you want to contribute to, like `MicrosoftDocs/PowerShell-Docs`.
4. Leave all other settings as their default.
5. Select the "Create codespace" button.

After following these steps, GitHub creates a new codespace for that repository and sets it up for you. When the codespace is ready, the page refreshes and shows the web editor UI for the codespace. The UI is based on VS Code and works the same way.

Opening your GitHub Codespace

To open your GitHub Codespace in the browser, follow these steps:

1. Open <https://github.com/codespaces> in your browser.
2. The page lists your Codespaces. Find the created codespace for the repository you want to contribute to and select it.

After you select your codespace, GitHub opens it in the same window. From here, you're ready to contribute.

To open your GitHub Codespace in VS Code, follow the steps in [Using GitHub Codespaces in Visual Studio Code](#).

Authoring in your GitHub Codespace

Once you have your GitHub Codespace open in your browser or VS Code, contributing to the documentation follows the same process.

The rest of this article describes a selection of tasks you can do in your GitHub Codespace while writing or editing your contribution.

Extract a reference link

When you want to turn an inline link, like `[some text](destination.md)`, into a reference link like `[some text][01]`, select the link destination in the editor. Then you can either:

1. Right-click on the link destination and select "Refactor..." in the context menu.
2. Press `Ctrl + Shift + R`.

Either action raises the refactoring context menu. To replace the `(destination.md)` in the link with `[def]`, select **Extract to link definition** in the context menu. You can rename the definition by typing a name in.

For the PowerShell documentation, we use two-digit numerical reference link definitions, like `[01]` or `[31]`. Only use reference link definitions in about articles and conceptual documentation. Don't use reference link definitions in cmdlet reference documentation.

Fix prose style violations

When you review an article in your codespace, Vale automatically checks the article when you first open it and every time you save it. If Vale finds any style violations, it highlights them in the document with colored squiggles.

Hover over a violation to see more information about it.

To open a web page that explains the rule, select the rule's name in the hover information. To open the rule and review its implementation, select the rule's filename (ending in `.yml`).

If the rule supports a quick fix, you can select "Quick Fix..." in the hover information for the violation and apply one of the suggested fixes by selecting it from the context menu. You can also press `ctrl + .` when your cursor is on a highlighted problem to apply a quick fix if the rule supports it.

If the rule doesn't support quick fixes, read the rule's message and fix it if you can. If you're not sure how to fix it, the editors can make a suggestion when reviewing your PR.

Fix syntax problems

When you review an article in your codespace, Markdownlint automatically checks the article when you open it and as you type. If Markdownlint finds any syntax problems, it highlights them in the document with colored squiggles.

Hover over a violation to see more information about it. To open a web page that explains the rule, select the rule's ID in the hover information.

If the rule supports a quick fix, you can select "Quick Fix..." in the hover information for the violation and apply one of the suggested fixes by selecting it from the context menu. You can also press `ctrl + .` when your cursor is on a highlighted problem to apply a quick fix if the rule supports it.

If the rule doesn't support quick fixes, read the rule's message and fix it if you can. If you're not sure how to fix it, the editors can make a suggestion when reviewing your PR.

You can also apply fixes to all syntax violations in an article. To do so, open the command palette and type `Fix all supported markdownlint violations in the document`. As you type, the command palette filters the available commands. Select the "Fix all supported markdownlint violations in the document" command. When you do, Markdownlint updates the document to resolve any violations it has a quick fix for.

Format a table

To format a Markdown table, place your cursor in or on the table in your Markdown. Open the Command Palette and search for the `Table: Format Current` command. When you select that command, it updates the Markdown for your table to align and pad the table for improved readability.

It converts a table defined like this:

```
markdown
| foo | bar | baz |
|---|---|-|
| a | b | c |
```

Into this:

```
markdown
|   foo   |   bar   |   baz   |
| :---: | :---: | ---: |
|     a   |     b   |       c |
```

Insert an alert

The documentation uses [alerts](#) to make information more notable to a reader.

To insert an alert, you can, open the Command Palette and search for the [Learn: Alert](#) command. When you select that command, it opens a context menu. Select the alert type you want to add. When you do, the command inserts the alert's Markdown at your cursor in the document.

Make a heading use sentence casing

To convert a heading's casing, highlight the heading's text except for the leading `#` symbols, which set the heading level. When you have the text highlighted, open the Command Palette and search for the [Change case sentence](#) command. When you select that command, it converts the casing of the highlighted text.

You can also use the casing commands for any text in the document.

Open the Command Palette

You can use VS Code's [Command Palette](#) to run many helpful commands.

To open the Command Palette in the UI, select "View" in the top menu bar. Then select "Command Palette..." in the context menu.

To open the Command Palette with your keyboard, press the key combination for your operating system:

- Windows and Linux: `Ctrl + Shift + P`
- macOS: `Cmd + Shift + P`

Preview your contribution

To preview your contribution, open the Command Palette and search for the [Markdown: Open Preview](#) command. When you select that command, VS Code opens a preview of the active document. The preview's style matches the Learn platform.

Note

Site-relative and cross-reference links don't work in the preview.

Reflow your content

To limit the line lengths for a paragraph in a document, place your cursor on the paragraph. Then open the Command Palette and search for the `Reflow Markdown` command. When you select the command, it updates the current paragraph's line lengths to the configured length. For our repositories, that length is 99 characters.

When using this command for block quotes, make sure the paragraph in the block quote you're reflowing is surrounded by blank lines. Otherwise, the command reflows every paragraph together.

✖ Caution

Don't use this command when editing about articles. The lines in those documents must not be longer than 80 characters. There's currently no way for a repository to configure different line lengths by folder or filename, so reflow doesn't work for about article documents.

Review all problems in a document

To review all syntax and style rule violations in a document, open the Problems View.

To open the Problems View in the UI, select "View" in the top menu bar. Then select "Problems" in the context menu.

To open the Problems View with your keyboard, press the key combination for your operating system:

- Windows and Linux: `Ctrl + Shift + M`
- macOS: `Cmd + Shift + M`

The Problems View displays all errors, warnings, and suggestions for the open document. Select a problem to scroll to it in the document.

You can filter the problems by type or text matching.

Updating the `ms.date` metadata

To update the `ms.date` metadata for an article, open the Command Palette and search for the `Learn: Update "ms.date" Metadata Value` command. When you select the command, it updates the metadata to the current date.

Additional resources

The tasks and commands described in this article don't cover everything you can do with VS Code or the installed extensions.

For more information on using VS Code, see these articles:

Markdown best practices

Article • 04/29/2025

This article provides specific guidance for using Markdown in our documentation. It isn't a tutorial for Markdown. If you need a tutorial for Markdown, see this [Markdown cheatsheet](#).

The build pipeline that builds our documentation uses [markdig](#) to process the Markdown documents. Markdig parses the documents based on the rules of the latest [CommonMark](#) specification. OPS follows the CommonMark specification and adds some extensions for platform-specific features, such as tables and alerts.

The CommonMark specification is stricter about the construction of some Markdown elements. Pay close attention to the details provided in this document.

We use the [markdownlint](#) extension in VS Code to enforce our style and formatting rules. This extension is installed as part of the [Learn Authoring Pack](#).

Blank lines, spaces, and tabs

Blank lines also signal the end of a block in Markdown.

- Put a single blank between Markdown blocks of different types; for example, between a paragraph and a list or header.
- Don't use more than one blank line. Multiple blank lines render as a single blank line in HTML, therefore the extra blank lines are unnecessary.
- Don't use put multiple consecutive blank lines in a code block, consecutive blank lines break the code block.

Spacing is significant in Markdown.

- Remove extra spaces at the end of lines. Trailing spaces can change how Markdown renders.
- Always use spaces instead of tabs (hard tabs).

Titles and headings

Use [ATX headings](#) only (# style, as opposed to = or - style headers).

- Use sentence case - only proper nouns and the first letter of a title or header should be capitalized
- Include a single space between the # and the first letter of the heading
- Surround headings with single blank line

- Don't use more than one H1 per document
 - It should be the first header
 - It should match the title of the article
- Increment header levels by one - don't skip levels
- Limit depth to H3 or H4
- Avoid using bold or other markup in headers

Limit line length to 100 characters

For conceptual articles and cmdlet reference, limit lines to 100 characters. For `about_` articles, limit the line length to 79 characters. Limiting the line length improves the readability of `git` diffs and history. It also makes it easier for other writers to make contributions.

Use the [Reflow Markdown](#) extension in VS Code to reflow paragraphs to fit the prescribed line length.

Some content types can't be easily reflowed. For example, the code inside of code blocks can also be difficult to reflow, depending on the content and the code language. You can't reflow a table. In these cases, use your best judgment to keep the content as close to the 100-character limit as possible.

Emphasis

For emphasis, Markdown supports bold and italics. Markdown allows you to use either `*` or `_` to mark the emphasis. However, to be consistent and show intent:

- Use `**` for bold
- Use `_` for italics

Following this pattern makes it easier for others to understand the intent of the markup when there's a mix of bold and italics in a document.

Lists

If your list has multiple sentences or paragraphs, consider using a sublevel header rather than a list.

Surround lists with a single blank line.

Unordered lists

- Don't end list items with a period unless they contain multiple sentences.
- Use the hyphen character (-) for list item bullets to avoid confusion with emphasis markup that uses the asterisk (*).
- To include a paragraph or other elements under a bullet item, insert a line break and align indentation with the first character after the bullet.

For example:

Markdown

This is a list that contains child elements under a bullet item.

- First bullet item
 - Sentence explaining the first bullet.
 - Child bullet item
 - Sentence explaining the child bullet.
 - Second bullet item
 - Third bullet item

This is a list that contains child elements under a bullet item.

- First bullet item
 - Sentence explaining the first bullet.
 - Child bullet item
 - Sentence explaining the child bullet.
 - Second bullet item
 - Third bullet item

Ordered lists

- All items in a numbered list should use the number 1 rather than incrementing each item.
 - Markdown rendering increments the value automatically.
 - This makes reordering items easier and standardizes the indentation of subordinate content.
- To include a paragraph or other elements under a numbered item, align indentation with the first character after the item number.

For example:

Markdown

1. For the first element, insert a single space after the `1`. Long sentences should be wrapped to the next line and must line up with the first character after the numbered list marker.

To include a second element, insert a line break after the first and align indentations. The indentation of the second element must line up with the first character after the numbered list marker.

1. The next numbered item starts here.

The resulting Markdown is rendered as follows:

1. For the first element, insert a single space after the `1`. Long sentences should be wrapped to the next line and must line up with the first character after the numbered list marker.

To include a second element, insert a line break after the first and align indentations. The indentation of the second element must line up with the first character after the numbered list marker.
2. The next numbered item starts here.

Images

The syntax to include an image is:

Markdown

```
![alt text](<code>folderPath</code>)
```

Example:

```
![Introduction](<code>./media/overview/Introduction.png</code>)
```

Where `alt text` is a brief description of the image and `<FolderPath>` is a relative path to the image.

- Alternate text is required to support screen readers for the visually impaired.
- Images should be stored in a `media/<article-name>` folder within the folder containing the article.

- Create a folder that matches the filename of your article under the `media` folder. Copy the images for that article to that new folder.
- Don't share images between articles.
 - If an image is used by multiple articles, each folder must have a copy of that image.
 - This prevents a change to an image in one article from affecting another article.

The following image file types are supported: `*.png`, `*.gif`, `*.jpeg`, `*.jpg`, `*.svg`

Markdown extension - Alert boxes

The [Learn Authoring Pack](#) contains tools that support features unique to our publishing system. Alerts are a Markdown extension to create blockquotes that render with colors and icons highlighting the significance of the content. The following alert types are supported:

Markdown

```
> [!NOTE]
> Information the user should notice even if skimming.

> [!TIP]
> Optional information to help a user be more successful.

> [!IMPORTANT]
> Essential information required for user success.

> [!CAUTION]
> Negative potential consequences of an action.

> [!WARNING]
> Dangerous certain consequences of an action.
```

These alerts look like this on Microsoft Learn:

Note block

!Note

Information the user should notice even if skimming.

Tip block

💡Tip

Optional information to help a user be more successful.

Important block

Important

Essential information required for user success.

Caution block

Caution

Negative potential consequences of an action.

Warning block

Warning

Dangerous certain consequences of an action.

Markdown extension - Tables

A table is an arrangement of data with rows and columns consisting of:

- A single header row
- A delimiter row separating the header from the data
- Zero or more data rows

Each row consists of cells containing arbitrary text separated by pipes (`|`). A leading and trailing pipe is also recommended for clarity. Spaces between pipes and cell content are trimmed. Block-level elements can't be inserted in a table. All content of a row must be on a single line.

The delimiter row consists of cells whose only content are hyphens (`-`), and optionally, a leading or trailing colon (`:`), or both, to indicate left, right, or center alignment respectively.

For small tables, consider using a list instead. Lists are:

- Easier to maintain and read
- Can be reflowed to fit within the 100-character line limit
- More accessible for users that use screen readers for visual assistance

For more information, see *Tables* section of [Markdown reference for Microsoft Learn](#).

Hyperlinks

- Hyperlinks must use Markdown syntax `[friendlyname](url-or-path)`.
- The publishing system supports three types of links:
 - URL links
 - File links
 - Cross-reference links
- All URLs to external websites should use HTTPS unless that isn't valid for the target site.
- Links must have a friendly name, usually the title of the linked article
- Avoid using backticks, bold, or other markup inside the brackets of a hyperlink.
- Bare URLs can be used when you're documenting a specific URI but must be enclosed in backticks. For example:

Markdown

```
By default, if you don't specify this parameter, the DMTF standard resource
URI
`http://schemas.dmtf.org/wbem/wscim/1/cim-schema/2/` is used and the class
name is appended to it.
```

- Use [link references](#) where allowed. Link references within paragraphs make the paragraphs more readable.

Link references divide a Markdown link into two parts:

- the link reference - `[friendlyname][id]`
- the link definition - `[id]: url-or-path`

URL-type Links

- URL links to other articles on `learn.microsoft.com` must use site-relative paths. The simplest way to create a site-relative link is to copy the URL from your browser then remove `https://learn.microsoft.com/en-us` from the value you paste into markdown.
- Don't include locales in URLs on Microsoft properties (remove `/en-us` from URL) or Wikipedia links.
- Remove any unnecessary query parameters from the URL. Examples that should be removed:
 - `?view=powershell-5.1` - used to link to a specific version of PowerShell

- `?redirectedfrom=MSDN` - added to the URL when you get redirected from an old article to its new location
- If you need to link to a specific version of a document, you must add the `&preserve-view=true` parameter to the query string. For example: `?view=powershell-5.1&preserve-view=true`
- On Microsoft sites, URL links don't contain file extensions (for example, no `.md`)

File-type links

- A file link is used to link from one reference article to another, or from one conceptual article to another in the same docset.
 - If you need to link from a conceptual article to a reference article you must use a URL link.
 - If you need to link to an article in another docset or across repositories you must use a URL link.
- Use relative filepaths (for example: `../folder/file.md`)
- All file paths use forward-slash (`/`) characters
- Include the file extension (for example, `.md`)

Cross-reference links

Cross-reference links are a special feature supported by the publishing system. You can use cross-reference links in conceptual articles to link to .NET API or cmdlet reference.

- For links to .NET API reference, see [Use links in documentation](#) in the central Contributor Guide.
- Links to cmdlet reference have the following format: `xref:<module-name>.<cmdlet-name>`. For example, to link to the `Get-Content` cmdlet in the `Microsoft.PowerShell.Management` module.

`[Get-Content](xref:Microsoft.PowerShell.Management.Get-Content)`

Deep linking

Deep linking is allowed on both URL and file links.

- The anchor text must be lowercase
- Add the anchor to the end of the target path. For example:
 - `[about_Splatting](about_Splatting.md#splatting-with-arrays)`

- [custom key bindings]
(https://code.visualstudio.com/docs/getstarted/keybindings#_custom-keybindings-for-refactorings)

For more information, see [Use links in documentation](#).

Code spans

Code spans are used for inline code snippets within a paragraph. Use single backticks to indicate a code span. For example:

Markdown

```
PowerShell cmdlet names use the `Verb-Noun` naming convention.
```

This example renders as:

PowerShell cmdlet names use the `Verb-Noun` naming convention.

Code blocks

Code blocks are used for command examples, multi-line code samples, query languages, and outputs. There are two ways to indicate a section of text in an article file is a code block: by fencing it in triple-backticks (```) or by indenting it.

Never use indentation because it's too easy to get wrong and it may be difficult for another writer to understand your intent when they need to edit your article.

Fenced code blocks can include an optional tag that indicates the language syntax contained in the block. The publishing platform supports a list of [language tags](#). The language tag is used to provide syntax highlighting when the article is rendered on the webpage. The language tag is not case-sensitive, but you should use lowercase except for a few special cases.

- Code fences without tags can be used for syntax blocks or other types of content where syntax highlighting is not required.
- When showing output from a command, use a tagged code fence with the language tag `Output`. The rendered box is labeled as **Output** and doesn't have syntax highlighting.
- If the output is in a specific supported language, use the appropriate language tag. For example, many commands output JSON, so use the `json` tag.
- If you use an unsupported language tag, the code block will render without syntax highlighting. The language tag becomes the label for the rendered code box on the webpage. Capitalize the tag so that the label is capitalized on the webpage.

Next steps

[PowerShell style guide](#)

PowerShell-Docs style guide

Article • 03/30/2025

This article provides style guidance specific to the PowerShell-Docs content. It builds on the information outlined in the [Overview](#).

Formatting command syntax elements

Use the following rules to format elements of the PowerShell language when the elements are used in a sentence.

- Always use the full name for cmdlets and parameters in the proper Pascal case
- Only use an alias when you're specifically demonstrating the alias
- PowerShell keywords and operators should be all lowercase
- The following items should be formatted using **bold** text:
 - Type names
 - Class names
 - Property names
 - Parameter names
 - By default, use the parameter without the hyphen prefix.
 - Use parameter name with the hyphen if you're illustrating syntax. Wrap the parameter in backticks.

For example:

markdown

```
The parameter's name is **Name**, but it's typed as ` -Name` when used on  
the command  
line as a parameter.
```

- The following items should be formatted using backticks (`):
 - Property and parameter values
 - Type names that use the bracketed style - For example: [System.Io.FileInfo]

- o Referring to characters by name. For example: Use the asterisk character (*) to as a wildcard.
- o Language keywords and operators
- o Cmdlet, function, and script names
- o Command and parameter aliases
- o Method names - For example: The `Tostring()` method returns a string representation of the object
- o Variables
- o Native commands
- o File and directory paths
- o Inline command syntax examples - See [Markdown for code samples](#)

This example shows some backtick examples:

markdown

The following code uses `Get-ChildItem` to list the contents of `C:\Windows` and assigns the output to the `\$files` variable.

```
```powershell
$files = Get-ChildItem C:\Windows
```
```

This example shows command syntax inline:

markdown

To start the spooler service on a remote computer named DC01, you type:
`sc.exe \\DC01 start spooler`.

Including the file extension ensures that the correct command is executed according to PowerShell's command precedence.

Markdown for code samples

Markdown supports two different code styles:

- **Code spans (inline)** - marked by a single backtick (`) character. Used within a paragraph rather than as a standalone block.
- **Code blocks** - a multi-line block surrounded by triple-backtick (``` strings. Code blocks can also have a language label following the backticks. The language label enables syntax highlighting for the contents of the code block.

All code blocks should be contained in a code fence. Never use indentation for code blocks. Markdown allows this pattern but it can be problematic and should be avoided.

A code block is one or more lines of code surrounded by a triple-backtick (``` code fence. The code fence markers must be on their own line before and after the code sample. The opening marker can have an optional language label. The language label enables syntax highlighting on the rendered webpage.

For a full list of supported language tags, see [Fenced code blocks](#) in the centralized contributor guide.

Publishing also adds a **Copy** button that can copy the contents of the code block to the clipboard. This allows you to paste the code into a script to test the code sample. However, not all examples are intended to be run as written. Some code blocks are basic illustrations of PowerShell concepts.

There are three types code blocks used in our documentation:

1. Syntax blocks
2. Illustrative examples
3. Executable examples

Syntax code blocks

Syntax code blocks are used to describe the syntactic structure of a command. Don't use a language tag on the code fence. This example illustrates all the possible parameters of the `Get-Command` cmdlet.

markdown

```
```
Get-Command [-Verb <String[]>] [-Noun <String[]>] [-Module <String[]>]
 [-FullyQualifiedModule <ModuleSpecification[]>] [-TotalCount <Int32>] [-Syntax]
 [-ShowCommandInfo] [[-ArgumentList] <Object[]>] [-All] [-ListImported]
 [-ParameterName <String[]>] [-ParameterType <PSTypeName[]>] [<CommonParameters>]
````
```

This example describes the `for` statement in generalized terms:

```
markdown
```

```
```  
for (<init>; <condition>; <repeat>)
{<statement list>}
```
```

Illustrative examples

Illustrative examples are used to explain a PowerShell concept. You should [Avoid using PowerShell prompts in examples](#) whenever possible. However, illustrative examples aren't meant to be copied and pasted for execution. They're most commonly used for simple examples that are easy to understand. You may include the PowerShell prompt and example output.

Here's a simple example illustrating the PowerShell comparison operators. In this case, we don't intend the reader to copy and run this example. Notice that this example uses `PS>` as a simplified prompt string.

```
markdown
```

```
```powershell  
PS> 2 -eq 2
True

PS> 2 -eq 3
False

PS> 1,2,3 -eq 2
2

PS> "abc" -eq "abc"
True

PS> "abc" -eq "abc", "def"
False

PS> "abc", "def" -eq "abc"
abc
```
```

Executable examples

Complex examples, or examples that are intended to be copied and executed, should use the following block-style markup:

markdown

```
```powershell
<Your PowerShell code goes here>
```
```

The output displayed by PowerShell commands should be enclosed in an **Output** code block to prevent syntax highlighting. For example:

markdown

```
```powershell
Get-Command -Module Microsoft.PowerShell.Security
```

```Output
CommandType Name Version Source
----- ----
Cmdlet ConvertFrom-SecureString 3.0.0.0 Microsoft.PowerShell.Security
Cmdlet ConvertTo-SecureString 3.0.0.0 Microsoft.PowerShell.Security
Cmdlet Get-Acl 3.0.0.0 Microsoft.PowerShell.Security
Cmdlet Get-AuthenticodeSignature 3.0.0.0 Microsoft.PowerShell.Security
Cmdlet Get-CmsMessage 3.0.0.0 Microsoft.PowerShell.Security
Cmdlet Get-Credential 3.0.0.0 Microsoft.PowerShell.Security
Cmdlet Get-ExecutionPolicy 3.0.0.0 Microsoft.PowerShell.Security
Cmdlet Get-PfxCertificate 3.0.0.0 Microsoft.PowerShell.Security
Cmdlet New-FileCatalog 3.0.0.0 Microsoft.PowerShell.Security
Cmdlet Protect-CmsMessage 3.0.0.0 Microsoft.PowerShell.Security
Cmdlet Set-Acl 3.0.0.0 Microsoft.PowerShell.Security
Cmdlet Set-AuthenticodeSignature 3.0.0.0 Microsoft.PowerShell.Security
Cmdlet Set-ExecutionPolicy 3.0.0.0 Microsoft.PowerShell.Security
Cmdlet Test-FileCatalog 3.0.0.0 Microsoft.PowerShell.Security
Cmdlet Unprotect-CmsMessage 3.0.0.0 Microsoft.PowerShell.Security
```
```

```

The **Output** code label isn't an official *language* supported by the syntax highlighting system. However, this label is useful because our publishing system adds the **Output** label to the code box frame on the web page. The **Output** code box has no syntax highlighting.

## Coding style rules

### Avoid line continuation in code samples

Avoid using line continuation characters (`) in PowerShell code examples. Backtick characters are difficult to see and can cause problems if there are extra spaces at the end of the line.

- Use PowerShell [splatting](#) to reduce line length for cmdlets that have several parameters.

- Take advantage of PowerShell's natural line break opportunities, like after pipe ( | ) characters, opening braces ( { ), parentheses ( ( ), and brackets ( [ ).

## Avoid using PowerShell prompts in examples

Use of the prompt string is discouraged and should be limited to scenarios that are meant to illustrate command-line usage. For most of these examples, the prompt string should be PS>. This prompt is independent of OS-specific indicators.

Prompts are required in examples to illustrate commands that alter the prompt or when the path displayed is significant to the scenario. The following example illustrates how the prompt changes when using the Registry provider.

```
PowerShell

PS C:\> cd HKCU:\System\
PS HKCU:\System\> dir

 Hive: HKEY_CURRENT_USER\System

Name Property
---- -----
CurrentControlSet
GameConfigStore GameDVR_Enabled : 1
 GameDVR_FSEBehaviorMode : 2
 Win32_AutoGameModeDefaultProfile : {2, 0, 1, 0...}
 Win32_GameModeRelatedProcesses : {1, 0, 1, 0...}
 GameDVR_HonorUserFSEBehaviorMode : 0
 GameDVR_DXGIIHonorFSEWindowsCompatible : 0
```

## Don't use aliases in examples

Use the full name of all cmdlets and parameters unless you're specifically documenting the alias. Cmdlet and parameter names must use the proper [Pascal-cased](#) names.

## Using parameters in examples

Avoid using positional parameters. To reduce the chance of confusion, you should include the parameter name in an example, even if the parameter is positional.

## Formatting cmdlet reference articles

Cmdlet reference articles have a specific structure. [PlatyPS](#) defines this structure. PlatyPS generates the cmdlet help for PowerShell modules in Markdown. After you edit the Markdown files, PlatyPS can create the MAML help files used by the `Get-Help` cmdlet.

PlatyPS has a schema that expects a specific structure for cmdlet reference. The PlatyPS [schema document](#) describes this structure. Schema violations cause build errors that must be fixed before we can accept your contribution.

- Don't remove any of the ATX header structures. PlatyPS expects a specific set of headers in a specific order.
- The H2 **INPUTS** and **OUTPUTS** headers must have an H3 type. If the cmdlet doesn't take input or return a value, then use the value `None` for the H3.
- Inline code spans can be used in any paragraph.
- Fenced code blocks are only allowed in the **EXAMPLES** section.

In the PlatyPS schema, **EXAMPLES** is an H2 header. Each example is an H3 header. Within an example, the schema doesn't allow code blocks to be separated by paragraphs. The schema only allows the following structure:

```
Example X - Title sentence

0 or more paragraphs
1 or more code blocks
0 or more paragraphs.
```

Number each example and add a brief title.

For example:

```
markdown

Example 1: Get cmdlets, functions, and aliases

This command gets the PowerShell cmdlets, functions, and aliases that are
installed on the
computer.

```powershell
Get-Command
```

Example 2: Get commands in the current session

```powershell
```

```
Get-Command -ListImported  
...
```

Formatting About_ files

About_* files are written in Markdown but are shipped as plain text files. We use [Pandoc](#) to convert the Markdown to plain text. About_* files are formatted for the best compatibility across all versions of PowerShell and with the publishing tools.

Basic formatting guidelines:

- Limit paragraph lines to 80 characters
- Limit code blocks to 76 characters
- Limit blockquotes and alerts to 78 characters
- When using these special meta-characters \, \$, and <:
 - Within a header, these characters must be escaped using a leading \ character or enclosed in code spans using backticks (`)
 - Within a paragraph, these characters should be put into code spans. For example:

```
markdown  
  
### The purpose of the \$foo variable  
  
The `\$foo` variable is used to store ...
```

- Markdown tables
 - For About_* articles, tables must fit within 76 characters
 - If the content doesn't fit within 76 character limit, use bullet lists instead
 - Use opening and closing | characters on each line

Next steps

[Editorial checklist](#)

Editor's checklist

Article • 03/30/2025

This article contains a summarized list of rules for writing or editing PowerShell documentation. See other articles in the Contributor's Guide for detailed explanations and examples of these rules.

Metadata

- `ms.date`: must be in the format MM/DD/YYYY
 - Change the date when there's a significant or factual update
 - Reorganizing the article
 - Fixing factual errors
 - Adding new information
 - Don't change the date if the update is insignificant
 - Fixing typos and formatting
- `title`: unique string of 43-59 characters long (including spaces)
 - Don't include site identifier (it's autogenerated)
 - Use sentence case - capitalize only the first word and any proper nouns
- `description`: 115-145 characters including spaces - this abstract displays in the search result

Formatting

- Backtick syntax elements that appear, inline, within a paragraph
 - Cmdlet names `Verb-Noun`
 - Variable `$counter`
 - Syntactic examples `Verb-Noun -Parameter`
 - File paths `C:\Program Files\PowerShell`, `/usr/bin/pwsh`
 - URLs that aren't meant to be clickable in the document
 - Property or parameter values
- Use bold for property names, parameter names, class names, module names, entity names, object, or type names
 - Bold is used for semantic markup, not emphasis
 - Bold - use asterisks `**`
- Italic - use underscore `_`
 - Only used for emphasis, not for semantic markup
- Line breaks at 100 columns (or at 80 for `about_Topic`)
- No hard tabs - use spaces only

- No trailing spaces on lines
- PowerShell keywords and operators should be all lowercase
- Use proper (Pascal) casing for cmdlet names and parameters

Headers

- Start with H1 first - only one H1 per article
- Use [ATX Headers](#) only
- Use sentence case for all headers
- Don't skip levels - no H3 without an H2
- Limit header depth to H3 or H4
- Add blank lines before and after
- Don't add or remove headers - PlatyPS enforces specific headers in its schema

Code blocks

- Add blank lines before and after
- Use tagged code fences - **powershell**, **Output**, or other appropriate language ID
- Use untagged code fence for syntax blocks
- Put output in separate code block except for basic examples where you don't intend for the reader to use the **Copy** button
- See list of [supported languages](#)

Lists

- Indent properly
- Add blank lines before first item and after last item
- Use hyphen (-) for bullets not asterisk (*) to reduce confusion with emphasis
- Use 1. for all items in a numbered list

Terminology

- Use *PowerShell* vs. *Windows PowerShell*
- See [Product Terminology](#)

Cmdlet reference examples

- Must have at least one example in cmdlet reference
- Examples should be only enough code to demonstrate the usage

- PowerShell syntax
 - Use full names of cmdlets and parameters - no aliases
 - Use splatting for parameters when the command line gets too long
 - Avoid using line continuation backticks - only use when necessary
- Remove or simplify the PowerShell prompt (`PS>`) except where required for the example
- Cmdlet reference example must follow the following PlatyPS schema

markdown

```
### Example 1 - Descriptive title

Zero or more short descriptive paragraphs explaining the context of the
example followed by one or
more code blocks. Recommend at least one and no more than two.

```powershell
... one or more PowerShell code statements ...
```

```Output
Example output of the code above.
```

Zero or more optional follow up paragraphs that explain the details of the
code and output.
```

- don't put paragraphs between the code blocks. All descriptive content must come before or after the code blocks.

Linking to other documents

- When linking outside the docset or between cmdlet reference and conceptual
 - Use site-relative URLs when linking to Microsoft Learn (remove `https://learn.microsoft.com/en-us`)
 - don't include locales in URLs on Microsoft properties (remove `/en-us` from URL)
 - All URLs to external websites should use HTTPS unless that's not valid for the target site
- When linking within the docset
 - Use the relative filepath (`../folder/file.md`)
- All paths use forward-slash (/) characters
- Image links should have unique alt text

Product terminology and branding guidelines

Article • 03/30/2025

When you write about any product, it's important to use the proper product names and terminology. This guide defines product names and terminology related to PowerShell. Note the capitalization of specific words or use cases.

PowerShell (collective name)

Use **PowerShell** to describe the scripting language and an interactive shell.

PowerShell (product name)

The cross-platform version of PowerShell built on .NET (core), rather than the .NET Framework. PowerShell can be installed on Windows, Linux, and macOS.

PowerShell Core (product deprecated)

The name used for PowerShell v6, built on .NET Core. This name shouldn't be used.

Windows PowerShell (product name)

The version of PowerShell that ships in Windows, which requires the full .NET Framework.

Guidelines

- First mention - use "Windows PowerShell"
- Subsequent mentions - Use "PowerShell" unless the use case requires "Windows PowerShell" to be more specific:

In PowerShell, the `Invoke-WebRequest` cmdlet returns
`BasicHtmlWebResponseObject`

In Windows PowerShell, the `Invoke-WebRequest` cmdlet returns
`HtmlWebResponseObject`

PowerShell modules

PowerShell modules are add-ons that contain PowerShell cmdlets to manage specific products or services.

For example:

- Azure PowerShell
- Az.Accounts module
- Windows management module
- Hyper-V module
- Microsoft Graph PowerShell SDK
- Exchange PowerShell

Guidelines

- Always use the collective name or the more specific module name when referring to a PowerShell module
- Never refer to a module as "PowerShell"

Azure PowerShell (collective name)

The branded group of products containing PowerShell modules used to manage Azure.

There are several versions of Azure PowerShell products available. Each product contains multiple named modules.

Guidelines

- Use "Azure PowerShell" as the collective name for the product
- Always use the collective name, never just "PowerShell"
- Use the more specific product name when referring to a specific version

Az PowerShell (product name)

The currently supported collection of modules for managing Azure resources with PowerShell.

AzureRM PowerShell (product name)

The previous generation of modules that use the Azure Resource Manager (ARM) model for managing Azure resources. This product is deprecated, no longer maintained or supported, and not recommended.

Azure Service Management PowerShell (product name)

The earliest collection of modules for managing legacy Azure resources that use Azure Service Manager (ASM) APIs. This legacy PowerShell module isn't recommended when creating new resources since ASM is scheduled for retirement.

Azure-related PowerShell modules

These products are used to manage Azure resources but aren't part of the Azure PowerShell collective product. They should never be described using the "Azure PowerShell" collective name.

- Azure Information Protection PowerShell
- Azure Deployment Manager PowerShell
- Azure Elastic Database Jobs PowerShell
- Azure Service Fabric PowerShell
- Azure Stack PowerShell
- Microsoft Graph PowerShell SDK
- Microsoft Entra PowerShell

Guidelines

- Always use the full proper name of the product or the specific PowerShell module name

Other PowerShell-related products

Visual Studio Code (VS Code)

This is Microsoft's free, open source editor.

Guidelines

- First mention - use the full name
- Subsequent mentions - you can use "VS Code"
- Never use "VSCode"

PowerShell Extension for Visual Studio Code

The extension turns VS Code into the preferred IDE for PowerShell.

Guidelines

- First mention - use the full name
- Subsequent mentions - you can use "PowerShell extension"

How to file a PowerShell-Docs issue

Article • 03/30/2025

There are two ways to create an issue:

1. Use the feedback controls at the bottom of the page.
2. File an issue in GitHub directly

Using the feedback controls

For a full description of the feedback controls, see the Docs Team blog announcing this [feature](#).

At the bottom of most pages on `learn.microsoft.com`, there are two feedback buttons. One is a link for product feedback and one is for documentation feedback. The documentation feedback requires a GitHub account. Clicking the button takes you in GitHub and presents an issue template. Enter your feedback and submit the form.

Note

The feedback tool not a support channel. It's a way to ask questions to clarify documentation or to report errors and omissions. If you need technical support, see [Community resources](#).

Filing issues on GitHub

To file a GitHub issue directly, you can select the [New issue ↗](#) button in the PowerShell-Docs repository. Select the **Get started** button for the issue you want to create. The GitHub issue template helps you provide the information needed to address the problem you're reporting.

To avoid duplication, search the existing issues to see if someone else has already reported it. If you find an existing issue, you can add your comments, related questions, or answers.

Next steps

See [Get started writing](#).

Additional resources

[How we manage issues](#)

How to submit pull requests

Article • 03/30/2025

To make changes to content, submit a pull request (PR) from your fork. A pull request must be reviewed before it can be merged. For best results, review the [editorial checklist](#) before submitting your pull request.

Using git branches

The default branch for PowerShell-Docs is the `main` branch. Changes made in working branches are merged into the `main` branch before then being published. The `main` branch is merged into the `live` branch every weekday at 3:00 PM (Pacific Time). The `live` branch contains the content that is published to learn.microsoft.com.

Before starting any changes, create a working branch in your local copy of the PowerShell-Docs repository. When working locally, be sure to synchronize your local repository before creating your working branch. The working branch should be created from an up-to-date copy of the `main` branch.

All pull requests should target the `main` branch. Don't submit changes to the `live` branch. Changes made in the `main` branch get merged into `live`, overwriting any changes made to `live`.

Make the pull request process work better for everyone

The simpler and more focused you can make your PR, the faster it can be reviewed and merged.

Avoid pull requests that update large numbers of files or contain unrelated changes

Avoid creating PRs that contain unrelated changes. Separate minor updates to existing articles from new articles or major rewrites. Work on these changes in separate working branches.

Bulk changes create PRs with large numbers of changed files. Limit your PRs to a maximum of 50 changed files. Large PRs are difficult to review and are more prone to contain errors.

Renaming or deleting files

There must be an issue associated with the PR when you rename or delete files. That issue must discuss the need to rename or delete the files.

Avoid mixing content additions or changes with file renames and deletes. Any file that you rename or delete must be added to the appropriate redirection file. When possible, update any files that link to the renamed or deleted content, including any TOC files.

Avoid editing repository configuration files

Avoid modifying repository configuration files. Limit your changes where possible to the Markdown content files and any supporting image files needed for the content.

Incorrect modifications to repository configuration files can break the build, introduce vulnerabilities or accessibility issues, or violate organizational standards. Repository configuration files are any files that match one or more of these patterns:

- `*.yml`
- `.github/**`
- `.localization-config`
- `.openpublishing*`
- `LICENSE*`
- `reference/docfx.json`
- `reference/mapping/**`
- `tests/**`
- `ThirdPartyNotices`
- `tools/**`

For safety and security, don't change these files. If you think one of these files should be changed, [file an issue ↗](#). After the maintainers triage the issue, they'll make the appropriate changes.

Use the PR template

When you create a PR, a template is automatically inserted into the PR body for you. It looks like this:

```
Markdown

# PR Summary

<!--
    Delete this comment block and summarize your changes and list
    related issues here. For example:
-->
```

```

This changes fixes problem X in the documentation for Y.

- Fixes #1234
- Resolves #1235
-->

## PR Checklist

<!--
These items are mandatory. For your PR to be reviewed and merged,
ensure you have followed these steps. As you complete the steps,
check each box by replacing the space between the brackets with an
x or by clicking on the box in the UI after your PR is submitted.
-->

- [ ] **Descriptive Title:** This PR's title is a synopsis of the changes it
proposes.
- [ ] **Summary:** This PR's summary describes the scope and intent of the change.
- [ ] **Contributor's Guide:** I have read the [contributors guide][contrib].
- [ ] **Style:** This PR adheres to the [style guide][style].
```

<!--

If your PR is a work in progress, please mark it as a draft or prefix it with "(WIP)" or "WIP:"

This helps us understand whether or not your PR is ready to review.

-->

[contrib]: /powershell/scripting/community/contributing/overview
[style]: /powershell/scripting/community/contributing/powershell-style-guide

In the "PR Summary" section, write a short summary of your changes and list any related issues by their issue number, like #1234. If your PR fixes or resolves the issue, use GitHub's [autoclose](#) feature so the issue is automatically closed when your PR is merged.

Review the items in the "PR Checklist" section and check them off as you complete each one. You must follow the directions and check each item for the team to approve your PR.

If your PR is a work-in-progress, set it to [draft mode](#) or prefix your PR title with [WIP](#).

Expectations Comment

After you submit your PR, a bot will comment on your PR. The comment provides resources and sets expectations for the rest of the process. We might update this comment periodically, so always review the comment, even if this isn't your first contribution.

github-actions bot commented 9 days ago

...

Expectations

Thanks for your submission! Here's a quick note to provide you with some context for what to expect from the docs team and the process now that you've submitted a PR. Even if you've contributed to this repo before, we strongly suggest reading this information; it might have changed since you last read it.

To see our process for reviewing PRs, please read our [editor's checklist](#) and process for [managing pull requests](#) in particular. Below is a brief, high-level summary of what to expect, but our contributor guide has expanded details.

The docs team begins to review your PR if you [request them to](#) or if your PR meets these conditions:

- It is not a [draft PR](#).
- It does not have a [WIP](#) prefix in the title.
- It passes validation and build steps.
- It does not have any merge conflicts.
- You have checked every box in the [PR Checklist](#), indicating you have completed all required steps and marked your PR as [Ready to Merge](#).

You can [always](#) request a review at any stage in your authoring process, the docs team is here to help! You do not need to submit a fully polished and finished draft; the docs team can help you get content ready for merge.

While reviewing your PR, the docs team may make suggestions, write comments, and ask questions. When all requirements are satisfied, the docs team marks your PR as [Approved](#) and merges it. Once your PR is merged, it is included the next time the documentation is published. For this project, the documentation is published daily at 3 p.m. Pacific Standard Time (PST).

Docs PR validation service

The Docs PR validation service is a GitHub app that runs validation rules on your changes. You must fix any errors or warnings reported by the validation service.

The following steps outline the validation behavior:

1. You submit a PR.
2. In the GitHub comment that indicates the status of the "checks" enabled on the repository. In this example, there are two checks enabled, "Commit Validation" and "OpenPublishing.Build":

Validation status: errors

| File | Status | Preview URL | Details |
|---|--|-------------|-------------------------|
| reference/powershell-6/Microsoft.PowerShell.Management/Set-Content.md |  Error | | Details |
| |  Error | | Details |

[reference/powershell-6/Microsoft.PowerShell.Management/Set-Content.md](#)

- [Error] Unable to load file: powershell-6/Microsoft.PowerShell.Management/Set-Content.md via processor: AzureCliDocumentProcessor.
- [Error] :70:(338) `powershell
Get-Content test.xml | Set-Content ...`
Expect Heading
- [Warning] 'W:\ewzo-s\gallery/index.md' would be overwritten by redirection rule configured in master redirection file .openpublishing.redirection.json. Please remove the original file to resolve this warning.
- [Warning] 'W:\ewzo-s\jea/index.md' would be overwritten by redirection rule configured in master redirection file .openpublishing.redirection.json. Please remove the original file to resolve this warning.

For more details, please refer to the [build report](#).

Note: If you changed an existing file name or deleted a file, broken links in other files to the deleted or renamed file are listed only in the full build report.

The build can pass even if commit validation fails.

3. Select **Details** for more information. The **Details** page shows all the validation checks that failed and includes information about how to fix the issues.
4. When validation succeeds, the following comment is added to the PR:

Validation status: passed

| File | Status | Preview URL | Details |
|---|---|---|---------|
| reference/docs-conceptual/PowerShell-Scripting.md |  Succeeded | View (powershell-3.0)
View (powershell-4.0)
View (powershell-5.0)
View (powershell-5.1)
View (powershell-6) | |

For more details, please refer to the [build report](#).

Note: If you changed an existing file name or deleted a file, broken links in other files to the deleted or renamed file are listed only in the full build report.

Note

If you're an external contributor (not a Microsoft employee), you don't have access to the detailed build reports or preview links.

When the PR is reviewed, you might be asked to make changes or fix validation warning messages. The PowerShell-Docs team can help you understand validation errors and editorial requirements.

GitHub Actions

Several different GitHub Actions run against your changes to validate and provide context for you and the reviewers.

Checklist verification

If your PR isn't in [draft mode](#) and isn't prefixed with `WIP`, a GitHub Action inspects your PR to verify that you selected every item in the PR template's checklist. The maintainers won't review or merge your PR until you complete the checklist. The checklist items are mandatory.

Authorization verification

If your PR targets the `live` branch or modifies any repository configuration files, a GitHub Action checks your permissions to verify that you're authorized to submit those changes.

Only repository administrators are authorized to target the `live` branch or modify repository configuration files.

Versioned content change reporting

If your PR adds, removes, or modifies any versioned content a GitHub Action analyzes your changes and writes a report summarizing the types of changes made to versioned content.

This report can show if there are other versions of the files that you need to update in this PR.

To find the versioned content report for your PR:

1. Selecting the "Checks" tab on your PR page.
2. Select the "Reporting" job from the list of jobs.
3. Select the "..." button in the top right.
4. Select "View job summary."

Versioned Content Change Report

Pull Request:

Owner: MicrosoftDocs
Repo: PowerShell-Docs
Number: 9065

This report is organized by base folder (a folder containing multiple versions of content) with child folders beneath. Each child folder section enumerates all of the changes to files in that folder across the versions in tables.

Each table includes the version-relative path to the files and the change status of those files for each version. The version-relative path is the remainder of the path from the version folder. For example, the file `reference/5.1/Foo/Bar/Baz.md` is in the `reference` base folder and has a version-relative path of `Foo/Bar/Baz.md`. For change status, every versioned file will have one of the following statuses:

- **Added:** The file was added. Git status `A`.
- **Changed:** The file's type was changed. Git status `T`.
- **Copied:** The file was copied. Git status `C`.
- **Modified:** The file's contents were changed. Git status `M`.
- **Removed:** The file was deleted. Git status `D`.
- **Renamed:** The file was renamed. Git status `R`.
- **Unchanged:** The file was not modified.
- **N/A:** The file does not exist for this version.

In cases where the change status of a file is not the same across versions, the Pull Request author and reviewer should both double check the file to understand if the discrepancy is intentional or accidental.

Base Folder: `reference`

Changed 1 versioned files in `reference`. See below for details per folder.

Change Sets for `Microsoft.PowerShell.LocalAccounts`

| Version-Relative Path | 5.1 | 7.0 | 7.2 | 7.3 |
|-------------------------------|----------|-----|-----|-----|
| <code>Set-LocalUser.md</code> | Modified | N/A | N/A | N/A |

Job summary generated at run-time

[How we manage pull requests](#)

Contributing quality improvements

Article • 03/30/2025

For [Hacktoberfest 2022](#), we [piloted a process](#) for contributing quality improvements to the PowerShell content. This guide generalizes that process to define a low-friction way for community members to improve to the quality of the documentation.

We're focusing on these quality areas:

- [Formatting code samples](#)
- [Formatting command syntax](#)
- [Link References](#)
- [Markdown linting](#)
- [Spelling](#)

Project Tracking

We're tracking contributions with the [PowerShell Docs Quality Contributions](#) GitHub Project.

The project page has several views for the issues and PRs related to this effort:

- The [Open issues](#) view shows all open issues.
- The [Completed](#) view shows merged PRs.
- The [PowerShell](#) view shows open issues for documentation in the [PowerShell-Docs](#), [PowerShell-Docs-DSC](#), and [PowerShell-Docs-Modules](#) repositories.
- The [Windows PowerShell](#) view shows open issues for documentation in the [windows-powershell-docs repository](#).
- The [Azure PowerShell](#) view shows open issues for documentation in the [azure-docs-powershell repository](#).
- The [Open PRs](#) view shows all open PRs.

Formatting code samples

All code samples should follow the [style guidelines](#) for PowerShell content. Those rules are repeated in abbreviated form here for convenience:

- All code blocks should be contained in a triple-backtick code fence (`````).
- Line length for code blocks is limited to 90 characters for cmdlet reference articles.
- Line length for code blocks is limited to 76 characters for `about_*` articles.
- Avoid using line continuation characters (`) in PowerShell code examples.

- Use splatting or natural line break opportunities, like after pipe (|) characters, opening braces ({), parentheses ((), and brackets ([) to limit line length.
- Only include the PowerShell prompt for illustrative examples where the code isn't intended for copy-pasting.
- Don't use aliases in examples unless you're specifically documenting the alias.
- Avoid using positional parameters. Use the parameter name, even if the parameter is positional.

Formatting command syntax

All prose should follow the [style guidelines](#) for PowerShell content. Those rules are repeated here for convenience:

- Always use the full name for cmdlets and parameters. Avoid using aliases unless you're specifically demonstrating the alias.
- Property, parameter, object, type names, class names, class methods should be **bold**.
 - Property and parameter values should be wrapped in backticks (`).
 - When referring to types using the bracketed style, use backticks. For example:
`[System.IO.FileInfo]`
- PowerShell module names should be **bold**.
- PowerShell keywords and operators should be all lowercase.
- Use proper (Pascal) casing for cmdlet names and parameters.
- When you refer to a parameter by name, the name should be **bold**.
- Use parameter name with the hyphen if you're illustrating syntax. Wrap the parameter in backticks.
- When you show example usage of an external command, the example should be wrapped in backticks. Always include the file extension of the external command.

Link references

For maintainability and readability of the markdown source for our documentation, we're converting our conceptual documentation to use link references instead of inline links.

For example, instead of:

Markdown

The [\[Packages tab\]](#)^[31] displays all available packages in the PowerShell Gallery.

It should be:

Markdown

The [Packages tab][31] displays all available packages in the PowerShell Gallery.

! Note

When you replace an inline link, reflow the content to wrap at 100 characters. You can use the [reflow-markdown](#) VS Code extension to quickly reflow the paragraph.

At the bottom of the file, add a markdown comment before the definition of the links.

Markdown

```
<!-- Link references -->
[01]: https://www.powershellgallery.com/packages
```

Make sure that:

1. The links are defined in the order they appear in the document.
2. Every link points to the correct location.
3. The link reference definitions are at the bottom of the file after the markdown comment and are in the correct order.

Markdown linting

For any article in one of the participating repositories, opening the article in VS Code displays linting warnings. Address any of these warnings you find, except:

- [MD022/blanks-around-headings/blanks-around-headers](#) for the `Synopsis` header in cmdlet reference documents. For those items, the rule violation is intentional to ensure the documentation builds correctly with PlatyPS.

Make sure of the line lengths and use the [Reflow Markdown](#) extension to fix any long lines.

Spelling

Despite our best efforts, typos and misspellings get through and end up in the documentation. These mistakes make documentation harder to follow and localize. Fixing these mistakes makes the documentation more readable, especially for non-English speakers who rely on accurate translations.

Process

We encourage you to choose one or more of the quality areas and an article (or group of articles) to improve. Use the following steps to guide your work:

1. Check the [project ↗](#) for issues filed for this effort to avoid duplicating efforts.
2. Open a new issue in the appropriate repository:
 - Open an issue in [MicrosoftDocs/PowerShell-Docs ↗](#) for PowerShell reference and conceptual content.
 - Open an issue in [MicrosoftDocs/PowerShell-Docs-Dsc ↗](#) for DSC content
 - Open an issue in [MicrosoftDocs/PowerShell-Docs-Modules ↗](#) for Crescendo, PlatyPS, PSScriptAnalyzer, SecretManagement, and SecretStore content.
 - Open an issue in [MicrosoftDocs/azure-docs-powershell ↗](#) for Azure PowerShell content.
 - Open an issue in [MicrosoftDocs/windows-powershell-docs ↗](#) for Windows PowerShell module content.
3. Follow our [contributor's guide](#) to get setup for making your changes.
4. Submit your pull request. Ensure:
 - a. Your PR title has the `Quality:` prefix.
 - b. Your PR body references the issue it resolves as an unordered list item and uses one of the [linking keywords ↗](#).

For example, if you're working on issue `123`, the body of your PR should include the following Markdown:

Markdown

```
- resolves #123
```

After you submit the PR, the maintainers will review your work and work with you to get it merged.

Hacktoberfest and other hack-a-thon events

Article • 05/29/2025

Hacktoberfest is an annual worldwide event held during October. The event encourages open source developers to contribute to repositories through pull requests (PR). GitHub hosts many open source repositories that contribute to Microsoft Learn content. Several repositories actively participate in Hacktoberfest.

How to contribute

Before you can contribute to an open source repo, you must first configure your account to contribute to Microsoft Learn. If you're new to this process, start by signing up for a [GitHub account](#). Be sure to [install Git and the Markdown tools](#).

To get credit for participation, register with [Hacktoberfest](#) and read their participation guide.

Find a repo that needs your help

The PowerShell-Docs team is supporting Hacktoberfest contributions for several PowerShell documentation repositories. We defined a set of cleanup tasks designed to be simple for first time contributors. Full information can be found in the [Hacktoberfest meta-issue](#).

To be successful with these tasks, you should:

- Have a general understanding of PowerShell syntax
- Have an understanding of [splatting](#)
- Be able to read and follow the [PowerShell-Docs style guide](#) and [Editorial checklist](#)
- Have basic familiarity with Markdown

Before contributing should read the meta-issue. When you're ready to start, open a new Hacktoberfest using one of the following links:

- [MicrosoftDocs/PowerShell-Docs](#)
- [MicrosoftDocs/PowerShell-Docs-DSC](#)
- [MicrosoftDocs/PowerShell-Docs-Modules](#)
- [MicrosoftDocs/windows-powershell-docs](#)
- [MicrosoftDocs/azure-docs-powershell](#)

Quality expectations

To have a successful contribution to an open source Microsoft Learn repository, create a meaningful and impactful PR. The following examples from the official Hacktoberfest site are considered ***low-quality contributions***:

- PRs containing bulk automated changes
 - Example: scripted PRs to remove whitespace, fix common spelling, or optimize images
 - Submit an issue first describing the automated changes you want to make
- PRs deemed disruptive (for example, taking someone else's branch or commits and making a PR)
- PRs deemed a hindrance vs. helping
- PRs that are clearly an attempt to increment your PR count for October

Open a PR

A *PR* provides a convenient way for a contributor to propose a set of changes. Successful PRs have these common characteristics:

- The PR adds value.
- The contributor is receptive to feedback.
- The intended changes are well articulated.
- The changes are related to an existing issue.

If you're proposing a PR without a corresponding issue, create an issue first. For more information, see [GitHub: About pull requests ↗](#).

- [Official Hacktoberfest site ↗](#)

How we manage issues

Article • 03/30/2025

This article documents how we manage issues in the PowerShell-Docs repository. This article is designed to be a job aid for members of the PowerShell-Docs team. We publish this information here to provide process transparency for our public contributors.

Sources of issues

- Community contributors
- Internal contributors
- Transcriptions of comments from social media channels
- Feedback via the Docs feedback form

Response time targets

80% of new issues are closed within 3 business days.

- Triaged - 1 business day
- Fix or change - 10 business days

Labeling & Milestones

Label Types

- **Area** - Identifies the part of PowerShell or the docs that the issue is discussing
- **Issue** - The type of issue: like bug, feedback, or idea
- **Priority** - The priority of the issue; value range 0-3 (high-low)
- **Quality** - The [quality improvement](#) effort the issue commits to resolving
- **Status** - The status of the work item or why it was closed
- **Tag** - Used to for additional classification like availability or doc-a-thons
- **Waiting** - Shows that we're waiting on some external person or event

For more information on specific labels, see [Labeling](#).

Milestones

Issues and PRs should be tagged with the appropriate milestone. If the issue doesn't apply to a specific version, then no milestone is used. PRs and related issues for changes that have yet to

be merged into the PowerShell code base should be assigned to the **Future** milestone. After you merge the change, update the milestone to the appropriate version.

[] [Expand table](#)

| Milestone | Description |
|-----------|---|
| 7.0.0 | Work items related to PowerShell 7.0 |
| 7.2.0 | Work items related to PowerShell 7.2 |
| 7.3.0 | Work items related to PowerShell 7.3 |
| Future | Work items a future version of PowerShell |

Triage process

PowerShell docs team members review the issues daily and triage new issues as they arrive. The team meets weekly to discuss difficult issues need triage and prioritize the work.

Misplaced product feedback

- Enter a comment redirecting the customer to the correct feedback channel.
- Optional: Copy the issue to the appropriate product feedback location, add a link to the copied item, and close the issue.

The default location for PowerShell issues is

<https://github.com/PowerShell/PowerShell/issues/new/choose>.

Support requests

- If the support question is simple, answer it politely and close the issue.
- If the question is more complicated, or the submitter replies with more questions, redirect them to forums and support channels. Suggested text for redirecting to forums:

Markdown

```
> This is not the right forum for these kinds of questions. Try posting your  
question in a  
> community support forum. For a list of community forums see:  
> https://learn.microsoft.com/powershell/scripting/community/community-support
```

Code of conduct violations

- Edit the issue to remove any offensive content, if necessary
- Enter a comment indicating the issue is spam, close the issue, and then lock it to prevent further comments
- Discuss each violation in the regular triage meeting to determine the need for further action

Managing pull requests

Article • 03/30/2025

This article documents how we manage pull requests in the PowerShell-Docs repository. This article is designed to be a job aid for members of the PowerShell-Docs team. We publish this information here to provide process transparency for our public contributors.

Best practices

- Request a review. The person submitting the PR shouldn't merge the PR without a peer review.
- Assign the peer reviewer when the PR is submitted. Early assignment allows the reviewer to respond sooner with editorial remarks.
- Use comments to describe the nature of the change being submitted. For example, if the change is minor, explain the change and that you don't need a full technical review. Be sure to @mention the reviewer.
- Use the comment suggestion feature to make it easier for the author to accept the suggested change. For more information, see [Reviewing proposed changes in a pull request ↗](#).

PR Process steps

1. Writer: Create PR

- Fill out the [PR template](#)
- Link any issues resolved by the PR
- Use GitHub's [autoclose ↗](#) feature to close the issue
- Work through and check off each item in the checklist

2. Writer: Assign peer reviewer

3. Reviewer: proofreads and comments (as necessary)

4. Writer: Incorporate review feedback

5. Both: Review preview rendering

6. Both: Review validation report - fix warnings and errors

7. Reviewer: Mark review "Approved"

8. Repo Maintainer: Merge PR

Content Reviewer Checklist

See the [editorial checklist](#) for a more comprehensive list.

- Proofread for grammar, style, concision, technical accuracy
- Ensure examples still apply for the target version
- Check Preview rendering
- Check metadata - ms.date, remove ms.assetid, ensure required fields
- Validate markdown correctness
 - See style guide for content-specific formatting rules
- Reorganize examples as follows:
 - Intro paragraph
 - Code and output
 - Detailed explanation of code (as necessary)
- Check hyperlinks for accuracy
 - Replace or remove TechNet/MSDN links
 - Ensure minimum number of redirects to target
 - Ensure HTTPS
 - Correct link type
 - File links for local files
 - URL links for files outside of the docset
 - Remove locales from URLs
 - Simplify URLs pointing to `learn.microsoft.com`
- Verify versioned content is correct across all versions
 - Review the [versioned content change report](#)

Branch Merge Process

The `main` branch is the only branch that should be merged into `live`. Merges from short-lived (working) branches should be squashed before merging into `main`.

[] [Expand table](#)

| Merge from/to | <i>release-branch</i> | <i>main</i> | <i>live</i> |
|-----------------------------|------------------------------|--------------------|--------------------|
| <code>working-branch</code> | squash and merge | squash and merge | Not allowed |
| <code>release-branch</code> | — | merge | Not allowed |
| <code>main</code> | rebase | — | merge |

PR Merger checklist

- Content review complete
- Correct target branch for the change

- No merge conflicts
- All validation and build step pass
 - Warnings and suggestions should be fixed (see [Notes](#) for exceptions)
 - No broken links
 - The [Checklist](#) action ran and passed
 - If an [Authorization](#) check was triggered, it passed
- Merge according to table

Notes

The following warnings can be ignored:

Can't find service name for `<version>/<modulepath>/About/About.md`

Metadata with following name(s) are not allowed to be set in YAML header, or as file level metadata in docfx.json, or as global metadata in docfx.json: `locale`. They are generated by Docs platform, so the values set in these 3 places will be ignored. Please remove them from all 3 places to resolve the warning.

When a PR is merged, the HEAD of the target branch is changed. Any open PRs that were based on the previous HEAD are now outdated. A Maintainer has the right required to override the merge warnings and merge the outdated PR in GitHub. Merging an outdated PR is safe if the previously merged PRs didn't touch the same files.

To update the PR, select the **Update Branch** button. Choose **Update with rebase** option. For more information, see [Updating your pull request branch ↗](#).

Publishing to Live

Periodically, the changes accumulated in the `main` branch need to be published to the live website.

- The `main` branch is merged to `live` each weekday at 3pm PST.
- The `main` branch should be merged to `live` after any significant change.
 - Changes to 50 or more files
 - After merging a release branch

- Changes to repo or docset configurations (docfx.json, OPS configs, build scripts, etc.)
- Changes to the redirection file
- Changes to the TOC
- After merging a "project" branch (content reorg, bulk update, etc.)

Labeling in GitHub

Article • 03/30/2025

This article documents how we label issues and pull requests in the PowerShell-Docs repository. This article is designed to be a job aid for members of the PowerShell-Docs team. We publish this information here to provide process transparency for our public contributors.

Labels always have a name and a description that is prefixed with their type.

Area labels

Area labels identify the parts of PowerShell or the documentation that the issue relates to.

[+] Expand table

| Label | Related Content |
|---------------------|---|
| area-about | The <code>about_*</code> articles. |
| area-archive | The Microsoft.PowerShellArchive module. |
| area-cim | The CimCmdlets module. |
| area-community | Community-facing projects, including the contributor's guide and monthly updates. |
| area-conceptual | Conceptual articles (not cmdlet reference). |
| area-console | The console host |
| area-core | The Microsoft.PowerShellCore module. |
| area-crescendo | The Crescendo module. |
| area-debugging | Debugging PowerShell. |
| area-diagnostics | The Microsoft.PowerShellDiagnostics module. |
| area-dsc | PowerShell Desired State Configuration. |
| area-editorsvcs | The PowerShell editor services. |
| area-engine | The PowerShell engine. |
| area-error-handling | Error handling in PowerShell |

| Label | Related Content |
|-------------------------------------|---|
| <code>area-experimental</code> | PowerShell's experimental features |
| <code>area-gallery</code> | The PowerShell Gallery. |
| <code>area-helpsystem</code> | The Help services, including the pipeline and <code>*-Help</code> cmdlets. |
| <code>area-host</code> | The Microsoft.PowerShell.Host module. |
| <code>area-ise</code> | The PowerShell ISE. |
| <code>area-jea</code> | The Just Enough Administration feature. |
| <code>area-language</code> | The PowerShell syntax and keywords. |
| <code>area-learn</code> | The structured training content for PowerShell. |
| <code>area-localaccounts</code> | The Microsoft.PowerShell.LocalAccounts module. |
| <code>area-localization</code> | Localization problems or opportunities for the content. |
| <code>area-management</code> | The Microsoft.PowerShell.Management module. |
| <code>area-native-cmds</code> | Using native commands in PowerShell. |
| <code>area-omi</code> | Open Management Infrastructure & CDXML. |
| <code>area-ops-issue</code> | Building and rendering the content on the site. |
| <code>area-other</code> | Miscellaneous modules. |
| <code>area-overview</code> | The overview section in the conceptual content. |
| <code>area-packageManagement</code> | The PackageManagement module. |
| <code>area-parallelism</code> | Content covering parallel processing, such as using <code>ForEach-Object</code> or PowerShell Jobs. |
| <code>area-platypus</code> | The Platypus module. |
| <code>area-portability</code> | Cross-platform compatibility. |
| <code>area-powershellget</code> | The PowerShellGet module. |
| <code>area-providers</code> | PowerShell providers. |
| <code>area-psreadline</code> | The PSReadLine module. |
| <code>area-release-notes</code> | The PowerShell release notes. |

| Label | Related Content |
|---------------------|--|
| area-remoting | The PowerShell remoting feature and cmdlets. |
| area-scriptanalyzer | The PSScriptAnalyzer module. |
| area-sdk-docs | The conceptual documentation for the PowerShell SDK. |
| area-sdk-ref | The .NET API reference documentation for the PowerShell SDK. |
| area-security | The Microsoft.PowerShell.Security module and security concepts in general. |
| area-setup | Installing and configuring PowerShell. |
| area-threadjob | The ThreadJob module. |
| area-utility | The Microsoft.PowerShell.Utility module. |
| area-versions | Issues with the versioning of the documentation. |
| area-vscode | The VS Code PowerShell extension. |
| area-wincompat | The Windows Compatibility feature. |
| area-wmf | The Windows Management Framework. |
| area-workflow | The Windows PowerShell Workflow feature. |

Issue labels

Issue labels distinguish issues by purpose.

[\[\] Expand table](#)

| Label | Issue Category |
|------------------------|---|
| issue-doc-bug | Errors or ambiguities in the content |
| issue-doc-idea | Requests for new content |
| issue-kudos | Praise, positive feedback, or thanks rather than work items |
| issue-product-feedback | Feedback or problems with the product itself |
| issue-question | Support questions |

Priority labels

Priority labels rank which work items need to be worked on before others. These labels are only used when needed to manage large sets of work items.

[\[\] Expand table](#)

| Label | Priority Level |
|-------|----------------|
| Pri0 | Highest |
| Pri1 | High |
| Pri2 | Medium |
| Pri3 | Low |

Project Labels

Project labels indicate what ongoing GitHub Project a work item is related to. These labels are used for automatically adding work items to a project on creation.

[\[\] Expand table](#)

| Label | Project |
|-----------------|---|
| project-quality | The quality improvement project |

Quality labels

Quality labels categorize work items for the [quality improvement](#) effort.

[\[\] Expand table](#)

| Label | Improvement |
|-------------------------------|---|
| quality-aliases | Ensure cmdlet aliases are documented |
| quality-format-code-samples | Ensure proper casing, line length, and other formatting in code samples |
| quality-format-command-syntax | Ensure proper casing and formatting for command syntax |
| quality-link-references | Ensure links in conceptual docs are defined as numbered references |

| Label | Improvement |
|----------------------|---|
| quality-markdownlint | Ensure content follows markdownlint rules |
| quality-spelling | Ensure proper casing and spelling for words |

Status labels

Status labels indicate why a work item was closed or shouldn't be merged. Issues are only given status labels when they're closed without a related PR.

[\[+\] Expand table](#)

| Label | Status |
|-----------------------------|---|
| resolution-answered | Closed by existing documentation |
| resolution-duplicate | Closed as duplicate issue |
| resolution-external | Closed by customer or outside resource |
| resolution-no-repro | Unable to reproduce the reported issue |
| resolution-refer-to-support | Closed and referred to community or product support |
| resolution-wont-fix | Closed as won't fix |

Tag labels

Tag labels add independent context for work items.

[\[+\] Expand table](#)

| Label | Purpose |
|-------------------------|---|
| in-progress | Someone is actively working on the item |
| go-live | The work item is related to a specific release |
| doc-a-thon | The work item is related to a doc-a-thon |
| up-for-grabs | Any contributor can volunteer to resolve the work item |
| hacktoberfest-accepted | The PR is accepted for inclusion in #hacktoberfest |
| hacktoberfest-candidate | The PR is a candidate for inclusion in #hacktoberfest |

| Label | Purpose |
|-----------------|--|
| needs-triage | The issue must be triaged by the team before it's ready to be worked |
| code-of-conduct | Closed for spam, trolling, or code of conduct violations |
| do-not-merge | The PR isn't meant to be merged |

Waiting labels

Waiting labels indicate that a work item can't be resolved until an external condition is met.

[\[\] Expand table](#)

| Label | Waiting For |
|---------------------|---|
| hold-for-pr | Upstream PR to be merged |
| hold-for-release | Upstream product to release |
| needs-investigation | Waiting for team member to verify or research |
| needs-more-info | Additional details or clarification from work item author |
| needs-response | Response from work item author |
| review-shiproom | Shiproom discussion with the PowerShell team |

PowerShell Support Lifecycle

Article • 02/25/2025

ⓘ Note

This document is about support for PowerShell. Windows PowerShell (1.0 - 5.1) is a component of the Windows operating system. For more information, see [Product and Services Lifecycle Information](#).

PowerShell follows the [Microsoft Modern Lifecycle Policy](#). Support dates follow the [.NET Support Policy](#). In this servicing approach, customers can choose Long Term Support (LTS) releases or current releases.

An **LTS** release of PowerShell is built on an **LTS** release of .NET. Updates to an **LTS** release only contain critical security updates and servicing fixes that are designed to minimize impact on existing workloads.

A **current** release is a release that occurs between **LTS** releases. Current releases can contain critical fixes, innovations, and new features. Microsoft supports a **current** release for six months after the next **LTS** release.

Both **LTS** and **current** versions of PowerShell receive security updates and bug fixes. Microsoft only supports the latest update version of a release.

Getting support

Microsoft provides support for PowerShell on a best-effort basis. Support for Windows PowerShell 5.1 is provided through Windows support channels. You can use the standard paid support channels to get support for PowerShell.

- [Support for business](#)
- [Contact support](#)

There are many free support options available from the PowerShell community. The most active community support channels are available through **Discord** or **Slack**. The discussion channels are mirrored on both platforms, so you can choose the platform that you prefer. These channels can help you troubleshoot issues, answer questions, and provide guidance on how to use PowerShell.

If you think that you found a bug, you can file an issue on [GitHub](#). The PowerShell team can't provide support through GitHub, but they welcome bug reports. The

[community support page](#) provides links to the most popular community support channels.

Supported platforms

PowerShell runs on multiple operating systems (OS) and processor architecture platforms. The platform must meet the following criteria:

- The target platform (OS version and processor architecture) is supported by .NET.
- Microsoft has tested and approved PowerShell on the target platform.
- The OS version is supported by the distributor for at least one year.
- The OS version isn't an interim release or equivalent.
- The OS version is currently supported by the distributor.

Support for PowerShell ends when either of the following conditions are met:

- The target platform reaches end-of-life as defined by the platform owner
- The specific version of PowerShell reaches end-of-life

After a version of PowerShell reaches end-of-life, no further updates, including security updates, are provided. Microsoft encourages customers to upgrade to a supported version of PowerShell to continue receiving updates and support.

Windows

Microsoft supports PowerShell until [PowerShell reaches end-of-support](#) or the version of [Windows reaches end-of-support](#).

- Docker images containing PowerShell 7.4 and PowerShell 7.5-preview for x64 for Windows Server 2022, Windows Server Core 2022, and Windows Server Nano build 1809 are available from the [Microsoft Artifact Registry](#).
- PowerShell 7.4 and higher can be installed on Windows 10 build 1607 and higher, Windows 11, Windows Server 2016 and higher.

Note

Support for a specific version of Windows is determined by the Microsoft Support Lifecycle policies. For more information, see:

- [Windows client lifecycle FAQ](#)
- [Modern Lifecycle Policy FAQ](#)

macOS

Microsoft supports PowerShell until [PowerShell reaches end-of-support](#) or the version of macOS reaches end-of-support.

- macOS 15 (Sequoia) x64 and Arm64
- macOS 14 (Sonoma) x64 and Arm64
- macOS 13 (Ventura) x64 and Arm64

Apple determines the support lifecycle of macOS. For more information, see the following:

- [macOS release notes ↗](#)
- [Apple Security Updates ↗](#)

Alpine Linux

Microsoft supports PowerShell until [PowerShell reaches end-of-support](#) or the version of [Alpine reaches end-of-life ↗](#).

Docker images containing PowerShell 7.4 and PowerShell 7.5-preview for x64 are available from the [Microsoft Artifact Registry ↗](#) for the following versions of Alpine:

- Alpine 3.20 - OS support ends on 2026-04-01

Docker images of PowerShell aren't available for Alpine 3.21.

Important

The Docker images are built from official operating system (OS) images provided by the OS distributor. These images may not have the latest security updates. Microsoft recommends that you update the OS packages to the latest version to ensure the latest security updates are applied.

Debian Linux

Microsoft supports PowerShell until [PowerShell reaches end-of-support](#) or the version of [Debian reaches end-of-life ↗](#).

Install package files (.deb) are also available from <https://packages.microsoft.com/> ↗.

Docker images containing PowerShell 7.4 and PowerShell 7.5-preview for x64 are available from the [Microsoft Artifact Registry ↗](#) for the following versions of Debian:

- Debian 12 (Bookworm) - OS support ends on 2026-06-10

Important

The Docker images are built from official operating system (OS) images provided by the OS distributor. These images may not have the latest security updates.

Microsoft recommends that you update the OS packages to the latest version to ensure the latest security updates are applied.

Red Hat Enterprise Linux (RHEL)

Microsoft supports PowerShell until [PowerShell reaches end-of-support](#) or the version of [RHEL reaches end-of-support](#).

Install package files (.rpm) are also available from <https://packages.microsoft.com/>.

Docker images containing PowerShell 7.4 and PowerShell 7.5-preview for x64 are available from the [Microsoft Artifact Registry](#) for the following versions of RHEL:

- RHEL 9 - OS support ends on 2032-05-31
- RHEL 8 - OS support ends on 2029-05-31

PowerShell is tested on Red Hat Universal Base Images (UBI). For more information, see the [UBI information page](#).

Important

The Docker images are built from official operating system (OS) images provided by the OS distributor. These images may not have the latest security updates.

Microsoft recommends that you update the OS packages to the latest version to ensure the latest security updates are applied.

Ubuntu Linux

Microsoft supports PowerShell until [PowerShell reaches end-of-support](#) or the version of [Ubuntu reaches end-of-support](#).

Install package files (.deb) are also available from <https://packages.microsoft.com/>.

Docker images containing PowerShell 7.4 and PowerShell 7.5-preview for x64 and Arm32 are available from the [Microsoft Artifact Registry](#) for the following versions of

Ubuntu:

- Ubuntu 24.04 (Noble Numbat) - OS support ends on 2029-04-01
- Ubuntu 22.04 (Jammy Jellyfish) - OS support ends on 2027-04-01
- Ubuntu 20.04 (Focal Fossa) - OS support ends on 2025-04-02

Ubuntu 24.10 (Oracular Oriole) is an interim release. Microsoft doesn't support [interim releases](#) of Ubuntu. For more information, see [Community supported distributions](#).

Important

The Docker images are built from official operating system (OS) images provided by the OS distributor. These images may not have the latest security updates. Microsoft recommends that you update the OS packages to the latest version to ensure the latest security updates are applied.

Support for PowerShell modules

The support lifecycle for PowerShell doesn't cover modules that ship outside of the PowerShell release package. For example, using the `ActiveDirectory` module that ships as part of Windows Server is supported under the [Windows Support Lifecycle](#).

Support for experimental features

[Experimental features](#) aren't intended to be used in production environments. We appreciate feedback on experimental features and we provide best-effort support for them.

Notes on licensing

PowerShell is released under the [MIT license](#). Under this license, and without a paid support agreement, users are limited to [community support](#). With community support, Microsoft makes no guarantees of responsiveness or fixes.

PowerShell end-of-support dates

The PowerShell support lifecycle follows the [support lifecycle of .NET](#). The following table lists the end-of-support dates for the current versions of PowerShell:

[\[+\] Expand table](#)

| Version | Release Date | End-of-support | .NET Version |
|--------------------------|--------------|----------------|---------------------------------------|
| PowerShell 7.6 (preview) | Future date | Future date | Built on .NET 9.0.0 ↗ |
| PowerShell 7.5 | 23-Jan-2025 | 12-May-2026 | Built on .NET 9.0.0 ↗ |
| PowerShell 7.4 (LTS) | 16-Nov-2023 | 10-Nov-2026 | Built on .NET 8.0.0 ↗ |

The following table lists the end-of-support dates for retired versions of PowerShell:

[\[+\] Expand table](#)

| Version | Release Date | End-of-support | .NET Version |
|----------------------|--------------|----------------|--|
| PowerShell 7.3 | 09-Nov-2022 | 08-May-2024 | Built on .NET 7.0 ↗ |
| PowerShell 7.2 (LTS) | 08-Nov-2021 | 08-Nov-2024 | Built on .NET 6.0 ↗ |
| PowerShell 7.1 | 11-Nov-2020 | 08-May-2022 | Built on .NET 5.0 ↗ |
| PowerShell 7.0 (LTS) | 04-Mar-2020 | 03-Dec-2022 | Built on .NET Core 3.1 ↗ |
| PowerShell 6.2 | 29-Mar-2019 | 04-Sep-2020 | Built on .NET Core 2.1 ↗ |
| PowerShell 6.1 | 13-Sep-2018 | 28-Sep-2019 | Built on .NET Core 2.1 ↗ |
| PowerShell 6.0 | 20-Jan-2018 | 13-Feb-2019 | Built on .NET Core 2.0 ↗ |

Windows PowerShell release history

The following table contains a historical timeline of the major releases of Windows PowerShell. Microsoft no longer supports Windows PowerShell versions lower than 5.1.

[\[+\] Expand table](#)

| Version | Release Date | Note |
|------------------------|--------------|--|
| Windows PowerShell 5.1 | Aug-2016 | Released in Windows 10 Anniversary Update and Windows Server 2016, WMF 5.1 |
